No evidence is available in the literature about more severe disease in breastfed infants compared with formula-fed infants. There is no evidence of the interperson transmission of dengue virus in the absence of a mosquito vector. There is one case report of apparent transmission of dengue virus via breast milk to a 4-day-old infant, however. The mother had clinical illness consistent with dengue virus disease at delivery, and the infant developed disease on day 4 of life. The mother's blood was positive for dengue virus by RT-PCR on days 0 to 6 after delivery, and her breast milk was positive on days 2 and 4 after delivery. The infant's blood from days 0 and 2 and the cord blood were repeatedly negative by RT-PCR, but subsequently, the infant's blood was PCR positive for dengue virus on days 4 to 13 of life.<sup>30</sup> There is one report of a factor in the lipid portion of breast milk, which inhibits the dengue virus, but no evidence for antibody activity against the dengue virus in human breast milk is known.<sup>140</sup> Given the apparent rarity of the transmission of dengue virus via breast milk, breastfeeding during maternal or infant dengue disease should continue, as determined by the mother's or infant's severity of illness.

## EPSTEIN-BARR VIRUS

Epstein-Barr virus (EBV) is a common infection in children, adolescents, and young adults. It is usually asymptomatic, but it most notably causes infectious mononucleosis and has been associated with chronic fatigue syndrome, Burkitt lymphoma, and nasopharyngeal carcinoma. Because EBV is one of the human herpesviruses, concern has been raised about lifelong latent infection and the potential risk for infection to a fetus and neonate from the mother. Primary EBV infection during pregnancy is unusual because few pregnant women are susceptible.<sup>165,207</sup> Although abortion, premature birth, and congenital infection from EBV are suspected, no distinct group of anomalies is linked to EBV infection in the fetus or neonate. Also, no virologic evidence of EBV as the cause of abnormalities was found in association with suspected EBV infection.

Culturing of EBV from various fluids or sites is difficult. The virus is detected by its capacity to transform B lymphocytes into persistent lymphoblastoid cell lines. PCR and DNA hybridization studies have detected EBV in the cervix and in breast milk. One study, which identified EBV DNA in breast milk cells in more than 40% of

women donating milk to a breast milk bank, demonstrated that only 17% had antibodies to EBV (only IgG, no IgM).<sup>225</sup> EBV DNA was identified in 33% of 40 human milk samples from normal lactating women in a separate study.<sup>169</sup> However, a study by Kusuvara et al. examining serologic specimens from breastfed and bottle-fed infants showed similar seroprevalence of EBV at 12 to 23 months of age (36/66 [54.5%] and 24/43 [55.8%]) in the breastfed and bottle-fed children, respectively.<sup>260</sup> This suggests that early acquisition of EBV infection in infants is not significantly affected by the consumption of breast milk.

The question of the timing of EBV infection and the subsequent immune response and clinical disease produced requires continued study. Differences exist among the clinical syndromes that manifest at different ages. Infants and young children are asymptomatic, have illness not recognized as related to EBV, or have mild episodes of illness, including fever, lymphadenopathy, rhinitis, cough, hepatosplenomegaly, and rash. Adolescents or young adults who experience primary EBV infection more often demonstrate infectious mononucleosis syndrome or are asymptomatic. Chronic fatigue syndrome is more common in adolescents and young adults. Burkitt lymphoma, observed primarily in Africa, and nasopharyngeal carcinoma, seen in southeast Asia, where primary EBV infection usually occurs in young children, are tumors associated with early EBV infection.<sup>273</sup> These tumors are related to "chronic" EBV infection and tend to occur in individuals with persistently high antibody titers to EBV viral capsid antigen and early antigen. The questions of why these tumors occur with much greater frequency in these geographic areas and what cofactors (including altered immune response to infection associated with coinfections, immune escape by EBV leading to malignancy, or increased resistance to apoptosis secondary to EBV gene mutations) may contribute to their development remain unanswered.<sup>23,326</sup>

It also remains unknown to what degree breast milk could be a source of early EBV infection, as compared to other sources of EBV infection in an infant's environment. Similar to the situation of postnatal transmission of CMV in immunocompetent infants, clinically significant illness rarely is associated with primary EBV infection in infants. More data concerning the pathogenesis of EBV-associated tumors should be obtained before proscribing against breastfeeding is warranted, especially in areas where these tumors are common but the protective benefits of breastfeeding are high. In areas where Burkitt lymphoma and nasopharyngeal carcinoma are uncommon, EBV infection in mother or infant is certainly not a contraindication to breastfeeding.

## FILOVIRIDAE

Marburg and Ebola viruses cause severe and highly fatal hemorrhagic fevers. The illness often presents with nonspecific symptoms (conjunctivitis, frontal headache, malaise, myalgia, bradycardia) and progresses with worsening hemorrhage to shock and subsequent death in 50% to 90% of patients. Person-to-person transmission through direct contact, droplet spread, or airborne spread is the common mode of transmission. However, the animal reservoir or source of these viruses in nature for human infection has not been identified. Attack rates in families are 5% to 16%.<sup>370</sup> No postexposure interventions have proved useful in preventing spread, and no treatment other than supportive is currently available.

One report documented the presence of Ebola virus in numerous body fluids, including breast milk. One acute breast milk sample on day 7 after the onset of illness in the mother and a "convalescent" breast milk sample on day 15 from the same woman were positive for Ebola virus by both culture and PCR testing.<sup>33</sup> In the same study, testing other body fluids in different persons, saliva remained virus positive for a mean of 16 days after disease onset, urine was positive for a mean of 28 days, and semen for a mean of 43 days after the onset of disease in survivors of Ebola infection.

No information is available concerning the risk for transmission of these viruses in breast milk or additional risks or benefits from breastfeeding in an area involved in an Ebola outbreak or with household members who are infected.

Contact precautions have been recommended for Marburg and Ebola virus infections and contact and airborne precautions for Ebola virus infection. The largest epidemic of EVD in West Africa (predominantly Guinea, Liberia, Sierra Leone), involving over 21,000 cases and over 8400 deaths, occurred through 2014 to 2015.<sup>92</sup> This outbreak has dramatically raised concerns about the transmission of Ebola to family members, close contacts, travelers, and health care personnel. To date, there are no newer publications for this epidemic on transmissibility from different body fluids and particularly from breast milk. The WHO and CDC have developed updated guidance for the use of personal protective equipment for health care workers (CDCP <http://www.cdc.gov/vhf/ebola/hcp/procedures-for-ppe.html>). This guidance continues to be updated (CDCP <http://www.cdc.gov/media/releases/2014/fs1020-ebola-personal-protective-equipment.html>). Both of these guidelines reinforce the high risk of Ebola virus infection without careful protection against contact with body fluids from a person with EVD. Given the high attack and mortality rates associated with EVD, these precautions should be

carefully instituted within health care facilities, and breastfeeding should not be allowed if the mother has suspected EVD. If any other suitable source of nutrition can be found for an infant, expressed breast milk should also be proscribed for the infant of a mother with either of these infections for at least 3 weeks postrecovery.

## Hepatitis in the Mother

The diagnosis of hepatitis in a pregnant woman or nursing mother causes significant anxiety. The first issue is determining the etiology of the hepatitis, which then allows for an informed discussion of risk to the fetus or infant. The differential diagnosis of acute hepatitis includes (1) common causes of hepatitis, such as hepatitis A, B, C, and D; (2) uncommon causes of hepatitis, such as hepatitis E and G, CMV, echoviruses, enteroviruses, EBV, HSV, rubella, varicella-zoster virus, yellow fever virus; (3) rare causes of hepatitis, such as Ebola virus, Junin virus, and Machupo virus (cause hemorrhagic fever), Lassa virus, and Marburg virus; and (4) non-viral causes, such as hepatotoxic drugs, alcoholic hepatitis, toxoplasmosis, autoimmune hepatitis, bile duct obstruction, ischemic liver damage, Wilson disease,  $\alpha_1$ -antitrypsin deficiency, and metastatic liver disease. The following sections focus on hepatitis viruses A to G. Other infectious agents that can cause hepatitis are considered individually in other sections. **Box 13-2** provides hepatitis terminology.

Martin et al.<sup>299</sup> outline a succinct diagnostic approach to a patient with acute viral hepatitis and chronic viral hepatitis (Figures 13-4 and 13-5). The approach involves using the four serologic markers (IgM anti-hepatitis A virus, hepatitis B surface antigen [HBsAg], IgM anti-HBcAg, anti-HCV) as the initial diagnostic tests. Simultaneous consideration of other etiologies of acute liver dysfunction is appropriate depending on a patient's history. If the initial diagnostic tests are all negative, subsequent additional testing for anti-hepatitis D virus (HDV), HCV RNA, hepatitis G virus (HGV) RNA, anti-hepatitis E virus (HEV), or HEV RNA may be necessary. If initial testing reveals positive HBsAg, testing for anti-HDV, HBeAg, and HBV DNA is appropriate. These additional tests are useful in defining the prognosis for a mother and the risk for infection to an infant. During the diagnostic evaluation, it is appropriate to discuss with the mother or parents the theoretic risk for transmitting infectious agents that cause hepatitis via breastfeeding. The discussion should include an evaluation of the positive and negative effects of suspending or continuing breastfeeding until the exact etiologic diagnosis is determined. The relative risk for

### BOX 13-2. Terminology for Hepatitis

#### Hepatitis A Virus (HAV)

IgM anti-HAV	Immunoglobulin M (IgM) antibody against HAV
HAV RNA	HAV ribonucleic acid

#### Hepatitis B Virus (HBV)

HBsAg	Hepatitis B surface antigen
HBeAg	Hepatitis Be antigen
HBcAg	Hepatitis B core antigen
Anti-HBc	Antibody against hepatitis Be antigen
IgM anti-HBcAg	IgM antibody against hepatitis B core antigen
HBV DNA	HBV deoxyribonucleic acid
HBIG	Hepatitis B immunoglobulin

#### Hepatitis C Virus (HCV)

Anti-HCV	Antibody against HCV
HCV RNA	HCV ribonucleic acid

#### Hepatitis D Virus (HDV)

Anti-HDV	Antibody against HDV

NANBH	Non-A, non-B hepatitis
ISG	Immune serum globulin

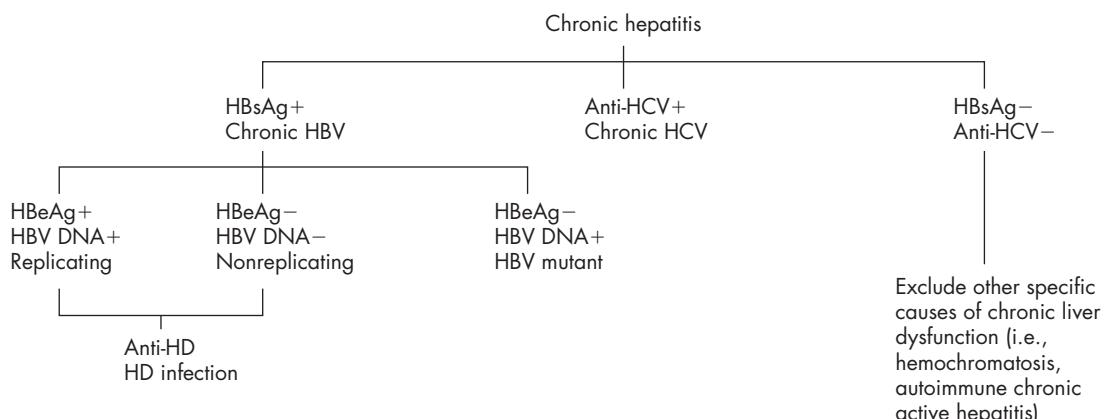

transmission of infection to an infant can be estimated and specific preventive measures provided for the infant (Table 13-2).

## HEPATITIS A

Hepatitis A virus (HAV) is usually an acute self-limited infection. The illness is typically mild, and it is generally subclinical in infants. Occasionally, HAV infection is prolonged or relapsing, extending 3 to 6 months, and rarely, it is fulminant, but HAV infection does not lead to chronic infection. The incidence of prematurity after maternal HAV infection is increased, but no evidence to date indicates obvious birth defects or a congenital syndrome.<sup>415,517</sup> HAV infection in premature infants may lead to prolonged viral shedding.<sup>391</sup> Transmission is most often person to person (fecal-oral), and transmission in foodborne or waterborne epidemics has been described. Transmission via blood products and vertical transmission (mother to infant) are

**Figure 13-4.** Diagnostic approach to a patient with acute viral hepatitis. See Box 13-2 for definitions of abbreviations. (From Martin P, Friedman L, Dienstag J: Diagnostic approach. In Zuckerman A, Thomas H, editors: *Viral hepatitis: scientific basis and clinical management*, Edinburgh, 1993, Churchill Livingstone.)

**Figure 13-5.** Diagnostic approach to a patient with chronic viral hepatitis. See Box 13-2 for definitions of abbreviations. (From Martin P, Friedman L, Dienstag J: Diagnostic approach. In Zuckerman A, Thomas H, editors: *Viral hepatitis: scientific basis and clinical management*, Edinburgh, 1993, Churchill Livingstone.)

rare.<sup>488</sup> Transmission in day care settings has been clearly described.

Infection with HAV in newborns is uncommon and does not seem to be a significant problem. The usual period of viral shedding and presumed contagiousness lasts 1 to 3 weeks. Acute maternal HAV infection in the last trimester or in the postpartum period could lead to infection in an infant. Symptomatic infection can be prevented by immunoglobulin (Ig) administration, and 80% to 90% of disease can be prevented by Ig administration within 2 weeks of exposure. HAV vaccine can be administered simultaneously with Ig without

affecting the seroconversion rate to produce rapid and prolonged HAV serum antibody levels.

The transmission of HAV via breast milk has been implicated in one case report, but no data exist on the frequency of isolating HAV from breast milk.<sup>488</sup> Because HAV infection in infancy is rare and usually subclinical without chronic disease and because exposure has already occurred by the time the etiologic diagnosis of hepatitis in a mother is made, no reason exists to interrupt breastfeeding with maternal HAV infection. The infant should receive Ig and HAV vaccine, administered simultaneously.

**TABLE 13-2** Viral Hepatitis in Association With Breastfeeding\*

Hepatitis	Virus	Identified in Breast Milk	Factors for Perinatal/Postnatal Transmission	Prevention	Breastfeeding†
A	Picornaviridae (RNA)	?	Vertical transmission uncertain or rare	ISG	Limited evidence of transmission via breastfeeding or of serious disease in infants
					Breastfeeding OK after ISG and vaccine
B	Hepadnaviridae (DNA)	HBsAg	Increased risk for vertical transmission with HBeAg+, in countries where HBV is endemic, or early in maternal infection, before Ab production	HBIG	Low theoretic risk
		HBV DNA		HBV vaccine	Virtually no risk after HBIG and HBV vaccine, breastfeeding OK after HBIG and vaccine
C	Flavivirus (RNA)	HCV RNA detected	Increased risk when mother HIV+ and HCV+ or with increased HCV RNA titers  Vertical transmission uncommon	None	Positive theoretic risk, inadequate data on relative risk, breastfeeding OK after informed discussion with parents
D	Delavirdine (RNA—strand, circular)	?	Requires coinfection/superinfection with HBV	None (except to prevent HBV infection, give HBIG/HBV vaccine)	Prevent HBV infection with HBIG and vaccine
E	Caliciviridae (RNA)	+	Severe disease in pregnant women (20% mortality)	ISG and subunit vaccine being tested	Breastfeeding OK after HBIG and vaccine
G	Related to calicivirus and flavivirus (RNA)	?	Vertical transmission occurs	None	Inadequate data
TT	TT virus (DNA, circular, single stranded)	TTV DNA detected	Vertical transmission occurs	None	Inadequate data

\*See Box 13-2 for abbreviations. *Ab*, Antibody; *HIV*, human immunodeficiency virus.

†With any type of infectious hepatitis, discussion of what is known and not known concerning transmission should be related to the mother/parents, and an informed decision can then be made by the involved adults concerning breastfeeding.

## HEPATITIS B

HBV infection leads to a broad spectrum of illness, including asymptomatic seroconversion, nonspecific symptoms (fever, malaise, fatigue), clinical hepatitis with or without jaundice, extrahepatic manifestations (arthritis, rash, renal involvement),

fulminant hepatitis, and chronic HBV infection. Chronic HBV infection occurs in up to 90% of infants infected via perinatal and vertical transmission and in 30% of children infected between 1 and 5 years of age. Given the increased risk for significant sequelae from chronic infection (chronic

active hepatitis, chronic persistent hepatitis, cirrhosis, primary hepatocellular carcinoma), the prevention of HBV infection in infancy is crucial. Transmission of HBV is usually through blood or body fluids (stool, semen, saliva, urine, cervical secretions).<sup>102</sup>

Vertical transmission, either transplacentally or perinatally during delivery, has been well described throughout the world. Vertical transmission rates in areas where HBV is endemic (Taiwan and Japan) are high, whereas transmission to infants from HBV-carrier mothers in other areas where HBV carrier rates are low is uncommon.<sup>444</sup> The transmission of HBV to infants occurs in up to 50% of infants when the mothers are acutely infected immediately before, during, or soon after pregnancy.<sup>514</sup>

HBsAg is found in breast milk, but transmission by this route is not well documented. Beasley<sup>34</sup> and Beasley et al.<sup>35</sup> demonstrated that, although breast milk transmission is possible, seroconversion rates were no different between breastfed and non-breastfed infants in a long-term follow-up study of 147 HBsAg-positive mothers. Hill et al.<sup>194</sup> followed 101 breastfed infants and 268 formula-fed infants born to women who were chronically HBsAg positive. All infants received HBIG at birth and a full series of hepatitis B vaccine. None of the breastfed infants and nine of the formula-fed infants were positive for HBsAg after completion of the HBV vaccine series. Breastfeeding had occurred for a mean of 4.9 months (range: 2 weeks to 1 year). Transmission, when it does happen, probably occurs during labor and delivery. Another report from China followed 230 infants born to HBsAg-positive women. The infants received the appropriate dosing and timing of HBIG and HBV vaccine. At 1 year of age, anti-HBs antibodies were present in 90.9% of the breastfed infants and 90.3% of the bottle-fed infants.<sup>486</sup> Risk factors associated with immunoprophylaxis failure against vertical transmission of HBV include HBeAg-seropositive mothers and elevated HBV DNA "viral loads" in the mothers.<sup>437</sup> Zhang et al. also demonstrated in over 67,000 pregnant women and 1150 HBsAg-positive mothers that breastfeeding did not increase the risk of HBV mother-to-child transmission, as compared to formula-fed infants.<sup>516</sup> A systematic review and meta-analysis by Shi et al. including 10 controlled clinical trials reported an odds ratio for the development of hepatitis B surface antibodies in breastfeeding infants, compared with non-breastfeeding infants, of 0.98 (CI 0.69 to 1.40).<sup>424</sup> In 2009, the AAP Committee on Infectious Diseases stated "that breastfeeding of the infant by a HBsAg-positive mother poses no additional risk for acquisition of HBV infection by the infant with appropriate administration of hepatitis B vaccine and HBIG."<sup>103</sup>

Screening of all pregnant women for HBV infection is an essential first step to preventing vertical transmission. Universal HBV vaccination at birth and during infancy, with the administration of HBIG immediately after birth to infants of HBsAg-positive mothers, prevents HBV transmission in more than 95% of cases. Breastfeeding by HBsAg-positive women is not contraindicated, but the immediate administration of HBIG and HBV vaccine should occur. Two subsequent doses of vaccine should be given at appropriate intervals and dosages for the specific HBV vaccine product. This decreases the small theoretic risk for HBV transmission from breastfeeding to almost zero.

When acute peripartum or postpartum hepatitis occurs in a mother and HBV infection is a possibility, with its associated increased risk for transmission to the infant, a discussion with the mother or parents should identify the potential risks and benefits of continuing breastfeeding until the etiology of the hepatitis can be determined. If an appropriate alternative source of nutrition is available for the infant, breast milk should be withheld until the etiology of the hepatitis is identified. HBIG and HBV vaccine can be administered to the infant who has not already been immunized or has no documented immunity against HBV.<sup>445</sup> If acute HBV infection is documented in a mother, breastfeeding can continue after immunization has begun.

## HEPATITIS C

Acute infection with HCV can be indistinguishable from hepatitis A or B infection; however, it is typically asymptomatic or mild. HCV infection is the major cause of blood-borne non-A, non-B hepatitis (NANBH). Chronic HCV infection is reported to occur 70% to 85% of the time regardless of age at time of infection. Sequelae of chronic HCV infection are similar to those associated with chronic HBV infection. Bortolotti et al.<sup>54</sup> described two groups of children with HCV infection who they observed for 12 to 48 months. The first group of 14 children, who acquired HCV infection early in life, presumably from their mothers, demonstrated biochemical evidence of liver disease in the first 12 months of life. Two of these children subsequently cleared the viremia and had normal liver function, an additional three children developed normal liver function despite persistent HCV viremia, and the remaining children had persistent viremia and abnormal liver function. The second group of 16 children, with chronic HCV infection, remained free of clinical symptoms of hepatitis, but 10 (62%) of them had mild alanine aminotransferase elevations, and 7 of the 16

(44%) who had liver biopsies had histologic evidence of mild to moderate hepatitis.

The two commonly identified mechanisms of transmission of HCV are transfusions of blood or blood products and IV drug use. However, other routes of transmission exist because HCV infection occurs even in the absence of obvious direct contact with significant amounts of blood. Other body fluids contaminated with blood probably serve as sources of infection. Transmission through sexual contact occurs infrequently and probably requires additional contributing factors, such as coinfection with other sexually transmitted agents or high viral loads in serum and other body fluids. Studies of transmission in households without other risk factors have demonstrated either low rates of transmission or no transmission.

The reported rates of vertical transmission vary widely. In mothers with unknown HIV status or known HIV infection, the rates of vertical transmission were 4% to 100%, whereas the rates varied between 0% and 42% in known HIV-negative mothers.<sup>125</sup> These same studies suggest that maternal coinfection with HIV, HCV genotype, active maternal liver disease, and the serum titer of maternal HCV RNA may be associated with increased rates of vertical transmission.<sup>296,346,513</sup> The correlation between HCV viremia, the HCV viral load in a mother, and vertical transmission of HCV is well documented.<sup>325,397,451,507</sup> The clinical significance and risk for liver disease after vertical transmission of HCV are still unknown. The timing of HCV infection in vertical transmission is also unknown. In utero transmission has been suggested by some studies,<sup>138</sup> whereas intrapartum or postpartum transmission was proposed by Ohto et al.<sup>347</sup> when they documented the absence of HCV RNA in the cord blood of neonates who later became HCV RNA positive at 1 to 2 months of age. More recently, Gibb et al.<sup>166</sup> reported two pieces of data supporting the likelihood of intrapartum transmission as the predominant time of vertical transmission: (1) low sensitivity of PCR for HCV RNA testing in the first month of life with a marked increase in sensitivity after that for diagnosing HCV infection in infants and (2) a lower transmission risk for elective cesarean delivery (without prolonged rupture of membranes) compared with vaginal or emergency cesarean delivery.<sup>166</sup> Another group, McMenamin et al.,<sup>308</sup> analyzed vertical transmission in 559 mother-infant dyads. The overall vertical transmission rate was 4.1% (18/441), with another 118 infants not tested or lost to follow-up. Comparison of the vertical transmission rate was no different for vaginal delivery or emergency cesarean in labor versus planned cesarean (4.2% vs. 3.0%). This held true even when mothers had hepatitis C RNA detected antenatally (7.2% vs.

5.3%). The authors did not support planned cesarean delivery to decrease vertical transmission of hepatitis C infection. No prospective, controlled trials of cesarean versus vaginal delivery and the occurrence of vertical hepatitis C transmission are available.

The risk for HCV transmission via breast milk is uncertain. Anti-HCV antibody and HCV RNA has been demonstrated in colostrum and breast milk, although the levels of HCV RNA in milk did not correlate with the titers of HCV RNA in serum.<sup>40,180,285,397</sup> Nevertheless, transmission of HCV via breastfeeding (and not in utero, intrapartum, or from other postpartum sources) has not been proven in the small number infants studied. Transmission rates in breastfed and nonbreastfed infants appear to be similar, but various important factors have not been controlled, such as HCV RNA titers in mothers, examination of the milk for HCV RNA, exclusive breastfeeding versus exclusive formula feeding versus partial breastfeeding, and duration of breastfeeding.<sup>166,285,296,320,325,347,348,513</sup> Zanetti et al.<sup>513</sup> documented the absence of HCV transmission in 94 mother-infant dyads when the mother had only HCV (no HIV) infection and no transmission in 71 mother-infant dyads who breastfed, including 23 infants whose mothers were seropositive for HCV RNA. Eight infants in that study were infected with HCV and their mothers had both HIV and HCV, and 3 of these 8 infants were infected with both HIV and HCV. The HCV RNA levels were significantly higher in the mothers coinfected with HIV than they were in mothers with HCV alone.

Overall, the risk for HCV infection via breastfeeding is low, the risk for HCV infection appears to be more frequent in association with HIV infection and higher levels of HCV RNA in maternal serum, no effective preventive therapies (Ig or vaccine) exist, and the risk for chronic HCV infection and subsequent sequelae with any infection is high. It is therefore appropriate to discuss the theoretic risk for breastfeeding in HCV-positive mothers with the mother or parents and to consider prescribing breast milk when appropriate alternative sources of nutrition are available for the infants. HIV infection is a separate contraindication to breastfeeding. Additional study is necessary to determine the exact role of breastfeeding in the transmission of HCV, including the quantitative measurement of HCV RNA in colostrum and breast milk, the relative risk for HCV transmission in exclusively or partially breastfed infants versus the risk in formula-fed infants, and the effect of duration of breastfeeding on transmission.

The current position of the CDC is that no data indicate that HCV virus is transmitted through breast milk.<sup>88</sup> Therefore, breastfeeding by an

HCV-positive, HIV-negative mother is not contraindicated.

Infants born to HCV RNA-positive mothers require follow-up through 18 to 24 months of age to determine the infants' HCV status, regardless of the mode of infant feeding. Infants should be tested for alanine aminotransferase and HCV RNA at 3 months and 12 to 15 months of age. Alanine aminotransferase and anti-HCV antibody should be tested at 18 to 24 months of age to confirm an infant's status: uninfected, ongoing hepatitis C infection, or past HCV infection.

## HEPATITIS D

HDV is a defective RNA virus that causes hepatitis only in persons also infected with HBV. The infection occurs as either an acute coinfection of HBV and HDV or a superinfection of HBV carriers. This "double" infection results in more frequent fulminant hepatitis and chronic hepatitis, which can progress to cirrhosis. The virus uses its own HBV RNA (circular, negative-strand RNA) with an antigen, HDAg, surrounded by the surface antigen of HBV, HBsAg. HDV is transmitted in the same way as HBV, especially through the exchange of blood and body fluids. HDV infection is uncommon where the prevalence of HBV is low. In areas where HBV is endemic, the prevalence of HDV is highly variable. HDV is common in tropical Africa and South America, as well as in Greece and Italy, but it is uncommon in the Far East and in Alaskan Inuit despite the endemic occurrence of HBV in these areas.<sup>434</sup>

The transmission of HDV has been reported to occur from household contacts and, rarely, through vertical transmission. No data are available on the transmission of HDV by breastfeeding. HDV infection can be prevented by blocking infection with HBV; therefore, HBIG and HBV vaccine are the best protection. In addition to HBIG and HBV vaccine administration to the infant of a mother infected with both HBV and HDV, discussion with the mother or parents should include the theoretic risk for HBV and HDV transmission through breastfeeding. As with HBV, once HBIG and HBV vaccine have been given to the infant, the risk for HBV or HDV infection from breastfeeding is negligible. Therefore, breastfeeding after an informed discussion with the parents is acceptable.

## HEPATITIS E

Hepatitis E virus (HEV) is a cause of sporadic and epidemic, enterically transmitted NANBH, which is typically self-limited and without chronic

sequelae. HEV is notable for causing a high mortality rate in pregnant women. Transmission is primarily via the fecal-oral route, commonly via contaminated water or food. High infection rates have been reported in adolescents and young adults (ages 15 to 40 years). Tomar<sup>461</sup> reported that 70% of cases of HEV infections in the pediatric population in India manifest as acute hepatitis. Maternal-neonatal transmission was documented when the mother developed hepatitis E infection in the third trimester. Although HEV was demonstrated in breast milk, no transmission via breast milk was confirmed in this report. Five cases of transfusion-associated hepatitis E were reported.<sup>461</sup> In a review by Krain et al.,<sup>249</sup> vertical transmission was noted in reports from India and Ghana in the infants of pregnant women with acute viral hepatitis or fulminant hepatic failure.<sup>249</sup> Chibber et al.<sup>98</sup> reported on the presence of HEV RNA in the colostrum of HEV-infected mothers in significantly lower levels than in maternal serum. They also noted six infants who became infected within 2 weeks postpartum after being anti-HEV antibody and HEV RNA negative at birth. Four of these six infants were formula fed due to severe maternal illness. There was no transmission of HEV in 87 other infants who were exclusively breastfed and born to mothers positive for anti-HEV antibodies or HEV RNA in the third trimester.<sup>98</sup> Epidemics are usually related to contamination of water. Person-to-person spread is minimal, even in households and day care settings. Although Ig may be protective, no controlled trials have been done. Animal studies suggest that a recombinant subunit vaccine may be feasible.<sup>385</sup>

HEV infection in infancy is rare but does occur after maternal infection in the third trimester of pregnancy. Limited available data suggest that transmission of HEV by breastfeeding is rare. There is no evidence of clinically significant postnatal HEV infection or chronic sequelae in association with HEV infection in infants via breast milk. Currently no contraindication exists to breastfeeding with maternal HEV infection. Ig has not been shown to be effective in preventing infection, and no vaccine is available for HEV.

## HEPATITIS G

Hepatitis G virus (HGV) has recently been confirmed as a cause of NANBH distinct from hepatitis viruses A through E. Several closely related genomes of HGV, currently named GBV-A, -B, and -C, appear to be related to HCV; the pestiviruses and the flaviviruses. Epidemiologically, HGV is most often associated with the transfusion of blood, although studies have identified nontransfusion-related cases. HGV genomic RNA has been detected in some patients with acute

and chronic hepatitis and a small number of patients with fulminant hepatitis. GBV-C/HGV has also been found in some patients with inflammatory bile duct lesions, but the pathogenicity of this virus is unconfirmed. HGV RNA has been detected in 1% to 3% of healthy blood donors in the United States.<sup>9</sup> Feucht et al.<sup>141</sup> described maternal-to-infant transmission of HGV in three of nine children. Two of the three mothers were coinfected with HIV and the third with HCV. None of these infants developed signs of liver disease. Neither the timing nor the mode of transmission was clarified. Lin et al.<sup>284</sup> reported no HGV transmission in three mother-infant dyads after cesarean delivery and discussed transplacental spread via blood as the most likely mode of HGV infection in vertical transmission. Wejstal et al.<sup>490</sup> reported on perinatal transmission of HGV to 12 of 16 infants born to HGV-viremic mothers, identified by PCR. HGV did not appear to cause clinical hepatitis in these children.<sup>490</sup>

Fischler et al.<sup>144</sup> followed eight children born to HCV-positive mothers and found only one to be infected with HGV. That child remained clinically well, while his twin, also born by cesarean delivery and breastfed, remained HCV negative for 3 years of observation. Five of the other six children were breastfed for variable periods without evidence of HGV infection. Ohto et al.<sup>348</sup> examined HGV mother-to-infant transmission. Of 2979 pregnant Japanese women who were screened, 32 were identified as positive for GBV-C/HGV RNA by PCR; 26 of 34 infants born to the 32 HGV-positive women were shown to be HGV RNA positive. Reportedly, none of the infants demonstrated a clinical picture of hepatitis, although two infants had persistent mild elevations (less than two times normal) of alanine aminotransferase. The viral load in mothers, who transmitted HGV to their infants, was significantly higher than it was in nontransmitting mothers. Infants born by elective cesarean delivery had a lower rate of infection (3 in 7) compared with infants born by emergency cesarean delivery (2 of 2) or born vaginally (21 of 25). In this study, HGV infection in breastfed infants was four times more common than it was in formula-fed infants, but this difference was not statistically significant because only four infants were formula fed. The authors report no correlation between infection rate and duration of breastfeeding. Testing of the infants was not done frequently and early enough routinely through the first year of life to determine the timing of infection in these infants.<sup>348</sup> Schröter et al.<sup>413</sup> reported transmission of HGV to 3 of 15 infants born to HGV RNA-positive mothers at 1 week of age. None of 15 breast milk samples was positive for GBV-C/HGV RNA, and all of the children who were initially negative for HGV RNA in serum

remained negative at follow-up between 1 and 28 months of age.<sup>413</sup>

The foregoing data suggest that transmission is more likely to be vertical before or at delivery rather than via breastfeeding. The pathogenicity and the possibility of chronic disease due to HGV infection remain uncertain at this time. Insufficient data are available to make a recommendation concerning breastfeeding by HGV-infected mothers.

## HERPES SIMPLEX VIRUS

HSV types 1 and 2 (HSV-1 and HSV-2) can cause prenatal, perinatal, and postnatal infections in fetuses and infants. Prenatal infection can lead to abortion, prematurity, or a recognized congenital syndrome. Perinatal infection is the most common form of infection (1 in 2000 to 5000 live births, 700 to 1500 cases per year in the United States) and is often fatal or severely debilitating. The factors that facilitate intrapartum infection and predict the severity of disease have been extensively investigated. Postnatal infection is uncommon but can occur from a variety of sources, including oral or genital lesions and secretions in mothers or fathers, hospital workers and home caregivers, and breast lesions in breastfeeding mothers. A number of case reports have documented severe HSV-1 or HSV-2 infections in infants associated with HSV-positive breast lesions in the mothers.<sup>128,179,378,448</sup> Cases of infants with HSV gingivostomatitis inoculating the mothers' breasts have also been reported.

In the absence of breast lesions, breastfeeding in HSV-seropositive or culture-positive women is reasonable when accompanied by careful handwashing, covering the lesions, and avoiding fondling or kissing with oral lesions until all lesions are crusted. Breastfeeding during maternal therapy with oral or IV acyclovir or valacyclovir can continue safely as well. Inadequate information exists concerning famciclovir, ganciclovir, and foscarnet in breast milk to make a recommendation at this time. Breastfeeding by women with active herpetic lesions on their breasts should be proscribed until the lesions are dried. Treatment of the mothers' breast lesions with topical, oral, and/or IV antiviral preparations may hasten recovery and decrease the length of viral shedding.

## HUMAN HERPESVIRUS 6 AND HUMAN HERPESVIRUS 7

Human herpesvirus 6 (HHV-6) is a cause of exanthema subitum (roseola, roseola infantum) and is associated with febrile seizures. HHV-6 appears to be most similar to CMV based on genetic analysis. No obvious congenital syndrome of HHV-6

infection has been identified, although prenatal infection has been reported.<sup>130</sup> Seroepidemiologic studies show that most adults have already been infected by HHV-6. Therefore, primary infection during pregnancy is unlikely, but reactivation of latent HHV-6 infection may be more common. No case of symptomatic HHV-6 prenatal infection has been reported. The significance of reactivation of HHV-6 in a pregnant woman and the production of infection and disease in the fetus and infant remains to be determined. Primary infection in children occurs most often between 6 and 12 months of age, when maternally acquired passive antibodies against HHV-6 are waning. Febrile illnesses in infants younger than 3 months of age have been described with HHV-6 infection, but infection before 3 months or after 3 years is uncommon.

Various studies involving the serology and restriction enzyme analysis of HHV-6 isolates from mother-infant dyads support the idea that postnatal transmission and perhaps perinatal transmission from the mothers are common sources of infection. One study was unable to detect HHV-6 in breast milk by PCR analysis in 120 samples, although positive control samples seeded with HHV-6-infected cells did test positive.<sup>131</sup>

Given the limited occurrence of clinically significant disease and the absence of sequelae of HHV-6 infection in infants and children, the almost universal acquisition of infection in early childhood (with or without breastfeeding), and the absence of evidence that breast milk is a source of HHV-6 infection, breastfeeding can continue in women known to be seropositive for HHV-6.

Human herpesvirus 7 (HHV-7) is closely related to HHV-6 biologically. Primary infection with HHV-7 occurs most often in childhood, usually later in life than HHV-6 infection. The median age of infection is 26 months, with 75% of children becoming HHV-7 positive by 5 years of age.<sup>71</sup> The seroprevalence of HHV-7 antibodies has been reported to be 80% to 98% in adults, and passive antibodies are present in almost all newborns.<sup>345,454</sup> Like HHV-6, HHV-7 infection can be associated with acute febrile illness, febrile seizures, and irritability, but in general, it is a milder illness than with HHV-6, with fewer hospitalizations. Virus excretion of HHV-7 occurs in saliva, and PCR testing of blood cells and saliva is frequently positive in individuals with past infection.<sup>515</sup> Congenital infection of HHV-6 was detected via DNA PCR testing in 57 of 5638 of cord blood samples (1%), but HHV-7 was not detected in any of 2129 cord blood specimens.<sup>184</sup>

HHV-7 DNA was detected by PCR in 3 of 29 breast milk mononuclear cell samples from 24 women who were serum positive for the HHV-7 antibody.<sup>152</sup> In the same study, small differences

were seen in the HHV-7 seropositive rates between breastfed infants and bottle-fed infants at 12 months of age (21.7% versus 20%), at 18 months of age (60% versus 48.1%), and at 24 months of age (77.3% versus 58.3%). None of these differences was statistically significant. Given that HHV-6 infection generally occurs earlier than HHV-7 infection in most infants and that HHV-6 is rarely found in breast milk, it seems unlikely that HHV-7 in breast milk is a common source of infection in infants and children. The infrequent occurrence of significant illness with HHV-7 infection, with the absence of sequelae, except in patients who had transplantation surgery at older ages, and the common occurrence of infection in childhood suggests that there is no reason to proscribe breastfeeding for HHV-7-positive women.

## *Human Papillomavirus*

Human papillomavirus (HPV) is a DNA virus with at least 100 different types. These viruses cause warts, genital dysplasia, cervical carcinoma (types 6 and 11), and laryngeal papillomatosis. Transmission occurs through direct contact and sexual contact. Laryngeal papillomas are thought to result from acquiring the virus in passage through the birth canal. Infection in pregnant women or during pregnancy does not lead to an increase in abortions or the risk for prematurity, and no evidence indicates intrauterine infection. HPV is one of the most common viruses in adults and one of the most common sexually transmitted infections.

Diagnosis is usually by histologic examination or DNA detection. Spontaneous resolution does occur, but therapy for persistent lesions or growths in anatomically problematic locations is appropriate. Therapy can be with podophyllum preparations, trichloroacetic acid, cryotherapy, electrocautery, and laser surgery. Interferon is being tested in the treatment of laryngeal papillomas, with mixed results.<sup>121</sup> Prevention against transmission means limiting direct or sexual contact, but this may not be sufficient because lesions may not be evident and transmission may still occur.

Rintala et al.<sup>388</sup> examined the occurrence of HPV DNA in the oral and genital mucosa of infants during the first 3 years of life. HPV DNA was identified in 12% to 21% of the oral scrape samples and in 4% to 15% of the genital scrape samples by PCR. Oral HPV infection was acquired by 42% of children, cleared by 11%, and persisted in 10% of children; 37% of the children were never infected. The authors did not report on breast milk or breastfeeding in that study. The question of the source of the infection remains undetermined.

The breast is a rare site of involvement.<sup>123</sup> HPV types 16 and 18 can immortalize normal breast epithelium in vitro.<sup>489</sup> HPV DNA has been detected in breast milk in 10 of 223 (4.5%) milk samples from 223 mothers, collected 3 days postpartum.<sup>404</sup> No attempt was made to correlate the presence of HPV DNA in breast milk with the HPV status of an infant or to assess the viral load of HPV in breast milk or its presence over the course of lactation. A second study found the DNA of cutaneous and mucosal HPV types in 2 of 25 human milk samples and 1 of 10 colostrum samples.<sup>72</sup> Yoshida et al. analyzed 80 maternal milk samples for HPV DNA, and HPV-16 nucleic acid was detected in 2 of 80 samples (2.5%), but there was no evidence of transmission to either of the infants.<sup>510</sup> No reports of HPV lesions of the breast or nipple and documented transmission to an infant secondary to breastfeeding are available.

No increased risk for acquiring HPV from breast milk is apparent, and breastfeeding is acceptable. Even in the rare occurrence of an HPV lesion of the nipple or breast, no data suggest that breastfeeding or the use of expressed breast milk is contraindicated.

## MEASLES

Measles is another highly communicable childhood illness that can be more severe in neonates and adults. Measles is an exanthematous febrile illness following a prodrome of malaise, coryza, conjunctivitis, cough, and often Koplik spots in the mouth. The rash usually appears 10 to 14 days after exposure. Complications can include pneumonitis, encephalitis, and bacterial superinfection. With the availability of vaccination, measles in pregnancy is rare (0.4 in 10,000 pregnancies),<sup>164</sup> although respiratory complications (primary viral pneumonitis, secondary bacterial pneumonia), hepatitis, or other secondary bacterial infections often lead to more severe disease in these situations.

Prenatal infection with measles may cause premature delivery without disrupting normal uterine development. No specific group of congenital malformations have been described in association with *in utero* measles infection, although teratogenic effects of measles infection in pregnant women may rarely manifest in the infants.

Perinatal measles includes transplacental infection when measles occurs in an infant in the first 10 days of life. Infection from extrauterine exposure usually develops after 14 days of life. The severity of illness after the suspected transplacental spread of the virus to an infant varies from mild to severe and does not seem to vary with the antepartum or postpartum onset of rash in the mother. It is uncertain what role maternal antibodies play in the

severity of an infant's disease. More severe disease seems to be associated with severe respiratory illness and bacterial infection. Postnatal exposure leading to measles after 14 days of life is generally mild, probably because of passively acquired antibodies from the mother. Severe measles in children younger than 1 year of age may occur because of declining passively acquired antibodies and complications of respiratory illness and rare cases of encephalitis.

Measles virus has not been identified in breast milk, whereas measles-specific antibodies have been documented.<sup>1a</sup> A report in 2014 examining measles in pregnancy in France during a resurgence of measles in the community did not demonstrate acquired measles in any of the 13 breastfed infants.<sup>70</sup> Infants exposed to mothers with documented measles while breastfeeding should be given immunoglobulin (Ig) and isolated from the mother until 72 hours after the onset of rash, which is often only a short period after diagnosis of measles in the mother. The breast milk can be pumped and given to the infant because secretory IgA begins to be secreted in breast milk within 48 hours of the onset of the exanthem in the mother. Table 13-3 summarizes the management of the hospitalized mother and infant with measles exposure or infection.<sup>164</sup>

## MUMPS

Mumps is an acute transient benign illness with inflammation of the parotid gland and other salivary glands, and it often involves the pancreas, testicles, and meninges. Mumps occurs infrequently in pregnant women (1 to 10 cases in 10,000 pregnancies) and is generally benign. Mumps virus has been isolated from saliva, respiratory secretions, blood, testicular tissue, urine, CSF in cases of meningeal involvement, and breast milk. The period of infectivity is believed to be between 7 days before and 9 days after the onset of parotitis, with the usual incubation period being 14 to 18 days.

Prenatal infection with the mumps virus causes an increase in the number of abortions when infection occurs in the first trimester. A small increase in the number of premature births was noted in one prospective study of maternal mumps infection.<sup>427</sup> No conclusive evidence suggests congenital malformations are associated with prenatal infection, not even with endocardial fibroelastosis, as originally reported in the 1960s.

Perinatal mumps (transplacentally or postnatally acquired) has rarely if ever been documented. Natural mumps virus has been demonstrated to infect the placenta and infect the fetus, and live attenuated vaccine virus has been isolated from the placenta but not from fetal tissue in women

**TABLE 13-3** Guidelines for Preventive Measures After Exposure to Measles in Nursery or Maternity Ward

Type of Exposure or Disease	Measles (Prodrome or Rash) Present*		Disposition
	Mother	Neonate	
A. Siblings at home have measles* when neonate and mother are ready for discharge from hospital	No	No	<ol style="list-style-type: none"> <li>1. Neonate: Protective isolation and immunoglobulin (IG) indicated unless mother has unequivocal history of previous measles or measles vaccination†</li> <li>2. Mother: With history of previous measles or measles vaccination, she may either remain with the neonate or return to older children. Without previous history, she may remain with neonate until the older siblings are no longer infectious, or she may receive IG prophylactically and return to the older children</li> </ol>
B. Mother has no history of measles or measles vaccination exposure 6 to 15 days antepartum‡	No	No	<ol style="list-style-type: none"> <li>1. Exposed mother and infant: Administer IG to each and send home at the earliest date, unless siblings at home have communicable measles. Test mothers for susceptibility if possible. If susceptible, administer live measles vaccine 8 weeks after IG</li> <li>2. Other mothers and infants: Same approach, unless there is a clear history of previous measles or measles vaccination in the mother</li> <li>3. Hospital personnel: Unless there is a clear history of previous measles or measles vaccination, administer IG within 72 hours of exposure. Vaccinate 8 weeks or more later</li> </ol>
C. Onset of maternal measles occurs antepartum or postpartum§	Yes	Yes	<ol style="list-style-type: none"> <li>1. Infected mother and infant: Isolate together until clinically stable, then send home</li> <li>2. Other mothers and infants: Same as B-3, except infants should be vaccinated at 15 months of age</li> <li>3. Hospital personnel: Same as B-3.</li> </ol>
D. Onset of maternal measles occurs antepartum or postpartum§	Yes	No	<ol style="list-style-type: none"> <li>1. Infected mother: Isolate until no longer infectious§</li> <li>2. Infected mother's infant: Isolate separately from mother. Administer IG immediately. Send home when the mother is no longer infectious. Alternatively, observe in isolation for 18 days for modified measles¶ especially if IG administration was delayed for more than 4 days</li> <li>3. Other mothers and infants: Same as C-2</li> <li>4. Hospital personnel: Same as B-3</li> </ol>

\*Catarrhal stage or less than 72 hours after the onset of exanthem.

†Vaccination with live attenuated measles virus.

‡With exposure less than 6 days antepartum, the mother would not be potentially infectious until at least 72 hours postpartum.

§Considered infectious from the onset of prodrome until 72 hours after the onset of exanthem.

¶Incubation period for modified measles may be prolonged beyond the usual 10 to 14 days.

From Gershon AA: Chickenpox, measles and mumps. In Remington JS, Klein JO, editors: *Infectious diseases of the fetus and newborn infant*, ed 4, Philadelphia, 1995, WB Saunders.

vaccinated 10 days before induced abortion. Antibodies to mumps do cross the placenta.

Postnatal mumps in the first year of life is typically benign. No epidemiologic data suggest that mumps infection is more or less common or severe in breastfed infants compared with formula-fed infants. Although mumps virus has been identified in breast milk and mastitis is a rare complication of mumps in mature women, no evidence indicates that breast involvement occurs more frequently in lactating women. If mumps occurs in the mother, breastfeeding can continue because exposure has

already occurred throughout the 7 days before the development of symptoms in the mother, and secretory IgA in the milk may help to mitigate the symptoms in the infant.<sup>164</sup>

## PARVOVIRUS

Human parvovirus B19 causes a broad range of clinical manifestations, including asymptomatic infection (most frequent manifestation in all ages), erythema infectiosum (fifth disease), arthralgia and arthritis, red blood cell (RBC) aplasia (and, less

often, decreased white blood cells or platelets), chronic infection in immunodeficient individuals, and rarely myocarditis, vasculitis, or hemophagocytic syndrome.

Intrauterine vertical transmission can lead to severe anemia and immune-mediated hydrops fetalis, which can be treated, if accurately diagnosed, by intrauterine transfusion. Inflammation of the liver or CNS can be seen in the infant, along with vasculitis. If the child is clinically well at birth, hidden or persistent abnormalities are rarely identified. No evidence indicates that parvovirus B19 causes an identified pattern of birth defects.<sup>462</sup>

Postnatal transmission usually occurs person to person via contact with respiratory secretions, saliva, and rarely blood or urine. The seroprevalence in children at 5 years of age is less than 5%, with the peak age of infection occurring during the school-age years (5% to 40% of children infected). The majority of infections are asymptomatic or undiagnosed seroconversions.<sup>462</sup> Severe disease, such as prolonged aplastic anemia, occurs in individuals with hemoglobinopathies or abnormal RBC maturation. Attack rates have been estimated to be 17% to 30% in casual contacts and up to 50% among household contacts. In one study of 235 susceptible pregnant women, the annual seroconversion rate was 1.4%.<sup>245</sup>

No reports of transmission to an infant through breastfeeding are available. Excretion in breast milk has not been studied because of limitations in culturing techniques. Rat parvovirus has been demonstrated in rat milk. IgE antiparvovirus antibodies have been detected in human breast milk in one study.<sup>435</sup>

The very low seroconversion rate in young children and the absence of chronic or frequent severe disease suggest that the risk for parvovirus infection via breast milk is not significant. The possibility of antibodies against parvovirus or other protective constituents in breast milk has not been systematically studied. Breastfeeding by a mother with parvovirus infection is acceptable.

## POLIOVIRUSES

Poliovirus infections (types 1, 2, and 3) cause a range of illness, with 90% to 95% subclinical, 4% to 8% abortive, and 1% to 2% manifesting as paralytic poliomyelitis. A 1955 review by Bates<sup>32</sup> of 58 cases of poliomyelitis in infants younger than 1 month of age demonstrated paralysis or death in more than 70% and only one child without evidence of even transient paralysis. More than half the cases were ascribed to transmission from the mothers, although no mention was made of breastfeeding. Breastfeeding rates at the time were approximately 25%.

Prenatal infection with polioviruses does cause an increased incidence of abortion. Prematurity and stillbirth apparently occur more frequently in mothers who developed paralytic disease versus inapparent infection.<sup>206</sup> Although individual reports of congenital malformations in association with maternal poliomyelitis exist, no epidemiologic data suggest that polioviruses are teratogenic. Also, no evidence indicates that live attenuated vaccine poliovirus given during pregnancy is associated with congenital malformations.<sup>97,188</sup>

Perinatal infection has been noted in several case reports of infants, infected in utero several days before birth, who had severe disease manifesting with neurologic symptoms (paralysis) but without fever, irritability, or vomiting. Additional case reports of infection acquired postnatally demonstrate illness more consistent with poliomyelitis of childhood. These cases were more severe and involved paralysis, which may represent reporting bias.<sup>97</sup>

No data are available concerning the presence of poliovirus in breast milk, although antibodies to poliovirus types 1, 2, and 3 have been documented.<sup>304</sup> In this era of increasing worldwide poliovirus vaccination, the likelihood of prenatal or perinatal poliovirus infection is decreasing. Maternal susceptibility to poliovirus should be determined before conception and poliovirus vaccine offered to susceptible women. An analysis of the last great epidemic of poliovirus infection in Italy in 1958 was done using a population-based case-control study.<sup>376</sup> In 114,000 births, 942 infants were reported with paralytic poliomyelitis. A group of matched control subjects was selected from infants admitted to the hospital at the same time. Using the dichotomous variable of never breastfed and partially breastfed, 75 never-breastfed infants were among the cases and 88 among the control group. The authors determined an odds ratio of 4.2, with 95% confidence interval of 1.4 to 14, demonstrating that the risk for paralytic poliomyelitis was higher in infants never breastfed and lowest among those exclusively breastfed. Because by the time the diagnosis of poliomyelitis is made in a breastfeeding mother, the exposure of the infant to poliovirus from maternal secretions has already occurred, and because the breast milk already contains antibodies that may be protective, no reason exists to interrupt breastfeeding. Breastfeeding also does not interfere with successful immunization against poliomyelitis with oral or inactivated poliovirus vaccine.<sup>77</sup>

## RETROVIRUSES

### Human T-Cell Leukemia Virus Type I

The occurrence of human T-cell leukemia virus type I (HTLV-I) is endemic in parts of

southwestern Japan,<sup>74,228,501</sup> the Caribbean, South America,<sup>174</sup> and sub-Saharan Africa. HTLV-I is associated with adult T-cell leukemia/lymphoma and a chronic condition with progressive neuropathy. The progressive neuropathy is called HTLV-I-associated myelopathy or tropical spastic paraparesis.<sup>151</sup> Other illnesses have been reported in association with HTLV-I infection, including dermatitis, uveitis, arthritis, Sjögren syndrome in adults, and infective dermatitis and persistent lymphadenitis in children. Transmission of HTLV-I occurs most often through sexual contact, via blood or blood products, and via breast milk. Infrequent transmission does occur in utero or at delivery and with casual or household contact.<sup>328</sup>

Seroprevalence generally increases with age and varies widely in different regions and in populations of different backgrounds. In some areas of Japan, seropositivity can be as high as 12% to 16%, but in South America, Africa, and some Caribbean countries, the rates are 2% to 6%. In Latin America seropositive rates can be as high as 10% to 25% among female sex workers or attendees to STD clinics.<sup>174</sup> In blood donors in Europe, the seroprevalence of HTLV-I has been reported at 0.001% to 0.03%. The seroprevalence in pregnant women in endemic areas of Japan is as high as 4% to 5% and in nonendemic areas as low as 0.1% to 1.0%. HTLV-I is not a major disease in the United States. In studies from Europe, the seroprevalence in pregnant women has been noted to be up to 0.6%. These pregnant women were primarily of African or Caribbean descent.<sup>153</sup>

HTLV-I antigen has been identified in breast milk of HTLV-I-positive mothers.<sup>242</sup> Another report shows that basal mammary epithelial cells can be infected with HTLV-I and can transfer infection to peripheral blood monocytes.<sup>283</sup> Human milk from HTLV-I-positive mothers caused infection in marmosets.<sup>243,504</sup> HTLV-I infection clearly occurs via breastfeeding, and a number of reports document an increased rate of transmission of HTLV-I to breastfed infants compared with formula-fed infants.<sup>15,14,11–13,196,199,197,452</sup> Ando et al.,<sup>12,13</sup> in two separate reports, demonstrated a parallel decline in antibodies against HTLV-I in both formula-fed and breastfed infants to a nadir at approximately 1 year of age and a subsequent increase in antibodies from 1 to 2 years of age. The percentage of children seropositive at 1 year of age in the breastfed and formula-fed groups was 3.0% and 0.6%, respectively; at 1.5 years of age, it was 15.2% and 3.9%; and at 2 years of age, it was 41.9% and 4.6%. A smaller group of children, followed through 11 to 12 years of age, demonstrated no newly infected children after 2 years of age and no loss of antibodies in any child who was seropositive at 2 years of age.<sup>12,13</sup>

**TABLE 13-4** HTLV-I Transmission Related to the Duration of Breastfeeding

Author (Reference)	Duration (month)	Seroconversion Rate (%)	Number of Children*
Takahashi <sup>385</sup>	≤6	4.4	4/90
	≥7	14.4	20/139
	(bottle-fed)	5.7	9/158
Takezaki <sup>387</sup>	≤6	3.9	2/51
	>6	20.3	13/64
Wiktor <sup>423</sup>	<12	9.0	8/86
	≥12	32	19/60

HTLV, Human T-cell leukemia virus.

\*Number of children positive for HTLV-I over the number of children examined.

Transmission of HTLV-I infection via breastfeeding is also clearly associated with the duration of breastfeeding.<sup>452,453,497,498</sup> It has been postulated that the persistence of passively acquired antibodies against HTLV-I offers some protection through 6 months of life (Table 13-4).

Other factors relating to HTLV-I transmission via breast milk have been proposed. Yoshinaga et al.<sup>512</sup> presented data on the HTLV-I antigen-producing capacity of peripheral blood and breast milk cells and showed an increased mother-to-child transmission rate when the mother's blood and breast milk produced large numbers of antigen-producing cells in culture.<sup>512</sup> Hisada et al.<sup>201</sup> reported on 150 mothers and infants in Jamaica, demonstrating that a higher maternal provirus level and a higher HTLV-I antibody titer were independently associated with HTLV-I transmission to the infant. Ureta-Vidal et al.<sup>467</sup> reported an increased seropositivity rate in children of mothers with a high proviral load and elevated maternal HTLV-I antibody titers.

Various interventions have been proposed to decrease HTLV-I transmission via breastfeeding. Complete avoidance of breastfeeding was shown to be an effective intervention by Hino et al.<sup>197,198</sup> in a large population of Japanese in Nagasaki. Avoiding breastfeeding led to an 80% decrease in transmission. Breastfeeding for a shorter duration is another effective alternative. Ando et al.<sup>11</sup> showed that freezing and thawing breast milk decreased the infectivity of HTLV-I. Sawada et al.<sup>405</sup> demonstrated in a rabbit model that HTLV-I immunoglobulin protected against HTLV-I transmission via milk. It is reasonable to postulate that any measure that would decrease the maternal provirus load or increase the anti-HTLV-I antibodies available to infants might decrease the risk for transmission. The overall prevalence of HTLV-I infection during childhood is unknown because the majority of

individuals do not manifest illness until much later in life. The timing of HTLV-I infection in a breastfeeding population has been difficult to assess because of passively acquired antibodies from the mother and issues related to testing. Furnia et al.<sup>154</sup> estimated the time of infection for a cohort of 16 breastfed infants in Jamaica. The estimated median time of infection was 11.9 months, as determined by PCR, compared with the estimated time of infection, based on whole virus Western blot, of 12.4 months.

In areas where the prevalence of HTLV-I infection (in the United States, Canada, or Europe) is low, the likelihood that a single test for antibodies against HTLV-I would be a false positive test is high compared with the number of true positive tests.<sup>74</sup> Repeat testing is warranted in most situations.<sup>74</sup> Quantification of the antibody titer and the proviral load is appropriate in a situation when mother-to-child transmission is a concern. A greater risk for progression to disease in later life has not been shown for HTLV-I infection through breast milk, but early-life infections are associated with the greatest risk for adult T-cell leukemia.<sup>447</sup> The mother and family should be informed about all these issues. If the risk for lack of breast milk is not too great and formula is readily available and culturally acceptable, then the proscription of breastfeeding, or at least a recommendation to limit the duration of breastfeeding to 6 months or less, is appropriate to limit the risk for HTLV-I transmission to the infant. Given the substantial benefits of breastfeeding for the infant and mother, which is especially true in resource-poor countries, there is considerable debate about the cost and benefit of proscribing breastfeeding by HTLV-I mothers in all settings. Each individual situation should be evaluated and discussed with the family regarding the potential long-term benefits of not breastfeeding relative to HTLV-I infection versus the potential risks of not breastfeeding.<sup>324,386,474</sup> Freezing and thawing breast milk before giving it to an infant might be another reasonable intervention to decrease the risk for transmission, although no controlled trials document the efficacy of such an intervention. Neither Ig nor antiviral agents against HTLV-I are available at this time.

## **Human T-Cell Leukemia Virus Type II**

Human T-cell leukemia virus type II (HTLV-II) is endemic in specific geographic locations, including Africa, the Americas, the Caribbean, and Japan. Transmission is primarily through intravenous drug use, contaminated blood products, and breastfeeding. Sexual transmission occurs, but its overall contribution to the prevalence of HTLV-II in different populations remains uncertain. Many studies have examined the presence of HTLV-I and HTLV-II in blood products. PCR testing and selective

antibody tests suggest that about half of the HTLV seropositivity in blood donors is caused by HTLV-II.

HTLV-II has been associated with two chronic neurologic disorders similar to those caused by HTLV-I, tropical or spastic ataxia.<sup>290</sup> A connection between HTLV-II and glomerulonephritis, myelopathy, arthritis, T-hairy cell leukemia, and large granulocytic leukemia has been reported.

Mother-to-child transmission has been demonstrated in both breastfed and formula-fed infants. It appears that the rate of transmission is greater in breastfed infants.<sup>154,192,216,262,261,343,471,477</sup> HTLV-II has been detected in breast milk.<sup>192</sup> Nyambi et al.<sup>343</sup> reported that HTLV-II transmission did correlate with the duration of breastfeeding. The estimated rate of transmission was 20%. The time to seroconversion (after the initial loss of passively acquired maternal antibodies) for infected infants seemed to range between 1 and 3 years of age.<sup>343</sup> At this time avoidance of breastfeeding and limiting the duration of breastfeeding are the only two possible interventions with evidence of effectiveness for preventing HTLV-II mother-to-child transmission.<sup>228</sup>

With the current understanding of retroviruses, it is appropriate in cases of documented HTLV-II maternal infection to recommend avoiding or limiting the duration of breastfeeding and to provide alternative nutrition when financially practical and culturally acceptable. Mothers should have confirmatory testing for HTLV-II and measurement of the proviral load. Infants should be serially tested for antibodies to HTLV-II and have confirmatory testing if seropositive after 12 to 18 months of age. Further investigation into the mechanisms of transmission via breast milk and possible interventions to prevent transmission should occur as they have for HIV-1 and HTLV-I.

## **Human Immunodeficiency Virus Type 1**

Human immunodeficiency virus type 1 (HIV-1) is transmitted through human milk. Refraining from breastfeeding is a crucial aspect of preventing perinatal HIV infection in the United States and many other countries. The dilemma is the use of replacement feeding versus breastfeeding in countries where breastfeeding provides infants with significant protection from illness and death due to malnutrition or other infections.

**Breastfeeding and HIV Transmission.** The question of the contribution of breastfeeding in mother-to-child HIV-1 transmission is not a trivial one when one considers the following:

1. The WHO has estimated that 34 million people (estimated range: 31.4 to 35.9) were living with HIV-1 at the end of 2008.<sup>466</sup>

2. The WHO estimates that there were 330,000 (280,000 to 390,000) children younger than 14 years old who were newly infected with HIV-1 in 2011. This represents a drop of 24% compared with 2009. This number has declined due to increasing access to interventions to prevent mother-to-infant transmission.
3. The availability of antiretroviral therapy for the prevention of mother-to-child HIV transmission in developing countries in 2011 remained low at 30% of the mothers who needed it (compared with 54% of all eligible adults receiving antiretroviral therapy).<sup>466</sup>
4. Breastfeeding contributes an estimated 10% to 20% increase in the overall mother-to-child transmission rates, over and above intrauterine and intrapartum transmission, when no specific interventions to prevent transmission via breastfeeding are utilized.
5. Despite a dramatic increase in the number of people receiving antiretroviral therapy in developing countries, only 28% of children 0 to 14 years old who were eligible for antiretroviral medications based on current guidelines were receiving them. Depending on the age of the child this could lead to death within 12 to 24 months.<sup>466</sup>

The evidence of HIV transmission via breastfeeding is irrefutable. Multiple publications summarize the current evidence for HIV transmission via breastfeeding in the literature.<sup>254,382,465</sup> Since 1985, case reports have documented HIV transmission via breast milk to children around the world.<sup>200,218,277,518</sup> Primary HIV infection in breastfeeding mothers, with the concomitant high viral load, is associated with a particularly high rate of HIV transmission via breast milk. Palasanthiran et al.<sup>361</sup> estimated that risk at 27%. Large observational studies have demonstrated higher rates of HIV transmission in breastfed infants of mothers with chronic HIV infection compared with formula-fed infants.<sup>50,120,137</sup> A systematic analysis of published reports estimated the additional risk for perinatal HIV transmission due to breastfeeding to be 14% (95% confidence interval: 7% to 22%).<sup>129</sup> More recently published cohort studies similarly attributed additional risk for HIV transmission due to breastfeeding at 4% to 22% over and above the risk from prenatal and intrapartum transmission.<sup>42,116,133</sup> Laboratory reports demonstrate the presence of cell-free virus and cell-associated virus in breast milk, as well as various immunologic factors that could block or limit infection.<sup>62,176,256,330,334,355,396,457,469,482,483</sup> A dose-response relationship has been observed, correlating the HIV viral load in human milk, as well as a mother's plasma viral load, with an increased transmission risk for the breastfed infant.<sup>375,387,393,416</sup>

Many of the potential risk factors associated with human milk transmission of HIV have been described. The cumulative risk for HIV transmission is higher the longer the duration of breastfeeding.<sup>120,280,317,327,470</sup> Maternal characteristics related to the transmission of HIV via human milk include younger maternal age, higher parity, lower CD4+ counts, higher plasma viral loads, and breast abnormalities (mastitis, abscess, or nipple lesions). Characteristics of human milk that relate to a higher risk for transmission include higher viral load in the milk, lower concentrations of antiviral substances (lactoferrin, lysozyme), and lower concentrations of virus-specific cytotoxic T-lymphocytes, levels of various interleukins (IL-7, IL-15), secretory IgA, and IgM. Mixed breastfeeding is also associated with a higher risk for HIV transmission compared with exclusive breastfeeding.<sup>112,113,455</sup> The issue becomes how to balance the measurable benefits of breast milk (nutrition and protection against other causes of morbidity and mortality in infancy) against the relative risk for HIV transmission to the infant due to breastfeeding (with optimization of other factors to decrease HIV transmission) and how to provide optimal care for each mother-infant dyad within the context of local maternal and child health services. The actual measurable benefits of receiving breast milk versus the relative increased risk for HIV transmission will need to be determined in a prospective fashion in different nations and locales.<sup>250–257,274</sup>

**Interventions to Prevent Breastfeeding-Related Transmission.** A number of potential interventions to prevent breastfeeding transmission of HIV-1 can be utilized depending on the specific situation for the mother and infant. The simplest and most effective is the complete avoidance of human milk. This is a practical solution in places such as the United States where replacement feeding and other strictly medical interventions are feasible and reasonable, and the risk of not providing breast milk to the infant is minimal. In resource-poor situations, where the risk for other infections and malnutrition is high without the benefits of breast milk, exclusive breastfeeding is appropriate, with any other reasonable and culturally acceptable interventions to decrease HIV transmission via breast milk.<sup>108,250</sup>

Potentially effective interventions include exclusive breastfeeding; avoidance of mixed feeding; utilization of replacement feeding when it is acceptable, feasible, affordable, sustainable, and safe (AFASS) within the woman's community; and education and support to decrease the likelihood of mastitis or nipple lesions.<sup>209</sup>

Other possible interventions include treating a mother with antiretroviral therapy for her own

health or prophylactically to decrease the human milk viral load, treating an infant prophylactically for a prolonged period of time to protect against transmission via breastfeeding, treating the milk itself to decrease the viral load (by pasteurization or other methods),<sup>94,355,357</sup> treating acute conditions in mothers and infants (e.g., mastitis, breast lesions, infant candidiasis), and enhancing an infant's own defenses via vitamins and immunizations. Use of antiretroviral medications in the mother or the infant to specifically prevent transmission of HIV to the infant via breast milk and breastfeeding should continue through at least 1 week after stopping breastfeeding or stopping the use of mother's milk for that infant. Some of these may not be feasible in certain settings such as home pasteurization or maternal antiretroviral therapy. Others may not be culturally acceptable, such as treating expressed breast milk before giving it to an infant or even exclusive breastfeeding.

**Advantages of Breastfeeding.** Significant data demonstrate the advantage of breastfeeding, even for HIV-infected or HIV-exposed infants. The complete avoidance of breastfeeding in certain situations may lead to increased risk for illness and death due to other reasons besides HIV transmission.<sup>118</sup> A study from Kenya showed improved HIV-1-free survival rates in a formula-fed group of children born to HIV-positive mothers, but the breastfed and formula groups had similar mortality rates (24.4% versus 20.0%, respectively) and similar incidences of diarrhea and pneumonia in the first 2 years of life.<sup>306</sup> No difference in the two groups was seen in the prevalence of malnutrition, but the breastfed infants had better nutritional status in the first 6 months of life. Arpadi et al.<sup>22</sup> recommend additional nutritional interventions to complement breastfeeding in this population after 6 months of age. Two reports from Zambia document the benefit of exclusive breastfeeding for decreasing late HIV transmission and the lower mortality at 12 months in infants who had continued breastfeeding rather than had discontinued breastfeeding at 4 months of age.<sup>250,429</sup> In Malawi, HIV-infected and HIV-exposed infants who were breastfed (exclusive breastfeeding for 2 months and mixed feeding after that) had lower mortality at 24 months than those who were not breastfed.<sup>450</sup> A report from Botswana examined breastfeeding plus infant zidovudine (ZDV) prophylaxis for 6 months versus formula-feeding plus infant ZDV for 1 month. This study showed a decreased risk for vertical transmission with formula-feeding, but also increased cumulative mortality for the HIV-infected infants at 7 months of age who were in the formula-fed group.<sup>456</sup> A study from South Africa examining the use of vitamin A also demonstrated less morbidity in

HIV-infected children who were breastfed as compared to those not breastfed.<sup>114</sup> Other abstract reports have shown increased morbidity in HIV-infected children due to diarrhea, gastroenteritis, and hospitalization after weaning from breastfeeding.<sup>226,248,354,458</sup>

**Exclusive Breastfeeding.** Exclusive breastfeeding in most areas of the world is essential to infant health and survival, even in the situation of maternal HIV infection.<sup>108,112,113,250</sup> The duration of exclusive breastfeeding is crucial to decreasing the risk for HIV infection in infants versus the risk for malnutrition and other infections with early weaning. Becquet et al.<sup>36</sup> analyzed data from Côte d'Ivoire for 2001 to 2005; 47% of the HIV-exposed infants were breastfed for a median of 4 months, and 53% were formula fed and observed for 2 years. No significant difference in the rate of HIV infection was seen in the two groups, and no significant difference between the two groups was seen for morbid events (diarrhea, acute respiratory infections, or malnutrition), hospitalization, or death. The authors attributed these good outcomes to exclusive breastfeeding, effective nutritional counseling and care, access to clean water, and the provision of a safe and continuous supply of breast milk substitute.<sup>36</sup> Coovadia et al.<sup>108</sup> studied exclusive breastfeeding in the first 6 months of life as an intervention in South Africa. Of the exclusively breastfed infants, 14.1% at 6 weeks of age and 19.5% at 6 months of age were HIV infected. Breastfed infants who also were fed solids or formula milk were more likely to acquire infection than exclusively breastfed infants. The cumulative mortality at 3 months of age was markedly lower for exclusively breastfed infants (6.1%) versus 15.1% in the infants receiving mixed feedings.

**Early Weaning.** Kuhn et al.<sup>251</sup> examined the effects of early, abrupt weaning on HIV-free survival of 958 children in Zambia. Infants were randomly assigned to two different counseling programs that advised either abrupt weaning at 4 months or prolonged breastfeeding (PB). In the weaning intervention group, 69% of mothers stopped breastfeeding by 5 months compared with a median duration of breastfeeding of 16 months in the control group. The study found no significant difference in HIV-free survival at 24 months in the two groups (83.9% versus 80.7%). Children already infected by 4 months of age had a higher mortality if they were assigned to the early weaning group (73.6% versus 54.8%). Additional analysis showed that, in mothers with less severe HIV disease, early weaning was clearly harmful to the infant.<sup>252</sup> Arpadi et al.<sup>22</sup> studied the growth of HIV-exposed, uninfected children who were exclusively breastfed for 4 months with rapid weaning to replacement foods or exclusively breastfed

until 6 months and then continued breastfeeding with complementary foods. Weight-for-age z-scores dropped markedly in both groups from 4 to 15 months of age but less so in the continued breastfeeding group. Length-for-age z-score also dropped dramatically, but was not influenced by continued breastfeeding. Even in this HIV-exposed, uninfected group of children, additional nutritional interventions are essential to complement breastfeeding beyond 6 months of age.<sup>22</sup>

### **Antiretroviral Prophylaxis with Breastfeeding.**

Since 2009, the discussion around preventing HIV transmission via breastfeeding and the number of studies examining the important issues have increased.<sup>109,255,319</sup> The fact that intrapartum and perinatal transmission of HIV from mothers to infants has decreased markedly due to the increased utilization of antiretroviral therapy during pregnancy, delivery, and the postnatal period, for prevention, emphasizes the importance of now working harder to decrease breast milk transmission of HIV. In considering different possible interventions to decrease mother-infant HIV transmission, it is crucial to reemphasize the goals of optimizing maternal health and survival and optimizing infant health and survival at the same time.

A laboratory report shows that mothers receiving highly active antiretroviral therapy (HAART) while breastfeeding did have decreased whole breast milk HIV-1 viral loads (23 out of 26 mothers had less than 50 copies/mL) compared with mothers who did not receive HAART (9 out of 25 with less than 50 copies/mL). However, the whole milk HIV-1 DNA load (measured as "undetectable" at less than 10 copies/ $10^6$  cells) was not significantly different in the HAART (13 of 26 mothers) and non-HAART (15 of 23) groups.<sup>421</sup> HIV-1 DNA is incorporated into cells found in breast milk. Another group showed significantly lower HIV RNA levels in the breast milk of women treated with nevirapine (NVP), ZDV, and lamivudine, compared with women not receiving antiretroviral therapy.<sup>168</sup>

The use of maternal HAART seems to decrease HIV-1 transmission via breastfeeding. One group in Mozambique, Malawi, and Tanzania, working with mother-infant dyads receiving HAART as prevention during pregnancy, compared one cohort (809 mother-infant dyads) who received supplementary formula and water filters for the first 6 months of life with a second cohort (251 mother-infant dyads) breastfeeding exclusively and the mothers receiving HAART for the first 6 months. The cumulative incidence rate of HIV infection at 6 months of age was 2.7% for the formula-fed infants and 2.2% for breastfed infants. Through 6 months of age, no apparent additional

risk for late postnatal transmission of HIV was observed.<sup>362</sup> The Petra study team working in Tanzania, South Africa, and Uganda examined the efficacy of three short-course regimens of ZDV and lamivudine in preventing early and late HIV transmission in this predominantly breastfeeding population.<sup>372</sup> There were four regimens: (A) ZDV and lamivudine starting at 36 weeks' gestation plus intrapartum medication and 7 days' postpartum treatment; (B) same as A without the prepartum component; (C) intrapartum ZDV and lamivudine only; and (D) placebo. At week 6 the HIV transmission rates were 5.7% in group A, 8.9% in group B, 14.2% in group C, and 15.3% in group D. At 18 months the HIV infection rates were 15% in group A, 18% in group B, 20% in group C, and 22% in group D. Although a measurable decrease in transmission at 6 weeks of age was observed, limited protection was seen at 18 months of age. An observational study from Tanzania compared maternal HAART for 6 months with exclusive breastfeeding and abrupt weaning at 5 to 6 months of age with a historical control of the same feeding schedule without the postnatal maternal HAART. In the treatment group the cumulative HIV transmission was 4.1% at 6 weeks, 5.0% at 6 months, and 6.0% at 18 months of age. The cumulative HIV infection or death rate was 8.6% at 6 months and 13.6% at 18 months of age. The cumulative risk for HIV transmission was 1.1% between 6 and 18 months. The HIV transmission in this treatment group was half the transmission rate in the historical control group.<sup>240</sup> Another study in sub-Saharan Africa with 6 months of maternal HAART and exclusive breastfeeding for 6 months demonstrated 94% HIV-free survival at 12 months of age; the maternal and infant mortality rates for the treated mother-infant dyads were significantly lower than the country's maternal and infant mortality rates.<sup>297</sup>

Antiretroviral therapy prophylaxis for infants is another investigated intervention to decrease HIV transmission via breastfeeding. In a study from Cote d'Ivoire comparing different groups over time, infants received ZDV alone as ZDV prophylaxis, a single dose of NVP and 7 days of ZDV as NVP/ZDV prophylaxis, or a single dose of NVP plus ZDV and lamivudine (3TC) for 7 days as NVP/ZDV/3TC prophylaxis. Formula feeding (FF) was compared with exclusive shortened breastfeeding (ESB) up to 4 months of age, as well as PB. The cumulative transmission rates at 18 months were 22.3% in 238 infants in the ZDV + PB group, 15.9% in 169 infants in the NVP/ZDV + ESB group, 9.4% in the 195 infants in the NVP/ZDV + FF group, 6.8% in the 198 infants in the NVP/ZDV/3TC + ESB group, and 5.6% in the 126 infants in the NVP/ZDV/3TC + FF group.<sup>279</sup> Kumwenda et al.,<sup>259</sup> working in Malawi, demonstrated decreased HIV transmission

with breastfeeding and two different infant prophylaxis regimens. At 9 months of age, they observed a 10.6% occurrence of HIV transmission for infants receiving a single dose of NVP plus 1 week of ZDV, compared with 5.2% in the group receiving a single dose of NVP plus 1 week of ZDV plus 14 weeks of daily NVP, and 6.4% in the group receiving a single dose of NVP plus 1 week of ZDV plus 14 weeks of NVP and ZDV.<sup>259</sup> In the Mitra Study in Tanzania in which the median time of breastfeeding was 18 weeks, the HIV transmission rate at 6 months in the infants who received ZDV plus 3TC for 1 week plus 3TC alone for breastfeeding through 6 months of age was less than 50% of the transmission rate for those infants receiving only 1 week of ZDV plus 3TC.<sup>239</sup> A summary of three trials in Ethiopia, India, and Uganda compared a single dose of NVP at birth for infants with 6 weeks of daily NVP in predominantly breastfed infants whose mothers were counseled regarding feeding per the WHO/UNICEF guidelines.<sup>465</sup> At 6 months, 87 of 986 infants in the single-dose group and 62 of 901 in the extended-dose group were HIV infected, which was not statistically significant. The authors suggested that a longer course of infant antiretroviral prophylaxis might be more effective.<sup>432</sup> A Cochrane review by White et al.<sup>492</sup> examined seven studies of antiretroviral interventions relative to preventing transmission of HIV via breast milk. The trials considered maternal and infant prophylaxis, and the authors conclude that antiretroviral prophylaxis for the mother or infant while breastfeeding is effective in the prevention of mother-to-child HIV transmission. There remains research to be done, which documents the safety of antiretroviral therapy for the mother and infant and achieves the goals of optimizing maternal health and survival and optimizing infant health and survival at the same time.<sup>336,492</sup>

**Human Immune Deficiency Virus in Maternal Health and Breastfeeding.** The potential effect of breastfeeding on the HIV-positive mother needs to be adequately assessed in relation to the mother's health status. From Uganda and Zimbabwe, Mbizvo et al.<sup>305</sup> reported no difference in the number of hospital admissions or mortality between HIV-positive and HIV-negative women during pregnancy. In the 2 years after delivery, the HIV-positive women had higher hospital admission (approximately two times increased risk) and death rates (relative risk greater than 10) than HIV-negative women.<sup>305</sup> Chilongozi et al.<sup>99</sup> reported on 2292 HIV-positive mothers from four sub-Saharan sites followed for 112 months. Serious adverse events occurred in 166 women (7.2%); 42 deaths occurred in the HIV-positive women,

and no deaths occurred in 331 HIV-negative women.<sup>99</sup>

Several studies have examined breastfeeding relative to mothers' health and reported conflicting results. The first study from Kenya demonstrated a significantly higher mortality rate in breastfeeding mothers compared with a formula-feeding group in the 2 years after delivery. The hypothesized explanation offered by the authors for this difference was increased metabolic demands, greater weight loss, and nutritional depletion.<sup>331</sup> A second study from South Africa showed an overall lower mortality rate in the two groups with no significant difference in mortality rate in the 10 months of observation.<sup>111</sup> Kuhn et al.<sup>253</sup> reported no difference in mortality at 12 months after delivery between 653 women randomly assigned to a short breastfeeding group (4.93%, with 95% CI of 2.42 to 7.46. Out of 326 women, with a median breastfeeding duration of 4 months, 21% were still breastfeeding at 12 months) and a long breastfeeding group (4.89%, with 95% CI of 2.38 to 7.40. Out of 327 women, 90% were breastfeeding at 5 months, and 72% were breastfeeding at 12 months, for a median of 15 months). The HIV-related mortality rates were high but not associated with prolonged lactation.<sup>253</sup> Walson et al.<sup>481</sup> followed 535 HIV-positive women for 1 to 2 years in Kenya. The mortality risk was 1.9% at 1 year and 4.8% at 2 years of follow-up. Although less than 10% of women reported a hospitalization during the 2 years, they experienced various common infections (pneumonia, diarrhea, TB, malaria, STDs, urinary tract infections, mastitis). Breastfeeding was a significant cofactor for diarrhea and mastitis but not for pneumonia, TB, or hospitalization.<sup>481</sup>

## HIV Child-to-Breastfeeding Woman Transmission

HIV child-to-breastfeeding woman transmission (CBWT) has been a theoretical concern since the beginning of the HIV epidemic. There have been rare cases where this has been suspected but not sufficiently investigated to document its occurrence. Little et al. reviewed the topic in 2012, examining a number of published accounts in a systematic review.<sup>287</sup> Two larger studies from the Russian Federation and Libya examined outbreaks of nosocomial HIV spread in pediatric hospitals. The infants became infected through blood products, unsterilized needles, or injection equipment. The epidemiologic investigations tried to exclude the other possible sources of HIV infection in the women and delineate the character and timing of

the exposures of the mothers to their infants. In Russia, 12 mothers of 152 infected infants were documented to be HIV positive, and the odds of breastfeeding were greater in the HIV-infected group. Infant stomatitis and cracked nipples in the mothers seemed to also correlate, although the duration of breastfeeding did not seem to be a significant factor. In Libya, there were 20 infected mothers associated with 402 children (5.0%) found to be HIV infected. A substudy of 118 mother-infant dyads documented HIV infection in the 118 infants and 18 mothers, while at the same time confirming the HIV-negative status of the remaining 100 women and all 75 of the fathers tested. Fourteen of the 18 HIV-positive women had no other risk factors identified except breastfeeding their HIV-positive infants. Breastfeeding was an independent predictor of maternal HIV infection. Three other published reports in the same paper<sup>287</sup> were discussed, documenting the occurrence of CBWT via breastfeeding in Kazakhstan, Kyrgyzstan, and Romania. The authors raise the concern that many parts of the world where wet-nursing and cross-nursing are socially acceptable and more common may overlap with higher HIV-prevalence areas and raise the risk of CBWT. They discuss the very high rates of orphanhood in areas with high HIV prevalence and perinatal HIV transmission. They recognize the greater likelihood that female relatives of the orphaned children are wet- or cross-nursing without knowing that there is a risk of transmission of HIV to themselves in this practice. The authors conclude that, in addition to optimizing the ongoing efforts of HIV transmission prevention in adults and children, the WHO guidelines on infant feeding should include information about the risks of wet-nursing or cross-nursing HIV-infected infants. Women should be counseled about the possibility of CBWT, and the infants and women should be provided HIV testing in order to offer women the necessary knowledge and information to make informed feeding decisions.<sup>287</sup>

In summary, the breastfeeding of infants by HIV-positive mothers does lead to an increased risk for HIV infection in the infants. Much remains to be understood about the mechanisms of HIV transmission via breast milk and the action and efficacy of different interventions to prevent such transmission. The complete avoidance of breastfeeding is a crucial component for the prevention of perinatal HIV infection in the United States and many other countries.<sup>492</sup>

For resource-poor settings, where breastfeeding is the norm and where it provides vital nutritional and infection protective benefits, the WHO, UNICEF, and the Joint United Nations Programme on HIV/AIDS (UNAIDS) made updated recommendations in 2010: *Guidelines on HIV and infant*

*feeding: Principles and recommendations for infant feeding in the context of HIV and a summary of evidence*<sup>493</sup> ([http://www.who.int/maternal\\_child\\_adolescent/documents/9789241599535/en/](http://www.who.int/maternal_child_adolescent/documents/9789241599535/en/)). Although most of the recommendations are in line with previous WHO recommendations, this publication supports national authorities deciding on their own country's plan for infant-feeding practice to optimize the health of the mother and infant, to limit the mother-to-child transmission of HIV, and to accomplish this by incorporating the policy and interventions in the country's maternal and child health services. There are nine key principles proposed to guide national authorities (see Box 13-3).

Mothers choosing to breastfeed should receive additional education, support, and medical care to minimize the risk for HIV transmission and to optimize their own health status during and after breastfeeding. Mothers choosing to use replacement feedings should receive parallel education, support, and medical care for themselves and their infants to minimize the effect of the lack of breastfeeding.<sup>492</sup>

Good evidence now shows that antiretroviral prophylactic regimens for mothers or infants, while continuing breastfeeding, do decrease postnatal HIV transmission. Early weaning is associated with increased morbidity and mortality for the infants. Further carefully controlled research is indicated in order to adequately assess the risks and benefits

### BOX 13-3. Nine Key Principles for the Current Guidelines on HIV and Infant Feeding From the WHO

1. Balancing HIV prevention with protection from other causes of child mortality
2. Integrating HIV interventions into maternal and child health services
3. Set national and sub-national recommendations for infant feeding in the context of HIV
4. Provide breastfeeding to infants born to HIV-infected mothers with a greater chance of HIV-free survival even if antiretroviral drugs are not immediately available
5. Inform mothers known to be HIV-infected about infant feeding alternatives
6. Provide services to specifically support mothers to appropriately feed their infants
7. Avoid harm to infant feeding practices in the general population
8. Advise mothers who are HIV uninfected or whose HIV status is unknown about infant feeding alternatives
9. Invest in improvements in infant feeding practices in the context of HIV

to infants and mothers of PB with antiretroviral prophylaxis for either or both mothers and infants. Along with this, HIV-testing rates must be improved, and access to antenatal care, HIV-prevention services, and HIV medical care for everyone must be increased. The availability and free access to antiretroviral medications must also improve. The current WHO/UNAIDS/UNICEF infant-feeding guidelines are summarized at <http://www.unicef.org/programme/breastfeeding/feeding.htm><sup>493</sup> (accessed 18.01.15).

The decision about infant feeding for HIV-positive mothers remains a difficult one, but this is slowly improving with increasing options. The goals remain 100% HIV transmission prevention, optimal maternal health and survival, and long-term infant health and survival.

## HUMAN IMMUNODEFICIENCY VIRUS TYPE 2

Human immunodeficiency virus type 2 (HIV-2) is an RNA virus in the nononcogenic, cytopathic lentivirus genus of retroviruses. It is genetically closer to simian immunodeficiency virus than to HIV-1. The clinical disease associated with HIV-2 has similar symptoms to HIV-1 infection, but it progresses at a slower rate to severe immunosuppression.

HIV-2 is endemic in western Africa and parts of the Caribbean and found infrequently in Europe and North and South America.<sup>208,344</sup> It is transmitted via sexual contact, blood, or blood products, and from mother to child.

Routine testing for HIV-2 is recommended in blood banks. Antibody tests used for HIV-1 are only 50% to 90% sensitive for detecting HIV-2.<sup>73</sup> Specific testing for HIV-2 is appropriate whenever clinically or epidemiologically indicated.

Vertical transmission occurs infrequently. Ekpini et al.<sup>133</sup> followed a large cohort of west African mothers and infants: 138 HIV-1-positive women, 132 HIV-2-positive women, 69 women seropositive for both HIV-1 and -2, and 274 HIV-seronegative women. A few cases of perinatal HIV-2 transmission occurred, but no case of late postnatal transmission was observed.<sup>133</sup>

It is probable that HIV-2 transmission via breast milk is less common than HIV-1 transmission, but insufficient data support that the risk for transmission is zero. Mothers who test positive for HIV-2 should be tested for HIV-1, and guidelines for breastfeeding should follow those for HIV-1 until additional information is available.<sup>493</sup>

## RABIES

The rabies virus produces a severe infection with progressive CNS symptoms (anxiety, seizures,

altered mental status) that ultimately proceeds to death; few reports of survival exist. Rabies occurs worldwide, except in Australia, Antarctica, and several island groups. An estimated 60,000 people die from rabies related to dog bites yearly worldwide, and 20 million people receive human rabies vaccine (WHO Technical Report Series No. 982, "Who Expert consultation on Rabies—Second Report"<sup>494</sup>). In 2006, three cases of rabies occurred in humans in the United States, but, each year, postexposure prophylaxis is given to between 16,000 and 39,000 people who come in contact with potentially rabid animals.<sup>87c,295</sup>

The rabies virus is endemic in various animal populations, including raccoons, skunks, foxes, and bats.<sup>87b</sup> Because of aggressive immunization programs, rabies in domesticated dogs and cats in the United States is uncommon.<sup>87a</sup> The virus is found in the saliva, tears, and nervous tissue of infected animals. Transmission occurs by bites, licking, or simply contact of oral secretions with mucous membranes or nonintact skin. Many cases of rabies in humans now lack a history of some obvious contact with a rabid animal. This may be a result of the long incubation period (generally 4 to 6 weeks, but up to 1 year, with reports of incubation periods of several years), a lack of symptoms early in an infectious animal, or airborne transmission from bats in enclosed environments (caves, laboratories, houses).

Person-to-person transmission via bites has not been documented, although it has occurred in corneal transplants.<sup>51</sup> Rabies viremia has not been observed in the spread of the virus. No evidence exists indicating transmission through breast milk.

In the case of maternal infection with rabies, many scenarios can occur before the onset of progressive, severe CNS symptoms. The progression and severity of maternal illness can preclude breastfeeding, but separation of an infant from the mother is appropriate regardless of the mother's status and method of infant feeding (especially to avoid contact with saliva and tears). Breastfeeding should not continue when the mother has symptoms of rabies, and the infant should receive postexposure immunization and close observation. An infant may receive expressed breast milk, but the expression must occur without possible contamination with saliva or tears from the mother.

Depending on the scenario, the nature of a mother's illness, the possible exposure of an infant to the same source as the mother, and the exposure of a child to the mother, the postexposure immunization of an infant may be appropriate.<sup>494</sup>

A more common scenario is a mother's apparent exposure to rabies (without exposure for the infant), necessitating the postexposure immunization of the mother with rabies vaccine. In the

majority of cases, in the absence of maternal illness, breastfeeding can reasonably continue during the mother's four-dose immunization series in 14 days.<sup>398</sup> In a rare situation in which apparent exposure of mother and infant to rabies occurs together, the postexposure treatment of both mother and infant should be instituted, and breastfeeding can continue.

## RESPIRATORY SYNCYTIAL VIRUS

RSV is a common cause of respiratory illness in children and is relatively common in adults, usually producing milder upper respiratory tract infection in adults. No evidence indicates that RSV causes intrauterine infection, adversely affects the fetus, or causes abortion or prematurity. RSV does produce infection in neonates, causing asymptomatic infection, afebrile upper respiratory tract infection, bronchiolitis, pneumonia, and apnea. The mortality rate can be high in neonates, especially in premature infants and ill full-term infants, particularly those with preexisting respiratory disease (hyaline membrane disease, bronchopulmonary dysplasia) or cardiac disease associated with pulmonary hypertension.

RSV is believed to be transmitted via droplets or direct contact of the conjunctiva, nasal mucosa, or oropharynx with infected respiratory secretions. Documentation of RSV infection is rarely made in adults, and spread from a mother or other household contacts probably occurs before a diagnosis can be made. Therefore, risk for RSV transmission from breast milk is probably insignificant compared to transmission via direct or droplet contact in families. In nurseries, however, it is appropriate to make a timely diagnosis of RSV infection in neonates to isolate infants from the others in order to prevent spread in the nursery. Ribavirin is not recommended for routine use. It is infrequently used in patients with potentially life-threatening RSV infection.<sup>365</sup>

RSV infection should be suspected in any infant with rhinorrhea, nasal congestion, or unexplained apnea, especially in October through March in temperate climates. During this season, prophylaxis against RSV with RSV-specific immunoglobulin IV (RSV-IGIV) for infants at highest risk for severe disease is appropriate.

Debate surrounds the effect of passively acquired antibodies (in infants from mothers before birth) against RSV on the occurrence and severity of illness in neonates and infants. It appears that a higher level of neutralizing antibody against RSV in neonates decreases the risk for severe RSV disease.<sup>170,263</sup> Some controversy remains concerning the measurable benefit of breastfeeding for preventing serious RSV disease,<sup>4,61,127</sup> with some studies

showing benefit and others no effect. Controlling for possible confounding factors (e.g., smoking, crowded living conditions) in these studies has been difficult. There are well-done studies indicating that breastfeeding, independent of other factors, is protective against hospitalization with RSV or severe RSV disease.<sup>127,365</sup> At this point, no reason exists to stop breastfeeding because of maternal RSV infection, and a potential exists for benefit from nonspecific factors in breast milk against the RSV. Infants with RSV infection should breastfeed unless their respiratory status precludes it.

## ROTAVIRUSES

Rotavirus infections usually result in diarrhea, accompanied by emesis and low-grade fever. In severe infections the clinical course can include dehydration, electrolyte abnormalities, and acidosis and can contribute to malnutrition in developing countries. Generally, every child will have at least one episode of rotavirus infection by 5 years of age.<sup>175</sup> In developed countries, rotavirus is often associated with diarrhea requiring hospitalization in children younger than 2 years of age, but it is rarely associated with death. Worldwide rotavirus is the leading cause of diarrhea-related deaths in children younger than 5 years old. Estimates suggest that in children younger than 5 years old rotavirus infection leads to more than 100 million occurrences of diarrhea, 2 million hospital admissions, and 500,000 deaths each year.<sup>175</sup> Fecal-oral transmission is the most common route, but fomites and respiratory spread may also occur. Spread of infection occurs most often in homes with young children or in day care centers and institutions. In hospitalized infants or mothers with rotavirus infection, contact precautions are indicated for the duration of the illness. No evidence indicates prenatal infection from rotavirus, but perinatal or postnatal infection from contact with the mother or others can occur.

No case of transmission of rotavirus via breast milk has been documented. Breast milk does contain antibodies to rotavirus for up to 2 years. Human milk mucin has been demonstrated to inhibit rotavirus replication and to prevent experimental gastroenteritis.<sup>508</sup> Human milk oligosaccharides (HMO) have been related to the protective effect of breastfeeding against rotavirus diarrhea.<sup>136</sup> The mechanisms of rotavirus immunity are not well understood. They are thought to be multifactorial, with cell-mediated immunity limiting the severity and course of infection, while humoral immunity protects against subsequent infections. Innate and adaptive responses at the level of the mucosa are probably the most important.<sup>149</sup>

Exclusive breastfeeding may decrease the likelihood of severe rotavirus-related diarrhea by as much as 90%.<sup>101,420</sup> Although breastfeeding does not prevent infection with rotavirus, it seems to decrease the severity of rotavirus-induced illness in children younger than 2 years old.<sup>101,135,202</sup> At least one study suggested that this may simply represent the postponement of severe rotavirus infection until an older age.<sup>101</sup> Another study suggested that protection against rotavirus rapidly declines upon discontinuation of breastfeeding.<sup>399</sup> This delay in rotavirus infection until the child is older may be beneficial in that the older child may be able to tolerate the infection or illness with a lower likelihood of becoming dehydrated or malnourished. Continuing breastfeeding during an episode of rotavirus illness, with or without vomiting, is appropriate and often helpful to the infant. No reason to suspend breastfeeding by a mother infected with rotavirus is apparent.

Two rotavirus vaccines (RotaTeq and Rotarix) have been licensed for use in more than 90 countries, but fewer than 20 countries have routine immunization programs. Additional types of rotavirus vaccines are undergoing study in various countries, specifically examining the efficacy of the vaccines in low- and medium-income countries.<sup>495</sup> Some of the explanations for the slow global implementation of an effective vaccine include differences in protection with specific vaccines in high-income countries compared with low- or medium-income countries, the unfortunate association with intussusception in the United States, the delayed recognition of the significant rotavirus-related morbidity and mortality, and the cost of the new vaccines. The question of the variable efficacy of the specific rotavirus vaccines in developed and developing countries remains an important one.<sup>281</sup> Several trials are examining this issue and attempting to address factors such as transplacentally transferred maternal antibodies, breastfeeding practices (especially immediately before immunization with a live oral rotavirus vaccine), stomach acid, micronutrient malnutrition, interfering gut flora, and differences in the epidemiology of rotavirus in different locations.<sup>367</sup> Evidence indicates that maternal immunization with rotavirus vaccine can increase both the transplacental acquisition of antibodies and secretory IgA in breast milk.<sup>374</sup> Additionally, oral rotavirus vaccines have been able to stimulate a good serologic response in both formula-fed and breastfed infants, although the antigen titers may need to be modified to create an optimal response in all infants.<sup>93</sup> The actual protective effect of these vaccines in different situations and strategies will require measurement in ongoing prospective studies.

## RUBELLA VIRUS

Congenital rubella infection has been well described, and the contributing variables to infection and severe disease have been elucidated. The primary intervention to prevent congenital rubella has been to establish the existence of maternal immunity to rubella before conception, including immunization with rubella vaccine and reimmunization if indicated. Perinatal infection is not clinically significant. Postnatal infection occurs infrequently in children younger than 1 year of age because of passively acquired maternal antibodies. The predominant age of infection is 5 to 14 years old, and more than half of those with infections are asymptomatic. Postnatal rubella is a self-limited, mild viral infection associated with an evanescent rash, shotty adenopathy, and low-grade transient fever. It most often occurs in the late winter and spring. Infants with congenital infection shed the virus for prolonged periods from various sites and may serve as a source of infection throughout the year. Contact isolation is appropriate for suspected and proven congenital infection for at least 1 year, including exclusion from day care and avoidance of pregnant women, whereas postnatal rubella infection requires droplet precautions for 7 days after the onset of rash.

Rubella virus has been isolated from breast milk after natural infection (congenital or postnatal) and after immunization with live attenuated vaccine virus. Both IgA antibodies and immunoreactive cells against rubella have been identified in breast milk. Breastfed infants can acquire vaccine-virus infection via milk but are asymptomatic. Because postpartum infection with this virus (natural or vaccine) is not associated with clinically significant illness, no reason exists to prevent breastfeeding after congenital infection, postpartum infection with this virus, or maternal immunization with rubella vaccine.<sup>102</sup>

## SEVERE ACUTE RESPIRATORY SYNDROME

Severe acute respiratory syndrome (SARS) is a term that could be applied to any serious acute respiratory illness caused by or associated with a variety of infectious agents. Since 2003, it has been linked with SARS-associated coronavirus (SARS-CoV). In the global outbreak of 2002 to 2003, more than 8400 probable cases of SARS and more than 800 deaths occurred. More than the actual number of affected individuals or its associated mortality rate (approximately 10% mortality overall, and closer to 50% mortality in persons older than 65 years of age), the lack of data on this new unusual illness and the tremendous publicity surrounding it made SARS such a sensation. We now know the cause of this illness, known as the SARS-CoV. SARS-CoV

was shown not to be closely related to the previously characterized coronavirus groups.<sup>298,392</sup> Despite intense international collaboration to study the illness and the virus, many things are not known, such as the degree of infectiousness, the actual period of transmissibility, all the modes of transmission, how many people have an asymptomatic infection as compared to those with symptoms or severe illnesses, how to make a rapid diagnosis of confirmed cases, and where the virus originated.

At least 21 cases of probable SARS in children have been described in the literature.<sup>49,205,423,431</sup> In general, the illness in children is a mild, nonspecific respiratory illness, but in adolescents and adults, it is more likely to progress to severe respiratory distress. It has been reported that children are less likely to transmit SARS than adults.<sup>205</sup> The overall clinical course, the radiologic evolution, and the histologic findings of this illness are consistent with the host's immune response playing a significant role in disease production.

Five infants were born to mothers with confirmed SARS. The infants were born prematurely (26 to 37 weeks), presumably due to maternal illness. Although two of the five infants had serious abdominal illnesses (other coronaviruses have been associated with reported outbreaks of necrotizing enterocolitis), the presence of SARS-CoV could not be demonstrated in any of these infants.<sup>423</sup> No evidence of vertical transmission of SARS is available. The mode of feeding for any of the reported cases of young children with SARS or the infants born to mothers with SARS was not mentioned.

Since 2012, a second coronavirus (CoV) has been associated with epidemic SARS: Middle East respiratory syndrome (MERS-CoV), named after the initial outbreak described in Saudi Arabia. This illness has an estimated incubation period of 5 to 14 days and manifests similarly to SARS-CoV with a variety of extrapulmonary manifestations, and it seems to affect individuals with comorbid conditions.<sup>211</sup> It also appears to be transmitted primarily by respiratory droplets.

As with other respiratory viruses predominantly transmitted by droplets, transmission via breast milk is an insignificant mode of transmission, if it occurs at all. The benefits of breastfeeding being what they are, mothers with SARS or MERS should continue breastfeeding if they are able, or expressed breast milk can be given to an infant until the mother is able to breastfeed.

## SMALLPOX

In this era of worry about biologic terrorism, smallpox is an important concern. The concern for infants (breastfed or formula-fed) is direct contact

with mothers or household members with smallpox. Smallpox is highly contagious in the household setting due to person-to-person spread via droplet nuclei or aerosolization from the oropharynx and direct contact with the rash. Additional potential exposures for infants include the release of a smallpox aerosol into the environment by terrorists, contact with a smallpox-contaminated space or the clothes of household members exposed to an aerosol, and infection via contact with a mother's or a household member's smallpox vaccination site. These risks are the same for breastfed and formula-fed infants. No evidence for the transmission of the smallpox virus via breast milk exists.

A contact is defined as a person who has been in the same household or had face-to-face contact with a patient with smallpox after the onset of fever. Patients do not transmit infection until after progression from the fever stage to the development of the rash. An exposed contact does not need to be isolated from others during the postcontact observation period (usually 17 days) until that person develops fever. The temperature of the exposed contact should be monitored daily. Personal contact and breastfeeding between mother and infant can continue until the onset of fever, when immediate isolation (at home) should begin. Providing expressed breast milk for the infant of a mother with smallpox should be avoided because of the extensive nature of the smallpox rash and the possibility of contamination (from the rash) of the milk during the expression process. No literature documents transmission of the smallpox virus via expressed breast milk.

The other issue for breastfeeding infants is the question of maternal vaccination with smallpox in a preexposure-event vaccination program. Children older than 1 year of age can be safely and reasonably vaccinated with smallpox in the face of a probable smallpox exposure. The smallpox vaccination of infants younger than 1 year of age is contraindicated. Breastfeeding is listed as a contraindication to vaccination in the preevent vaccination program. It is unknown whether the vaccine virus or antibodies are present in breast milk. The risk for infection due to contact or aerosolization of virus from a mother's smallpox vaccination site is the same for breastfed and formula-fed infants. The Advisory Committee on Immunization Practices also does not recommend preventing the smallpox vaccination of children younger than 18 years old.<sup>491</sup>

One report documents tertiary-contact vaccination in a breastfeeding infant.<sup>155</sup> A United States military person received a primary smallpox vaccination and developed a local reaction at the inoculation site. Despite reportedly observing

appropriate precautions, the individual's wife developed vesicles on both areolae (secondary-contact vaccinia). Subsequently, the breastfeeding infant developed lesions on her philtrum, cheek, and tongue. Both the mother and infant remained well, and the infections resolved without therapy. Culture and PCR testing confirmed vaccinia in both the mother's and the infant's lesions. The breast milk was not tested.<sup>155</sup>

In a review of the literature from 1931 to 1981, Sepkowitz<sup>418</sup> reported on 27 cases of secondary vaccinia in households. The CDC reported 30 suspected cases of secondary/tertiary vaccinia, with 18 of those cases confirmed by culture or PCR. The 30 cases were related to 578,286 vaccinated military personnel. This is an incidence of 5.2 cases per 100,000 vaccinees and 7.4 cases per 100,000 primary vaccinees.<sup>85</sup> In a separate report on the civilian smallpox-prevention vaccination program, 37,802 individuals were vaccinated between January and June 2003, and no cases of contact vaccinia were reported.<sup>83</sup>

The risk for contact vaccinia is low. The risk is from close or intimate contact. In the mentioned case, the risk for the infant was contact with the mother's breasts, the inadvertent site of her contact vaccinia. Breastfed and formula-fed infants are equally at risk from close contact in the household of a smallpox vaccinee or a case of secondary vaccinia, and separation from the individual is appropriate in both situations. If the breast of the nursing mother is not involved, expressed breast milk can be given to the infant.

Another orthopoxvirus that has emerged in the past decade is monkeypox. Most commonly it is a zoonotic pathogen, spreading to humans through direct contact with infected animals. There are reports of transmission from person to person, but this seems to be an uncommon event.<sup>146</sup> Similar to smallpox, the likelihood of spread is probably similar for formula-fed or breastfed infants, and as long as the breast of a mother with monkeypox is not involved, then expressed breast milk can be given to the infant.

## TT VIRUS

TT virus (TTV) is a recently identified virus found in a patient (TT) with posttransfusion hepatitis not associated with the other hepatitis-related viruses, A through G. TTV has been described as an unenveloped, circular, single-stranded DNA virus.<sup>350</sup> This virus is prevalent in healthy individuals, including healthy blood donors, and it has been identified in patients with hepatitis. TTV DNA has been detected in infants of TTV-positive and TTV-negative mothers. Ohto et al.<sup>349</sup> reported no TTV DNA was detected in cord blood from

38 infants, and it was detected in only 1 of 14 samples taken at 1 month of age. They noted an increasing prevalence from 6 months (22%) to 2 years (33%), which they ascribed to acquisition via nonparenteral routes. In comparisons of the TTV DNA in TTV-positive mothers and their TTV-positive infants, 6 of 13 showed high-level nucleotide sequence similarity, and 7 of 13 differed by greater than 10%.<sup>349</sup>

Schröter et al.<sup>413</sup> reported on TTV DNA in breast milk examined retrospectively. Notably, TTV DNA was detected in 22 of 23 serum samples of infants at 1 week of age, who were born to 22 women viremic for TTV DNA. Twenty-four women who were negative for TTV DNA gave birth to 24 children who were initially negative for TTV DNA and remained negative throughout the observation period (mean 7.5 months, range 1 to 28 months). TTV DNA was detected in 77% of breast milk samples from TTV-viremic women and in none of the breast milk samples from TTV-negative women. No clinical or laboratory evidence of hepatitis was found in the 22 children who were observed to be TTV DNA positive during the period of the study.<sup>413</sup> Other authors have reported TTV in breast milk, as detected by PCR. They describe the absence of TTV DNA in infants at 5 days and 3 months of age, and 4 of 10 infants were positive for TTV DNA at 6 months of age, suggesting the late acquisition of infection via breastfeeding.<sup>217</sup>

The TTV is transmitted in utero and is found in breast milk.<sup>349</sup> No evidence of clinical hepatitis in infants related to TTV infection and no evidence for a late chronic hepatitis exist. Given the current available information, no reason to proscribe breastfeeding by TTV-positive mothers is compelling. Certainly, more needs to be understood concerning the chronic nature of this infection and the possible pathogenesis of liver disease.<sup>413</sup>

## TUMOR VIRUS IN BREAST MILK

No documented evidence indicates that women with breast cancer have RNA of tumor virus in their milk. No correlation between RNA-directed DNA polymerase activity has been found in women with a family history of breast cancer. RNA-directed DNA polymerase activity, a reserve transcriptase, is a normal feature of the lactating breast.<sup>100,142,394</sup>

Epidemiologic data conflict with the suggestion that the tumor agent is transmitted through the breast milk. The incidence of breast cancer is low among women who nursed their infants, including lower economic groups, foreign-born groups, and those in sparsely populated areas.<sup>294</sup> The frequency of breast cancer in mothers and sisters of a woman with breast cancer is two to three times that

expected by chance. This could be genetic or environmental. In actuality, cancer is equally common on both sides of the family of an affected woman. If breast milk were the cause, it should be transmitted from mother to daughter. When the mother-daughter incidence of cancer was studied, no relationship was found to breastfeeding.

Sarkar et al.<sup>403</sup> reported that human milk, when incubated with mouse mammary tumor virus, caused degradation of the particular morphology or the virions, while decreasing infectivity and reversing transcriptase activity. They suggest that the significance of this destructive effect of human milk on mouse mammary tumor virus may account for the difficulty in isolating the putative human mammary tumor agent. Sanner<sup>402</sup> showed that the inhibitory enzymes in milk can be removed using a special sedimentation technique. He ascribes the discrepancies in isolating virus particles in human milk to these factors, which inhibit RNA-directed DNA polymerase. Human mammary tumor virus (HMTV) sequences were detected in the breast milk of women who had had a history of breast biopsy for suspicion of cancer, as compared to a reference group of women who had not been biopsied. Of the eight women who had breast cancer (8/73), only one had HMTV sequences detected in her breast milk.<sup>329</sup> Melana et al. identified viral particles within human breast cancer cells that had a sequence homology of 95% with the HMTV proviruses as potential etiologic agents in human breast cancer pathogenesis.<sup>312</sup>

The fear of cancer in breastfed female offspring of a woman with breast cancer does not justify avoiding breastfeeding. Breastfed women have the same breast cancer experience as nonbreastfed women, and no increase is seen in benign tumors. Daughters of breast-cancer patients have an increased risk for developing benign and malignant tumors because of their heredity, not because of their breastfeeding history.<sup>314,323</sup>

Unilateral breastfeeding (limited to the right breast) is a custom of Tanka women of the fishing villages of Hong Kong. Ing et al.<sup>213</sup> investigated the question, "Does the unsuckled breast have an altered risk for cancer?" They studied breast cancer data from 1958 to 1975. Breast cancer occurred equally in the left and the right breasts. A comparison of patients who had nursed unilaterally with nulliparous patients and with patients who had borne children but not breastfed indicated a highly significantly increased risk for cancer in the unsuckled breast. The authors conclude that, in postmenopausal women who have breastfed unilaterally, the risk for cancer is significantly higher in the unsuckled breast. They propose that breastfeeding may help protect the suckled breast against cancer.<sup>213</sup>

Others<sup>307</sup> have suggested that Tanka women are an ethnically separate people and that left-sided breast cancer may be related to their genetic pool and not to their breastfeeding habits. No mention has been made of other possible influences, such as the impact of their role as "fishermen" or any inherent trauma to the left breast.<sup>307</sup>

In 1926, Lane-Claypon<sup>266</sup> stated that a breast that had never lactated was more liable to become cancerous. Nulliparity and absence of breastfeeding had been considered to be important risk factors for breast cancer. MacMahon et al.<sup>294</sup> reported in 1970 that age at first full-term pregnancy was the compelling factor, and the younger the mother, the less the risk.

In a collective review of the etiologic factors in cancer of the breast in humans, Papaioannou concludes, "Genetic factors, viruses, hormones, psychogenic stress, diet, and other possible factors, probably in that order of importance, contribute to some extent to the development of cancer of the breast."<sup>364</sup>

In her 1977 review on human milk and health, Wing<sup>500</sup> concluded that "in view of the complete absence of any studies showing a relationship between breastfeeding and increased risk of breast cancer, the presence of virus-like particles in breast milk should not be a contraindication to breastfeeding." Henderson et al.<sup>191</sup> made a similar statement in 1974, whereas Vorherr<sup>480</sup> concluded in 1979 that the roles of pregnancy and lactation in the development and prognosis of breast cancer had not been determined.

Gradually, additional studies have appeared, challenging the dogma. Brinton et al.,<sup>59</sup> McTiernan and Thomas,<sup>309</sup> and Layde et al.<sup>272</sup> showed the clearly protective effects of breastfeeding. Another example is a study conducted to clarify whether lactation has a protective role against breast cancer in an Asian people, regardless of the confounding effects of age at first pregnancy, parity, and closely related factors.<sup>509</sup> In a hospital-based case-control study of 521 women without breast cancer, statistical adjustment for potential confounders and a likelihood ratio test for a linear trend were done by unconditional logistic regression. Total months of lactation regardless of parity was the discriminator. Regardless of age of first pregnancy and parity, lactation had an independent protective effect against breast cancer in Japanese women.<sup>509</sup> Although breast cancer incidence is influenced by genetics, stress, hormones, and pregnancy, breastfeeding clearly has a protective effect. "There is a reduction in the risk of breast cancer among premenopausal women who have lactated. No reduction in the risk of breast cancer occurred among postmenopausal women with a history of lactation," according to Newcombe et al.,<sup>335</sup> reporting a multicenter study

in 1993. Ip et al. conducted a systematic review and analysis on breastfeeding and maternal and infant health in developed countries for the Agency of Healthcare Research and Quality, and they reported on two previously done meta-analyses that concluded that there was a reduced risk of breast cancer in women who breastfed their infants.<sup>214</sup> The original meta-analyses were evaluated as fair quality, estimating the reduced risk of breast cancer as 4.3% for each year of breastfeeding, and the second study estimated a decrease in breast cancer risk of 28% for 12 or more months of breastfeeding.<sup>41</sup>

There is good evidence that a longer duration of breastfeeding does decrease the risk of developing breast cancer, and there are no direct data suggesting that the presence of HMTV in breast milk is a reason to stop breastfeeding.

## VARICELLA-ZOSTER VIRUS

Varicella-zoster virus infection (varicella/chickenpox, zoster/shingles) is one of the most communicable diseases of humans, in a class with measles and smallpox. Transmission is thought to occur via respiratory droplets and virus from vesicles. Varicella in pregnancy is a rare event, although disease can be more severe with varicella pneumonia, and it can be fatal.

Congenital varicella-zoster virus infection occurs infrequently, causing abortion, prematurity, and congenital malformations. A syndrome of malformations has been carefully described with congenital varicella-zoster virus infection, typically involving limb deformity, skin scarring, and nerve damage, including to the eye and brain.<sup>164</sup>

Perinatal infection can lead to severe infection in infants if maternal rash develops 5 days or less before delivery and within 2 days after delivery. Illness in infants usually develops before 10 days of age and is believed to be more severe because of the lack of adequate transfer of antibody from the mother during this period and the transplacental spread of virus to the fetus and infant during viremia in the mother. Varicella in a mother occurring before 5 days before delivery allows the sufficient formation and transplacental transfer of antibodies to the infant to ameliorate disease, even if the infant is infected with varicella-zoster virus. Mothers who develop varicella rash more than 2 days after delivery are less likely to transplacentally transfer the virus to the infant. Such mothers do pose a risk to their infants from postnatal exposure, which can be diminished by the administration of varicella-zoster Ig to the infant. Postnatal transmission is believed to occur through aerosolized virus from skin lesions or the respiratory tract entering the susceptible infant's respiratory tract. Airborne

precautions are therefore appropriate in the hospital setting. Infants infected with varicella-zoster virus in utero or in the perinatal period (younger than 1 month of age) are more likely to develop zoster (reactivation of latent varicella-zoster virus) during childhood or as young adults. Table 13-5 summarizes the management of varicella in the hospitalized mother or infant.<sup>164</sup>

Postnatal varicella from nonmaternal exposure can occur, but it is generally mild when it develops after 3 weeks of age or when a mother has passed on antibodies against varicella-zoster virus via the placenta. Severe postnatal varicella does occur in premature infants or infants of varicella-susceptible mothers. When a mother's immune status relative to varicella-zoster virus is uncertain and the measurement of antibodies to varicella-zoster virus in the mother or infant cannot be performed promptly (less than 72 hours), the administration of VZIG<sup>86</sup> or IVIG to the infant exposed to varicella or zoster in the postnatal period is indicated. Ideally, a mother's varicella status should be known before pregnancy, when the varicella virus vaccine could be given if indicated.

The varicella-zoster virus has not been cultured from milk, but varicella-zoster virus DNA has been identified in breast milk.<sup>511</sup> Antibodies against varicella-zoster virus have also been found in breast milk.<sup>304</sup> Breast milk from mothers who had received the varicella vaccine in the postpartum period was tested for varicella-zoster virus DNA. Varicella DNA was not detected in any of the 217 breast milk samples from the 12 women, all of whom seroconverted after vaccination.<sup>52</sup> One case of suspected transfer of varicella-zoster virus to an infant via breastfeeding has been reported, but the virus may have been transmitted by respiratory droplets or exposure to rash before the mother began anti-viral therapy.<sup>511</sup>

The isolation of an infant from the mother with varicella and interruption of breastfeeding should occur only while the mother remains clinically infectious, regardless of the method of feeding. As soon as the infant has received the varicella-zoster Ig, expressed breast milk can be given to an infant if no skin lesions involve the breasts. Persons with varicella rash are considered noninfectious when no new vesicles have appeared for 72 hours and all lesions have crusted, usually in 6 to 10 days. Immunocompetent mothers who develop zoster can continue to breastfeed if the lesions do not involve the breast and can be covered because antibodies against varicella-zoster virus are provided to the infant via the placenta and breast milk, and these antibodies will diminish the severity of disease, even if not preventing it. Conservative management in this scenario would include giving an infant varicella-zoster Ig as well (see Table 13-5).

**TABLE 13-5** Guidelines for Preventive Measures After Exposure to Chickenpox in the Nursery or Maternity Ward

Type of Exposure or Disease	Chickenpox Lesions Present		Disposition
	Mother	Neonate	
A. Siblings at home have active chickenpox when the neonate and mother are ready for discharge from hospital	No	No	<ol style="list-style-type: none"> <li>1. Mother: If she has a history of chickenpox, she may return home. Without a history, she should be tested for the varicella-zoster virus antibody titer.* If the test is positive, she may return home. If the test is negative, varicella-zoster Ig† is administered and she is discharged home</li> <li>2. Neonate: May be discharged home with mother if the mother has a history of varicella or is varicella-zoster virus antibody positive. If the mother is susceptible, administer varicella-zoster Ig to the infant and discharge home or place in protective isolation</li> </ol>
B. Mother has no history of chickenpox; exposed during period 6-20 days antepartum‡	No	No	<ol style="list-style-type: none"> <li>1. Exposed mother and infant: Send home at the earliest date, unless siblings at home have communicable chickenpox.§ If so, may administer varicella-zoster Ig and discharge home, as above</li> <li>2. Other mothers and infants: No special management indicated</li> <li>3. Hospital personnel: No precautions indicated if there is a history of previous chickenpox or zoster. In absence of a history, immediate serologic testing is indicated to determine immune status.* Nonimmune personnel should be excluded from patient contact until 21 days after an exposure</li> <li>4. If the mother develops varicella 1 to 2 days postpartum, the infant should be given varicella-zoster Ig</li> </ol>
C. Onset of maternal chickenpox occurs antepartum‡ or postpartum	Yes	No	<ol style="list-style-type: none"> <li>1. Infected mother: Isolate until no longer clinically infectious. If seriously ill, treat with acyclovir¶</li> <li>2. Infected mother's infant: Administer varicella-zoster Ig† to neonates born to mothers with onset of chickenpox less than 5 days before delivery and isolate separately from mother. Send home with the mother if no lesions develop by the time the mother is noninfectious.</li> <li>3. Other mothers and infants: Send home at the earliest date. Varicella-zoster Ig may be given to exposed neonates</li> <li>4. Hospital personnel: Same as B-3</li> </ol>
D. Onset of maternal chickenpox occurs antepartum§			<ol style="list-style-type: none"> <li>1. Mother: Isolation unnecessary</li> <li>2. Infant: Isolate from other infants but not from the mother</li> <li>3. Other mothers and infants: Same as C-3 (if exposed)</li> <li>4. Hospital personnel: Same as B-3 (if exposed)</li> </ol>
E. Congenital chickenpox	No	Yes	<ol style="list-style-type: none"> <li>1. Infected infant and mother: Same as D-1 and D-2</li> <li>2. Other mothers and infants: Same as C-3</li> <li>3. Hospital personnel: Same as B-3</li> </ol>

ELISA, Enzyme-linked immunosorbent assay; FAMA, fluorescent antibody to membrane antigen; LA, latex agglutination.

\*Send serum to virus diagnostic laboratory for determination of antibodies to varicella-zoster virus by a sensitive technique (e.g., FAMA, LA, ELISA). Personnel may continue to work for 8 days after exposure, pending serologic results because they are not potentially infectious during this period. Antibodies to varicella-zoster virus greater than 1:4 are probably indicative of immunity.

†Varicella-zoster Ig is available as VariZIG under an investigational new drug (IND) application from the Food and Drug Administration. It is obtainable through FFF Enterprises at 800-843-7477. The dose for a newborn is 1.25 mL (1 vial). The dose for a pregnant woman is conventionally 6.25 mL (5 vials).

‡If exposure occurred less than 6 days antepartum, the mother would not be potentially infectious until at least 72 hours postpartum.

§Considered noninfectious when no new vesicles have appeared for 72 hours and all lesions have crusted.

¶The dosage of acyclovir for a pregnant woman is 30 mg/kg/day; for a seriously ill infant with varicella, 750 to 1500 mg/m<sup>2</sup>/day.

From Gershon AA: Chickenpox, measles and mumps. In Remington JS, Klein JO, editors: *Infectious diseases of the fetus and newborn infant*, ed 4, Philadelphia, 1995, WB Saunders.

## WEST NILE VIRUS

West Nile virus disease in the United States is one of the best examples of an emerging infectious disease taking on new importance in public awareness about health issues. In 2003, 9136 human cases of West Nile infection were reported to the CDC (through 2/11/2004). Cases were reported from 45 states, including 6256 cases (68%) of West Nile fever (milder cases), 2718 cases (30%) of West Nile meningoencephalitis, and 228 deaths related to West Nile disease.<sup>84</sup> West Nile virus is endemic in Israel and parts of Africa. Outbreaks have been reported from Romania (1996), Russia (1999), Israel (2000), and Canada (2002), as well as the United States (1999 to 2003).<sup>371</sup> In 2013, there were 2469 reported cases of West Nile virus illness reported, including 1267 cases with neuroinvasive disease.<sup>79-81</sup>

It is estimated that 150 to 300 asymptomatic cases of West Nile infection occur for every 20 febrile illnesses and for every one case of meningoencephalitis associated with West Nile virus. West Nile fever is usually a mild illness of 3 to 6 days' duration. The symptoms are relatively nonspecific, including malaise, nausea, vomiting, headache, myalgia, lymphadenopathy, and rash. West Nile disease is characterized by severe neurologic symptoms (e.g., meningitis, encephalitis, or acute flaccid paralysis, and occasionally optic neuritis, cranial nerve abnormalities, and seizures). Children are infrequently sick with West Nile virus infection, and infants younger than 1 year of age have rarely been reported.<sup>371</sup> The case-fatality rate for 2003 in the United States was approximately 2.5%, but the rate has been reported to be as high as 4% to 18% in hospitalized patients. The case-fatality rate for persons older than 70 years of age is considered to be higher, 15% to 29%, as documented among hospitalized patients in outbreaks in Romania and Israel.<sup>371</sup>

The primary mechanism of transmission is via a mosquito bite. Mosquitoes from the genus *Culex* are primary vectors. The bird-mosquito-bird cycle serves to maintain and amplify the virus in the environment. Humans and horses are incidental hosts. The pathogenesis of the infection is believed to occur via replication of the virus in the skin and lymph nodes, leading to a primary viremia that seeds secondary sites before a second viremia causes the infection of the CNS and other affected organs.<sup>66,122</sup> Transmission has been reported in rare instances during pregnancy,<sup>8,79</sup> via organ transplant,<sup>219</sup> and percutaneously in laboratory workers.<sup>81</sup>

A study of West Nile virus infection in pregnancy documented four miscarriages, two elective abortions, and 72 live births. Cord-blood samples

were tested in 55 infants, and 54 of 55 were negative for anti-West Nile virus IgM. Three infants had West Nile virus infection, which could have been acquired congenitally. Three of seven infants had congenital malformations that might have been caused by maternal West Nile virus infection based on timing in pregnancy, but no evidence of West Nile virus etiology was conclusively demonstrated.<sup>351</sup> West Nile virus transmission occurs via blood and blood-product transfusion,<sup>204</sup> and the incidence has been estimated to be as high as 21 per 10,000 donations during epidemics in specific cities.<sup>46</sup> No evidence of direct person-to-person transmission without the mosquito vector has been found.

One case of possible West Nile virus transmission via breastfeeding has been documented.<sup>80</sup> The mother acquired the virus via packed RBC transfusions after delivery. The second unit of blood she received was associated with other blood products from the same donation causing West Nile infection in another transfusion recipient. Eight days later, the mother had a severe headache and was hospitalized with fever and a CSF pleocytosis on day 12 after delivery. The mother's CSF was positive for West Nile virus-specific IgM antibody. The infant had been breastfed from birth through the second day of hospitalization of the mother. Samples of breast milk were West Nile virus-specific IgG and IgM positive on day 16 after delivery and West Nile virus-specific IgM positive on day 24. The same milk was West Nile virus RNA positive by PCR testing on day 16 but not on day 24 after delivery. The infant tested positive for West Nile virus-specific IgM in serum at day 25 of age but remained well without fever. No clear-cut exposure to mosquitoes for the infant were reported. The cord blood and placenta were not available to be tested. IgM antibodies can be found in low concentrations in breast milk, but this is not common or as efficient as the transfer of IgA, secretory IgA, or IgG into breast milk.<sup>80</sup>

A review of West Nile virus illness during breastfeeding identified six occurrences of breastfeeding during maternal West Nile virus illness.<sup>195</sup> Five of the six infants had no illness or detectable antibodies to West Nile virus in their blood. One infant developed a rash and was otherwise well after maternal West Nile virus illness, but was not tested for West Nile virus infection. Two infants developed West Nile virus illness while breastfeeding, but no preceding West Nile virus infection was demonstrated in their mothers. Two other breastfeeding infants developed West Nile virus-specific antibodies after their mothers acquired West Nile virus illness in the last week of pregnancy, but congenital infection could not be ruled out. Live virus was not cultured from 45 samples of breast milk

from mothers infected with West Nile virus during pregnancy, but West Nile virus RNA was detected in two samples and 14 samples had IgM antibodies to West Nile virus.<sup>195</sup>

The mentioned data suggest that West Nile virus infection through breastfeeding is rare. To date, evidence of significant disease due to West Nile virus infection in young breastfeeding children is lacking. At this time, no reason exists to proscribe breastfeeding in the case of maternal West Nile virus infection if a mother is well enough to breastfeed. As with many other maternal viral illnesses, by the time the diagnosis is made in a mother, the infant may have already been exposed during maternal viremia and possible virolactia. The infant can and should continue to receive breast milk for the potential specific and nonspecific antiviral immunologic benefits.

## YELLOW FEVER VIRUS

Yellow fever virus is a flavivirus that is transmitted to humans by infected *Aedes* and *Haemagogus* mosquitos in tropical areas of South America and Africa. Large outbreaks occur when mosquitos in a populated area become infected from biting viremic humans infected with yellow fever virus. Transmission from the mosquitos to other humans occurs after an incubation period in the mosquito of 8 days. Direct person-to-person spread has not been reported. Illness due to yellow fever virus usually begins after an incubation period of 3 to 6 days, with acute onset of headache, fever, chills, and myalgia. Photophobia, back pain, anorexia, vomiting, and restlessness are other common symptoms. The individual is usually viremic for the first 4 days of illness until the fever and other symptoms diminish. Liver dysfunction and even failure can develop, as can myocardial dysfunction. CNS infection is uncommon, but symptoms can include seizures and coma. Medical care should include intensive supportive care and fluid management.

One case of congenital infection after immunization of a pregnant woman with the attenuated vaccine strain has been reported. One of 41 infants whose mothers had inadvertently received the yellow fever virus vaccine during pregnancy developed IgM and elevated neutralizing antibodies against the yellow fever virus without any evidence of illness or abnormalities.<sup>463</sup> A more recent study<sup>449</sup> from Brazil examined inadvertent yellow fever virus immunization during pregnancy during a mass vaccination campaign in 2000; 480 pregnant women received the yellow fever virus at a mean of 5.7 weeks' gestation, the majority of whom did not know their pregnancy status at the time. Seroconversion occurred in 98.2% of the women after at least 6 weeks after vaccination. Mild

postvaccination illness (headache, fever, or myalgia) was reported by 19.6% of the 480 women. The frequency of malformations, miscarriages, stillbirths, and premature deliveries was similar to that found in the general population. At the 12-month follow-up point, 7% of the infants still demonstrated neutralizing antibodies against yellow fever virus, but after 12 months, only one child was still seropositive.<sup>449</sup>

Transmission of the yellow fever vaccine virus through breastfeeding was reported from Brazil in 2009.<sup>91</sup> The mother was immunized during a yellow fever epidemic in a nonendemic area in Brazil; 15 days after delivering a healthy female infant (39 weeks' gestational age) the mother received the 17DD yellow fever vaccine, and 5 days later, the mother reported headache, malaise, and low-grade fever that persisted for 2 days. The mother continued breastfeeding and did not seek medical care for herself. At 23 days of age the infant became irritable, developed fever, and refused to nurse. The infant developed seizures and subsequent evaluation of the infant demonstrated an abnormal CSF, and a CT of the brain showed bilateral areas of diffuse low density suggestive of inflammation and consistent with encephalitis. Yellow fever-specific IgM antibodies were identified in the infant's serum and CSF. Reverse-transcriptase polymerase chain reaction (RT-PCR) testing of the CSF also demonstrated yellow fever virus RNA identical to the 17DD yellow fever vaccine virus. Breast milk and maternal serum were not tested for yellow fever virus.<sup>91</sup> A second similar case of possible transmission of the vaccine strain of yellow fever virus was described in Canada.<sup>257</sup> Yellow fever virus, wild or vaccine type, has not been identified in human breast milk, although another flavivirus, West Nile virus, has been detected in milk from a few lactating women with West Nile virus infection.<sup>195</sup> (See the section on West Nile virus.) Yellow fever vaccine-associated neurologic disease occurs at different rates in different age-groups, including 0.5 to 4.0 cases per 1000 infants younger than 6 months of age.<sup>321</sup> The 17D-derived yellow fever vaccines are contraindicated in infants younger than 6 months of age.

Since 2002, the Advisory Committee on Immunization Practices has recommended, based on theoretical risk, that yellow fever vaccine be avoided in nursing mothers, except when exposure in high-risk yellow fever endemic areas is likely to occur.<sup>82</sup>

No case of transmission of yellow fever virus from an infected mother to her infant via breastfeeding or breast milk has been reported. Published information on the severity of yellow fever virus infection in infants younger than 1 year of age, potential protection from passively acquired antibodies, or protection from breast milk is limited.

No information on the differential risk for infection in breastfed versus formula-fed infants is available. Given the well-documented method of transmission of yellow fever virus via mosquitos, and the lack of evidence of transmission via breast milk, it makes more sense to protect all infants against mosquito bites than to proscribe breastfeeding, even when the mother is infected with yellow fever virus. Continued breastfeeding or use of expressed breast milk will depend on a mother's health status and ability to maintain the milk supply while acutely ill. If another source of feeding is readily available, then temporarily discarding expressed breast milk for at least 4 days of acute illness in the mother is a reasonable precaution.<sup>82,91</sup>

## SPIROCHETES

### Lyme Disease

Lyme disease, as with other human illnesses caused by spirochetes, especially syphilis, is characterized by a protean course and distinct phases (stages) of disease. Lyme borreliosis was described in Europe in the early twentieth century. Since the 1970s, tremendous recognition, description, and investigation of Lyme disease have occurred in the United States and Europe. Public concern surrounding this illness is dramatic.

Lyme disease is a multisystem disease characterized by involvement of the skin, heart, joints, and nervous system (peripheral and central). Stages of disease are identified as early localized (erythema migrans, often accompanied by arthralgia, neck stiffness, fever, malaise, and headache), early disseminated (multiple erythema migrans lesions, cranial nerve palsies, meningitis, conjunctivitis, arthralgia, myalgia, headache, fatigue, and, rarely, myocarditis), and late disease (recurrent arthritis, encephalopathy, and neuropathy). The varied manifestations of disease may relate to the degree of spirochtemia, the extent of dissemination to specific tissues, and the host's immunologic response.

The diagnosis of Lyme disease is often difficult, in part, because of the broad spectrum of presentations, inapparent exposure to the tick, and the lack of adequately standardized serologic tests. Culturing of the spirochete, *Borrelia burgdorferi*, is not readily available. Enzyme-linked immunosorbent assay (ELISA), immunofluorescent assay, and immunoblot assay are the usual tests. PCR detection of spirochetal DNA requires additional testing in clinical situations to clarify and standardize its utility.

Gardner<sup>156</sup> reviewed infection during pregnancy, summarizing a total of 46 adverse outcomes from 161 cases reported in the literature. The adverse outcomes included miscarriage and

stillbirth (11% of cases), perinatal death (3%), congenital anomalies (15%), and both early- and late-onset progressive infection in the infants. Silver<sup>428</sup> reviewed 11 published reports and concluded that Lyme disease during pregnancy is uncommon, even in endemic areas. Although the spirochete can be transmitted transplacentally, a significant immune response in the fetus is often lacking, and the association of Lyme infection with congenital abnormalities is weak.<sup>446,499</sup>

Little published information exists on whether *B. burgdorferi* can be transmitted via breast milk. One report showed the detection of *B. burgdorferi* DNA by PCR in the breast milk of two lactating women with untreated erythema migrans, but no evidence of Lyme disease or transmission of the spirochete in the one infant followed for 1 year.<sup>411</sup> No attempt to culture the spirochete was made, so it is not possible to determine if the detectable DNA was from viable spirochetes or noninfectious fragments. In that same study of 56 women with untreated erythema migrans who had detectable *B. burgdorferi* DNA in the urine, 32 still had detectable DNA in the urine 15 to 30 days after starting treatment, but none had it 6 months after initiating therapy. Ziska et al.<sup>519</sup> reported on the management of nine cases of Lyme disease in women, associated with pregnancy; seven of the nine women were symptomatic at conception, and six received antibiotics throughout pregnancy. Follow-up of the infants showed no transmission of Lyme disease, even in the seven infants who had been breastfed.<sup>519</sup>

The lack of adequate information on the transmission of *B. burgdorferi* via breast milk cannot be taken as proof that it is not occurring. If one extrapolates from data on syphilis and the *Treponema pallidum* spirochete, it would be prudent to discuss the lack of information on the transmission of *B. burgdorferi* via breast milk with the mother or parents and to consider withholding breast milk at least until therapy for Lyme disease has begun or has been completed. If the infection occurred during pregnancy and treatment has already been completed, an infant can breastfeed. If infection occurs postpartum or the diagnosis is made postpartum, infant exposure may have already occurred. Again, discussion with the mother or parents about withholding versus continuing breastfeeding is appropriate.

After prenatal or postnatal exposure, an infant should be closely observed and empiric therapy considered if the infant develops a rash or symptoms suggestive of Lyme borreliosis. The treatment of mother and infant with ceftriaxone, penicillin, or amoxicillin is acceptable during breastfeeding relative to the infant's exposure to these medications. Doxycycline should not be administered for more than 14 days while continuing breastfeeding

because of possible dental staining in the neonate. Continued surveillance for viable organisms in breast milk and evidence of transmission through breastfeeding is recommended.

A large body of information is available on various "Lyme vaccines" used in mouse models and dogs, but these vaccines are only partially protective and must be repeated yearly. Preliminary information suggests that a vaccine for use in humans safely produces good serologic responses, but protective efficacy has not been demonstrated, and no information exists on its use during pregnancy or breastfeeding.

## Syphilis

Syphilis is the classic example of a spirochetal infection that causes multisystem disease in various stages. Both acquired syphilis and congenital syphilis are well-described entities. Acquired syphilis is almost always transmitted through direct sexual contact with open lesions of the skin or mucous membranes of individuals infected with the spirochete, *T. pallidum*. Congenital syphilis occurs by infection across the placenta (placentitis) at any time during the pregnancy or by contact with the spirochete during passage through the birth canal. Any stage of the disease (primary, secondary, tertiary) in a mother can lead to infection of the fetus, but transmission in association with secondary syphilis approaches 100%. Infection with primary syphilis during pregnancy, without treatment, leads to spontaneous abortion, stillbirth, or perinatal death in 40% of cases. Similar to acquired syphilis, congenital syphilis manifests with moist lesions or secretions from rhinitis (snuffles), condylomata lata, or bullous lesions. These lesions and secretions contain numerous spirochetes and are therefore highly infectious.

Postnatal infection of an infant can occur through contact with open, moist lesions of the skin or mucous membranes of the mother or other infected individuals. If the mother or infant has potentially infectious lesions, isolation from each other and from other infants and mothers is recommended. If lesions are on the breasts or nipples, breastfeeding or using expressed milk is contraindicated until treatment is complete and the lesions have cleared. Spirochetes are rarely identified in open lesions after more than 24 hours of appropriate treatment. Penicillin remains the best therapy.

The evaluation of an infant with suspected syphilis should be based on the mother's clinical and serologic status, history of adequate therapy in the mother, and the infant's clinical status. Histologic examination of the placenta and umbilical cord, serologic testing of the infant's blood and CSF, complete analysis of the CSF, long bone

and chest radiographs, liver function tests, and a complete blood cell count are all appropriate, given the specific clinical situation. Treatment of the infant should follow recommended protocols for suspected, probable, or proven syphilitic infection.<sup>105</sup>

No evidence indicates transmission of syphilis via breast milk exists in the absence of a breast or nipple lesion. When a mother has no suspicious breast lesions, breastfeeding is acceptable as long as appropriate therapy for suspected or proven syphilis is begun in the mother and infant.

## PARASITES

### *Giardia lamblia*

Giardiasis is a localized infection limited to the intestinal tract, causing diarrhea and malabsorption. Immunocompetent individuals show no evidence of invasive infection, and no evidence indicates fetal infection from maternal infection during pregnancy. Giardiasis is rare in children younger than 6 months of age, although neonatal infection from fecal contamination at birth has been described.<sup>24</sup> Human milk has an in vivo protective effect against *Giardia lamblia* infection, as documented by work from central Africa, where the end of breastfeeding heralds the onset of *Giardia* infection.<sup>160</sup> This has been reaffirmed in undeveloped countries around the world.

The protective effect of breast milk has been identified in the milk of noninfected donors.<sup>167</sup> The antiparasitic effect does not result from specific antibodies but rather from lipase enzymatic activity. The lipase acts in the presence of bile salts to destroy the trophozoites as they emerge from their cysts in the GI tract. Hernell et al.<sup>193</sup> demonstrated that free fatty acids have a marked giardiacidal effect, which supports the conclusion that lipase activity releasing fatty acids is responsible for killing *G. lamblia*.

*G. lamblia* has also been reported to appear in the mother's milk, and the parasite has been transmitted to newborns via that route. The exact relationship of breastfeeding to the transmission of *G. lamblia* and the effect on infants continue to be studied, even though symptomatic infection in breastfed infants is rare.<sup>167</sup> One report from the Middle East suggests that even partial breastfeeding is protective against infection with intestinal parasites, including *Cryptosporidium* and *G. lamblia*.<sup>47</sup> A second report from Egypt suggests that breastfeeding has a protective effect against infantile diarrhea caused by intestinal protozoa.<sup>1</sup> The affected organisms included *Cryptosporidium* sp., *Entamoeba histolytica*, *Giardia*, and *Blastocystis*, although the number of infants studied was too small to demonstrate

significant protection against each individual protozoan.

Breastfeeding by mothers with giardiasis is problematic mainly because of the medications used for therapy. Metronidazole's safety in infants has not been established, although it is commonly used in premature neonates and infants. Little information is available on quinacrine hydrochloride and furazolidone in breast milk. Paromomycin, an orally nonabsorbable aminoglycoside, is a reasonable alternative recommended for treatment of pregnant women. Breastfeeding by a mother with symptomatic giardiasis is acceptable when consideration is given to the presence of the therapeutic agents in the breast milk.

## Hookworm Infection

Hookworm infection, most often caused by *Ancylostoma duodenale* and *Necator americanus*, is common in children younger than the age of 4 years, and there is at least one report on infantile hookworm disease from China.<sup>417</sup> This publication from the Chinese literature reports hundreds of cases of infantile hookworm disease that include the common symptoms of bloody stools, melena, anorexia, listlessness, and edema. Anemia, eosinophilia, and even leukemoid reactions occur as part of the clinical picture in young children. They also note at least 20 cases of hookworm diseases in newborn infants younger than 1 month of age. In the discussion of infantile hookworm infection, they note four routes of infection: direct contact with contaminated soil, "sand-stuffed" diapers, contaminated "washed/wet" diapers, and vertical transmammary transmission or transplacental transmission. They postulated that infection of infants before 40 to 50 days of age would most likely be due to transplacental transmission, and infection before environmental contact would most likely be due to transmammary transmission. Ample evidence is available in veterinary medicine of transmammary spread of helminths.<sup>341,426</sup> At least two reports suggest the possibility of transmammary transmission of hookworms in humans. Setasuban et al.<sup>419</sup> described the prevalence of *N. americanus* in 128 nursing mothers as 61% and identified *N. americanus* in breast milk in one case. Nwosu<sup>342</sup> documented stool samples positive for hookworms in 33 of 316 neonates (10%) at 4 to 5 weeks of age in southern Nigeria. The majority of neonatal infections were due to *A. duodenale*, although *N. americanus* is more prevalent in that area of Nigeria. Examination of colostral milk did not demonstrate any hookworm larvae.<sup>342</sup>

Additional epidemiologic work is necessary to determine the potential significance of the transmammary spread of helminths in humans, and more

careful examination of breast milk as a source of hookworm infection is required before reasonable recommendations are possible.

## Malaria

Malaria is recognized as a major health problem in many countries. The effect of malaria infection on pregnant and lactating women and thus on the developing fetus, neonate, and growing infant can be significant. The four species of malaria, *Plasmodium vivax*, *P. ovale*, *P. malariae*, and *P. falciparum*, vary in the specific aspects of the disease they produce. *P. vivax* exists throughout the world, but *P. falciparum* predominates in the tropics and is most problematic in its chloroquine-resistant form. Malaria in the United States is most often seen in individuals traveling from areas where malaria is endemic. The parasite can exist in the blood for weeks, and infection with *P. vivax* and *P. malariae* can lead to relapses years later. Transmission occurs through the bite of the anopheline mosquito and can occur via transfusion of blood products and transplacentally.

Congenital malaria is rare but seems to occur more often with *P. vivax* and *P. falciparum*. It usually presents in the first 7 days of life (range: 1 day to 2 months). It may resemble neonatal sepsis, with fever, anemia, and splenomegaly occurring in the most neonates and hyperbilirubinemia and hepatomegaly in less than half.

Malaria in infants younger than 3 months of age generally manifests with less severe disease and death than it does in older children. Possible explanations include the effect of less exposure to mosquitoes, passive antibody acquired from the mother, and the high level of fetal hemoglobin in infants at this age.<sup>24</sup> The variations in the infection rates in children younger than 3 months of age during the wet and dry seasons support the idea that postnatal infection is more common than congenital infection. No evidence indicates that malaria is transmitted through breast milk. The greatest risk to infants is exposure to the anopheline mosquito infected with malaria.

The main issues relative to malaria and breastfeeding are how to protect both mothers and infants effectively from mosquitoes and what drugs for treating malaria in mothers are appropriate during lactation. Protection from mosquito bites includes screened-in living areas, mosquito nets while sleeping, protective clothing with or without repellents on the clothes, and community efforts to eradicate the mosquitoes. Chloroquine, quinine, and tetracycline are acceptable during breastfeeding. Sulfonamides should be avoided in the first month of an infant's life, but pyrimethamine-sulfadoxine (Fansidar) can be used later.

Mefloquine is not approved for infants or pregnant women. However, the milk-to-plasma ratio for mefloquine is less than 0.25, there is a large volume of distribution of the drug, high protein-binding of the drug limits its presence in breast milk, and the relative importance of breastfeeding in areas where malaria is prevalent shifts the risk-to-benefit ratio in favor of treatment with mefloquine. The single dose recommended for treatment or the once-weekly dose for prevention allows for continued breastfeeding with discarding of the milk for short periods after a dose (1 to 6 hours). Maternal plasma levels of primaquine range from 53 to 107 ng/mL, but no information is available on levels in human milk. Primaquine is used in children, and once daily dosing in the mother would allow for discarding milk with peak levels of drug. Therefore, breastfeeding during maternal malaria even with treatment is appropriate with specific medications.

### ***Strongyloides***

*Strongyloides stercoralis* is a nematode (roundworm). Most infections are asymptomatic, but clinically significant infections in humans can include larval skin invasion, tissue migration, intestinal invasion with abdominal pain and GI symptoms, and a Loeffler-like syndrome due to migration to the lungs. Immune-compromised individuals can develop dissemination of larvae systemically, causing various clinical symptoms. Humans are the principal hosts, but other mammals can serve as reservoirs. Infection via the skin by filariform larvae is the most common form of transmission, and ingestion is an uncommon occurrence. The transmammary transmission of *Strongyloides* species has been described in dogs, ewes, and rats.<sup>232,341,426</sup> Only one report of transmammary passage of *Strongyloides* larvae in humans is available. In 76 infants younger than 200 days of age, 34% demonstrated the presence of *S. fuelleborni* on stool examination. The clinical significance of this was not elucidated. *Strongyloides* larvae were identified in only one sample of milk from 25 nursing mothers.<sup>60</sup>

In the absence of an understanding of the clinical significance of *Strongyloides* in the stools of young infants, given the lack of exclusion of the most common mechanism of transmission (through the skin) in the single report and the apparent infrequent evidence of these larvae in human milk, it is difficult to make any recommendations concerning breastfeeding and *Strongyloides*.

### **Toxoplasmosis**

Toxoplasmosis is one of the most common infections of humans throughout the world. The infective organism, *Toxoplasma gondii*, is ubiquitous in

nature. The prevalence of positive serologic test titers increases with age, indicating past exposure and infection. The cat is the definitive host, although infection occurs in most species of warm-blooded animals.

Postnatal infection with toxoplasmosis is usually asymptomatic. Symptomatic infection typically manifests with nonspecific symptoms, including fever, malaise, myalgia, sore throat, lymphadenopathy, rash, hepatosplenomegaly, and occasionally a mononucleosis-like illness. The illness usually resolves without treatment or significant complications.

Congenital infection or infection in an immunodeficient individual can be persistent and severe, causing significant morbidity and even death. Although most infants with congenital infection are asymptomatic at birth, visual abnormalities, learning disabilities, and mental retardation can occur months or years later. The syndrome of congenital toxoplasmosis is clearly defined, with the most severe manifestations involving the CNS, including hydrocephalus, cerebral calcifications, microcephaly, chorioretinitis, seizures, or simply isolated ocular involvement. The risk for fetal infection is related to the timing of primary maternal infection, although transmission can occur with preexisting maternal toxoplasmosis.<sup>267</sup> In the last months of pregnancy, the protozoan is more readily transmitted to the fetus, but the infection is more likely to be subclinical. Early in pregnancy the transmission to a fetus occurs less frequently, but it does result in severe disease. Treatment of documented congenital infection is currently recommended, although the duration and optimal regimen have not been determined, and reversal of preexisting sequelae generally does not occur.<sup>384</sup>

The prevention of infection in susceptible pregnant women is possible by avoiding exposure to cat feces or the organism in the soil. Pregnant or lactating women should not change cat litter boxes, but if they must, it should be done daily and while wearing gloves. The oocyst is not infective for the first 24 to 48 hours after passage. Mothers can avoid ingestion of the organism by fully cooking meats and carefully washing fruits, vegetables, and food preparation surfaces.<sup>102</sup>

In various animal models, *T. gondii* has been transmitted through the milk to the suckling young. The organism has been isolated from colostrum as well. The newborn animals became asymptotically infected when nursed by an infected mother whose colostrum contained *T. gondii*. Only one report has identified *T. gondii* in human milk, and some question surrounds the reliability of that report.<sup>267</sup> Transmission during breastfeeding in humans has not been demonstrated. Breast milk may contain appropriate antibodies against *T.*

*gondii*. Given the benign nature of postnatal infection, the absence of documented transmission in human breast milk, and the potential antibodies in breast milk, no reason exists to proscribe breastfeeding by a mother known to be infected with toxoplasmosis.

### **Trichomonas vaginalis**

*Trichomonas vaginalis* is a flagellated protozoan that can produce vaginitis (see Chapter 16 for a discussion of vaginitis), but it frequently causes asymptomatic infection in both men and women. The parasite is found in 10% to 25% of women in the childbearing years. It is transmitted predominantly by sexual intercourse, but it can be transmitted to the neonate by passage through the birth canal. This parasite often coexists with other STDs, especially gonorrhea.

Infection during pregnancy or while taking oral contraceptives is more difficult to treat. Some evidence suggests that infection with and growth of the parasite are enhanced by estrogens or their effect on the vaginal epithelium. No evidence indicates adverse effects on the fetus in association with maternal infection during pregnancy. Occasionally, female newborns have vaginal discharge during the first weeks of life caused by *T. vaginalis*. This is thought to be influenced by the effect of maternal estrogen on the infant's vaginal epithelium and the acquisition of the organism during passage through the birth canal. The organism does not seem to cause significant disease in a healthy infant. No documentation exists on transmission of *T. vaginalis* via breast milk.

The difficulty encountered with maternal infection during lactation stems from concerns regarding the use of metronidazole, the drug of choice. There are data on the use of metronidazole in premature infants and neonates without difficulty. Although topical agents containing povidone-iodine (Betadine) or sodium lauryl sulfate (Trichotone) can be effective when given as douches, creams, or suppositories, metronidazole remains the treatment of choice. The AAP advises using metronidazole only with a physician's direction and considers its effect on a nursing infant unknown but possibly a concern. The potential concerns are metronidazole's disulfiram-like effect in association with alcohol, tumorigenicity in animal studies, and leukopenia and neurologic side effects described in adults. On the other hand, metronidazole is given to neonates and children beyond the neonatal period to treat serious infections with various bacteria or other parasites, such as *E. histolytica*.

The current recommendation for lactating women is to try local treatments first, and if these

fail, then to try metronidazole. A 2-g single-dose treatment produces peak levels after 1 hour, and discarding expressed breast milk for the next 12 to 24 hours is recommended. If this treatment also fails, a 1-g twice-daily regimen for 7 days or a 2-g single daily dose for 3 to 5 days is recommended, with the discarding of breast milk close to the dose and timing of feedings distant from the dose.

### **Strongyloides**

*Strongyloides*, one of the intestinal nematodes with both skin and diffuse organ dissemination, is found worldwide in tropical and temperate environments. Its true prevalence is probably significantly underestimated because of subclinical infection and the resulting difficulty of diagnosing it. Acute infection can cause a cutaneous eruption. In more chronic infection, it is associated with the GI tract and malabsorption, chronic diarrhea, failure to thrive, fever, cachexia, abdominal pain, cramping, and alternating diarrhea and constipation. Hyperinfection and invasive disease are most often evident in the lungs, but *Strongyloides* can include many organs, such as the lymph nodes, skeletal muscle, heart, liver, and brain. There is a syndrome of infantile strongyloidiasis caused by *S. fuelleborni* affecting the infant in the first months of life with prolonged diarrhea, abdominal distention, failure to thrive, and malnutrition. Due to the timing, it is suspected that this syndrome appearing in early infancy is due to vertical transmission. *Strongyloides* is passed in the milk of a number of animal species.<sup>60</sup> Nevertheless, *Strongyloides* was detected in human milk of only one sample out of 113 samples tested by Brown and Girardeau.

Costa-Macedo and Rey reported that, although they identified a variety of intestinal parasites in 208 children less than 2 years of age in Rio de Janeiro, 12.7% of the children had one or more parasites in stool studies. *Ascaris lumbricoides* was the parasite most frequently detected in children less than 1 year of age. The presence of parasites was statistically less in the breastfed infants, and no exclusively breastfed child presented with infection.<sup>110</sup> Mota-Ferreira et al. identified IgA and IgG antibodies specific against *S. stercoralis* in breastmilk by ELISA (IgA in 28.9%, and IgG in 25.5% of the samples) and indirect fluorescent antibody test (IFAT) (IgA in 42.25%, and IgG in 18.9% of the samples, with over 90% concurrence).

Given the uncommon association of parasites with breastfed infants, the limited evidence of *Strongyloides* in human milk, and the presence of antibodies against specific antigens of *S. stercoralis*, there is no reason to proscribe breastfeeding relative to *Strongyloides* infection.

### ***Trypanosoma cruzi***

Chagas disease, caused by the protozoa *Trypanosoma cruzi*, is a major cause of disease in the Americas, and it is endemic in many parts of South America. Pregnant or breastfeeding women can be chronically infected (often asymptomatic) or acutely infected. Infection in pregnancy is associated with an increased risk of preterm birth, low birth weight, or stillbirth. There is a clinical picture of congenital Chagas disease that includes hepatosplenomegaly, myocarditis, anemia, anasarca, and meningoencephalitis in the severest form, but it is most commonly an asymptomatic infection. A systematic review and meta-analysis reported a prevalence ranging from 0.1% to 8.5% in pregnant women in Brazil, with congenital transmission rates of 0% to 5.2%.<sup>300</sup> In congenital infection, the treatment success is close to 90%. In Spain, a nonendemic country, Ramos et al. reported a seroprevalence rate in pregnant immigrant women from South America as 1.28%, but they were unable to identify a case of congenital Chagas disease in 545 infants.<sup>380</sup>

A recent review of Chagas disease and breastfeeding noted that *T. cruzi* has been identified in the milk of chronically infected mice, but transmission through breast milk has been uncommon, and histologic examination of the breasts did not reveal any parasites.<sup>338</sup> They summarized eight reports in the literature of possible transmission of *T. cruzi* via breastfeeding in humans. In the majority of cases, the parasite could not be identified in the human milk, the exact mechanism could not be effectively pinpointed, and contamination of the breast milk with blood or another mechanism of transmission could not be excluded. They also noted that the "blood-form trypomastigotes" that would be expected to be found in the human milk would potentially have different surface receptors than "infectious metacyclic trypomastigotes" and therefore have altered infectious capability across mucous membranes. They also discussed acute Chagas disease, with probable parasitemia, noting that in only one case was the *T. cruzi* identified in the breast milk and that infant was not breastfed.

In light of the very rare occurrence of possible transmission of *T. cruzi* through human milk, it is not reasonable to proscribe breastfeeding by women with chronic Chagas disease. Even in women with acute Chagas and an increased likelihood of a transient parasitemia, by the time the diagnosis is made in the mother, the infant has probably already been exposed. Treating the mother and continuing breastfeeding is appropriate. The medications benznidazole and nifurtimox have been used to treat congenital infection in infants.

### ***CANDIDA* INFECTIONS**

*Candida* consists of multiple species. The most common species affecting humans include *C. albicans*, as the dominant agent, and *C. tropicalis*, *C. krusei*, and *C. parapsilosis*, as well as many other uncommon species. In general, *Candida* exists as a commensal organism colonizing the oropharynx, GI tract, vagina, and skin without causing disease until some change disrupts the balance between the organism and the host. Mild mucocutaneous infection is the most common illness, which can lead to vulvovaginitis, mastitis, or, uncommonly, oral mucositis in a mother, and thrush (oral candidiasis) and candidal diaper rash in an infant.

Invasive candidal infection occurs infrequently, usually when a person has other illness, impaired resistance to infection (HIV, diabetes mellitus, neutropenia; decreased cell-mediated immunity in premature infants or LBW or VLBW infants), or disrupted normal mucosal and skin barriers and has received antibiotics or corticosteroids. Invasive disease can occur through local spread, and it may present more often in the genitourinary tract (urethra, bladder, ureters, kidneys), although it usually develops in association with candidemia. The bladder and kidney are more frequently involved, but when dissemination occurs via candidemia, a careful search for other sites of infection should be made (e.g., retina, liver, spleen, lung, meninges).<sup>315</sup>

Transmission usually occurs from healthy individuals colonized with *Candida* through direct contact or contact with their oral or vaginal secretions. Intrauterine infection can occur through ascending infection through the birth canal, but it is rare. This can cause congenital cutaneous candidiasis usually evident on the first day of life. Most often, an infant is infected in passing through the birth canal and remains colonized. Postnatal transmission can occur through direct contact with caregivers.

The mother and infant serve as an immediate source of recolonization for each other, especially during the direct contact of breastfeeding. For this reason, an infant and breastfeeding mother should be treated simultaneously when treating thrush, vulvovaginitis, diaper candidiasis, or mastitis. Colonization with this organism usually occurs in the absence of any clinical evidence of infection. Simultaneous treatment should occur even in the absence of any clinical evidence of *Candida* infection or colonization in the apparently uninvolved individual of the breastfeeding dyad.

No well-controlled clinical trials define the most appropriate or most effective method(s) of treatment for candidal infection in breastfeeding mother-infant dyads. The list of possible treatment products is extensive and includes many anecdotal and empirical regimens. In the face of this absence

of data, Brent<sup>58</sup> conducted a survey of members of the Academy of Breastfeeding Medicine concerning the respondents' approach to diagnosis and treatment of thrush in the breastfeeding dyad. Most of the respondents relied on the history and physical examination of the infant, but only a third rated the examination of the mother as very important in making a diagnosis. Only 7% reported using laboratory testing to make the diagnosis. Twenty-one percent of the respondents reported using only oral nystatin for the infant when the mother was asymptomatic. Almost half treated the infant and the mother with topical nystatin, and 13% used oral nystatin for the infant and oral fluconazole for the mother when the mother had breast pain. Less than 5% used oral fluconazole for both infant and mother, and other therapies were used by about 15% of the respondents. For recurrence of persistent thrush, more respondents reported treating the mother or both the infant and mother with fluconazole, and almost a quarter reported using other therapies.

Considerable discussion of mammary candidosis/candidiasis, the clinical diagnosis of candidal involvement of the breast, the significance of pain with breastfeeding, and the presence or absence of *C. albicans* in milk samples is ongoing.<sup>16,148,183</sup> A prospective longitudinal cohort study considered a case definition of "nipple and breast thrush" characterized by burning nipple pain and breast pain not associated with mastitis.<sup>10</sup> Nipple damage and identification of *Candida* in any of four samples from the mothers (nipple swabs, human milk collected midstream, and oral and vaginal swabs) were independent predictors of women who met the case definition. *Staphylococcus* was not more frequently associated with the burning nipple pain and breast pain in this study. A systematic review and meta-analysis of a number of trials found that women with deep breast pain or pain symptoms had higher occurrences of isolating microbial organisms from the milk or local site.<sup>44</sup> This finding was not dependent on the test method or the specific microbe (coagulase negative or positive, *Staphylococcus*, or *Candida*). However, the author noted a number of problems with the study designs of the original studies. This topic will continue to be debated because additional prospective studies are necessary to clarify specific issues. Data are inadequate to make specific recommendations about various clinical situations regarding *Candida* and breastfeeding. Clinical practice will vary with experience, especially for the more problematic clinical situations. Some general guidelines follow. (See Chapter 16 and the Academy of Breastfeeding Medicine website for a discussion of mastitis <http://www.bfmed.org/Resources/Protocols.aspx> [accessed 9/6/15]).<sup>9a</sup>

The treatment of mucocutaneous candidiasis should probably begin with a topical agent, such as nystatin, clotrimazole, miconazole, econazole,

butaconazole, terconazole, or ciclopirox. Treatment should continue for at least 2 weeks, even with obvious improvement in 1 or 2 days. Failures most often result from inadequate therapy involving the frequency of application, careful washing and drying before application, or, in the case of diaper candidiasis, decreasing the contact of the skin with moisture. Nystatin oral suspension is less effective for the treatment of oral candidiasis in infants, now compared with the past, supposedly due to increasing resistance.<sup>172</sup> Gentian violet (diluted to a ratio of 0.25% to 1.0%) applied to the breast or painted onto an infant's mouth is being recommended more frequently. Other topical preparations have been recommended for the mother's breast, including mupirocin, grapefruit seed extract, or mixtures of mupirocin, betamethasone ointments, and miconazole powder. Controlled clinical trials for efficacy and toxicity are not available.

When good adherence to the proposed regimen with topical agents fails, or when the infant or mother are severely affected by pain and decreased breastfeeding, systemic therapy is appropriate. Fluconazole and ketoconazole are the most commonly used systemic agents for oral or diaper candidiasis and vulvovaginitis or mastitis. Fluconazole has a better side effect profile than ketoconazole, and more data are available concerning its safe use in children younger than 6 months of age and even neonates and premature infants.<sup>95,172,230</sup> Fluconazole is not currently approved for use in infants younger than 6 months of age. For severe invasive infections in infants, amphotericin B with or without oral flucytosine, IV fluconazole, voriconazole, and caspofungin are reasonable choices in different situations. The use of itraconazole in infants has not been adequately studied to date. Maternal use of fluconazole during breastfeeding is not contraindicated, because only a small amount of medicine, compared with the usual infant dose, reaches the infant through breast milk. Amphotericin or caspofungin therapy in mothers is also not contraindicated, because these are both poorly absorbed from the GI tract. Whenever a mother is treated for candidal mastitis or vulvovaginitis, the infant should be treated simultaneously, at least with nystatin oral suspension as the first choice of medication.

Any predisposing risk factors for candidal infection in mothers and infants should be reduced or eliminated to improve the chance of rapid, successful treatment and to decrease the likelihood of chronic or recurrent disease. For mothers, such interventions might include decreasing sugar consumption, stopping antibiotic use as soon as possible, and consuming some form of probiotic bacteria, such as *Lactobacillus acidophilus* (in yogurt, milk, or pill form), to reestablish a normal

colonizing bacterial flora. For infants, breastfeeding can enhance the growth of specific colonizing bacterial flora such as *Lactobacillus*, which can successfully limit fungal growth. Breastfeeding should continue with appropriate support and problem-solving with a professional who is knowledgeable about breastfeeding.

## Summary

HIV-1, HIV-2, HTLV-I, and HTLV-II are the only infectious diseases that are considered absolute contraindications to breastfeeding in developed countries. When the primary route of transmission is via direct contact or respiratory droplets/particles, temporary separation of mother and infant may be appropriate (whether the infant is breastfed or formula fed), but expressed breast milk should be given to the infant for the organism-specific immunologic benefits in the mother's milk. In most instances, by the time a specific diagnosis of infection is made for a mother, the infant has already been exposed to the organism, and providing expressed breast milk to the infant should continue. (Refer to Appendix F for specific exceptions, such as EVD or Lassa fever.) Regarding antimicrobial therapy for mothers and continued breastfeeding, the majority of the medications commonly used in adults can be used to treat the same infection in infants. The additional amount of medication received by infants via breast milk is usually insignificant. In almost all instances, an appropriate antimicrobial agent for treating mothers that is also compatible with breastfeeding can be chosen.

Unless there is a documented risk to infants for transmission of an infectious agent via breast milk that leads to a clinically significant illness, breastfeeding should continue.

## CHAPTER 14

# *Breastfeeding Infants with Problems*

Breastfeeding is the ideal and preferred feeding method for a newborn. Occasionally infant problems interfere with breastfeeding and require the attention of the infant's physician to diagnose and treat the problem.

Breastfeeding is a natural behavior for infants and provides the ideal nourishment, but some infants with complicating issues may need special assistance or adjustments.<sup>7</sup> Prematurity is discussed in Chapter 15. Infants with structural abnormalities, metabolic challenges or neurologic difficulties, stressed infants, and twins and triplets will be discussed in this chapter.

### *Procedural Pain Relief*

Systematic review and meta-analysis of procedural pain relief for neonates was reported by Shah et al. Infants with congenital, developmental, and environmental problems in the newborn period are often subjected to multiple procedures. Compared to placebo, positioning, or no intervention, breastfeeding is best. Glucose and sucrose are a substitute of necessity when mother's milk is not available.

### *Perinatal Issues: Postmature Infants*

Postmature infants are full-grown, mature infants who have stayed in utero beyond the full vigor of the placenta and have begun to lose weight in utero.<sup>37</sup> They are usually "older looking" and have a wide-eyed countenance. Their skin is dry and peeling, and subcutaneous tissue is diminished; thus the skin appears too large. These infants have

lost subcutaneous fat and lack glycogen stores. Initially they may be hypoglycemic and require early feedings to maintain blood glucose levels of 40 mg/dL or higher. If breastfed, the infants should go to the breast early, taking special care to maintain body temperature, which is labile in postmature infants who lack the insulating fat layer. Blood sugar levels should be followed. Initially, these infants may feed poorly and require considerable prodding to suckle. If the infant becomes hypoglycemic despite careful management, a feeding of 10% glucose in water should be considered. In extreme cases of hypoglycemia, an intravenous (IV) infusion may be necessary, and management should follow guidelines for any infant who has hypoglycemia that is resistant to routine early feedings. Because the infants lack glycogen stores, hypoglycemia may persist, and glucagon is contraindicated because no glycogen stores are present to be stimulated. Calcium problems, on the other hand, although common in these infants, generally are rare if the infant is adequately breastfed early because of the physiologic calcium/phosphorus ratio in breast milk. After postmature infants begin to feed well, they tend to catch up quickly and adapt well. Problems with hyperbilirubinemia seldom occur because their livers are mature. Postmature infants gain well at the breast once they stabilize.

### **FETAL DISTRESS AND HYPOXIA AND LOW APGAR SCORES**

Infants who have been compromised in utero or during delivery because of insufficient placental reserve, cord accidents, or other causes of intrauterine

hypoxia have very low Apgar scores at birth and need special treatment.<sup>131</sup> An asphyxiated infant cannot be fed for at least 48 hours, and, depending on associated findings, it may be 96 hours or more before it is safe to put food in the gastrointestinal (GI) tract, which has been poorly perfused during the hypoxia. The infant must be maintained on IV fluids. If the mother is to breastfeed or donor milk is available, human milk can be started sooner. Her colostrum will be valuable to the infant and will be better tolerated by the infant's intestinal tract, which has usually suffered hypoxic damage in these circumstances. Small amounts of colostrum can be given in 24 hours. Hypoxia decreases the motility of the gut and decreases stimulating hormones. The colostrum should be pumped and become the first oral feedings drop by drop.

Mothers will need help initiating lactation and understanding the pathophysiology of the infants' disease. These infants often have a poor suck that does not coordinate with the swallow, making nursing at the breast and bottle equally difficult. The mother may need to hold her breast in place and hold the infant's chin as well. These infants are especially susceptible to "nipple confusion," so means of sustaining nourishment other than a bottle should be sought. Cup feeding has been well tolerated using a soft plastic one-ounce medicine cup. Even infants who will not be breastfed but feed poorly from a bottle for neurologic reasons will do better with a cup.<sup>69,70,90</sup> Weaning slowly from the IV hyperalimentation fluids while introducing breastfeeding is helpful. Using a dropper and employing the nursing supplementer are options if milk supply from the breasts is low. These infants

may continue to feed poorly for neurologic reasons. They do not do better with a bottle. If the mother is taught to cope with the problem, nursing should progress satisfactorily. She may always need to hold her breast in place, which would be the best evidence of residual damage from the hypoxia.

Infants can be held in positions that may help an individual baby adapt better. The "football hold" is a popular but poorly named position in which an infant is held close to the mother's body with the feet to her side. The head and face are squarely in front of the breast and steadied by the mother's arm and hand on that side. Cupping the breast and the jaw in one hand facilitates the infant's seal around the breast with the mouth (Figure 14-1). This position has been called the "dancer hold."<sup>104</sup> One of the most valuable suggestions is the use of a sling or pleat-seat to hold an infant's body in a flexed position, thus giving the mother both hands free to hold the head and the breast in position for feeding (Figure 14-2).

Pacing the feedings and pumping after feedings will increase a mother's milk supply when the infant is unable to suck vigorously enough. Giving the pumped milk by lactation supplementer, small cup, or dropper ensures proper weight gain in the early weeks.<sup>104</sup> Holding an infant in a flexed position that mimics the fetal position relaxes an infant who is hypertonic or arching away from the breast.

In a study of energetics and mechanics of nutritive sucking in preterm and term neonates, Jain et al.<sup>80</sup> compared 38-gestational-week infants with 35-gestational-week infants and noted that preterm infants use less energy to suck the same volume of milk. The preterm infant took only up to 0.5 mL per

**Figure 14-1.** Dancer hold. **A**, Hand position of mother. **B**, Infant in position at breast with support. (From McBride MC, Danner SC: Sucking disorders in neurologically impaired infants: assessment and facilitation of breastfeeding, *Clin Perinatol* 14:109, 1987.)

**Figure 14-2.** Pleat-seat or sling baby carrier holds the infant in a flexed position that facilitates infant suckling, leaving the mother's hands free to support her breast and the infant. (Redrawn from McBride MC, Danner SC: Sucking disorders in neurologically impaired infants: assessment and facilitation of breastfeeding. *Clin Perinatol* 14:109, 1987.)

suck and generated lower pressures and a lower frequency.

Exploring the hypothesis that milk flow achieved during feeding contributes to ventilatory depression during rubber-nipple feeding, Mathew<sup>103</sup> compared nipples with different flow rates. Decreases in minute ventilation and breathing frequency were significantly greater with high-flow nipples, thus confirming that milk flow influences breathing in premature infants who are unable to self-regulate the flow.

Tracings were made from the first oral feeding to time of discharge in term and premature infants. Serial oxygen pressure values showed small undulations across baseline (above and below) while breastfeeding. Substantial dips while bottle feeding were shown with recovery, but not above baseline. The quality and quantity of variation were different in the two modes of sucking (i.e., breast or bottle), with large drops in oxygen saturation occurring during actual sucking of the bottle but only during burping or repositioning while breastfeeding. Meier<sup>106,107</sup> concludes that the findings do not support the widely held view that breastfeeding is more stressful. The comparative data suggest that both pacifier and bottle feeding are more stressful than suckling at the breast. For further discussion of the stress of breastfeeding versus bottle feeding see Chapter 15, feeding the 28 to 32 week premature infant. If an infant has significant motor tone

disabilities or lacks the usual oral reflexes in response to stimulus of the rooting and sucking reflexes, a neonatal neurologist should assess the infant before any routine exercises are initiated.

It has been suggested that perioral stimulation enhances an immature or neurologically impaired infant's ability to suck and to coordinate suck and swallow.<sup>91</sup> Perioral stimulation, consisting of stimulating the skin overlying the masseter and buccinator muscles by manually applying a quick-touch pressure stimulus lasting 1 second, was studied. This is accomplished by simultaneously squeezing the buccal fat of both cheeks. Suck-monitoring equipment revealed that perioral stimulation increased the sucking rate, suggesting that this may facilitate sucking.<sup>91</sup> Exercising the mouths of infants who already have excessive mouth stimulation may not be appropriate. Many infants in a neonatal intensive care unit (NICU) are being suctioned, tube fed, and orally stimulated for other reasons, which may lead to oral aversion.

Kangaroo care is recommended for full-term infants who are neurologically or metabolically impaired. It involves holding the infant skin to skin inside the parent's shirt. It can stabilize temperature, respirations, and heart rate and be neurologically calming. For a mother who is to breastfeed, it facilitates milk production and helps a mother learn to handle her infant.<sup>72</sup> Kangaroo care is further discussed in Chapter 15.

## GALACTOGOGUES: MEDICATION-INDUCED MILK PRODUCTION WHEN PUMPING

Stimulating milk production pharmacologically in mothers of LBW infants who are pumping to provide milk for their infants has been recommended by several authors, as reported by Ehrenkranz and Ackerman.<sup>48</sup> They used 10-mg metoclopramide orally every 8 hours for 7 days, tapering during 2 days more. Milk production increased within 2 days, but after therapy decreased, milk production decreased. Prolactin levels also increased during the treatment. Extensive use (more than 2 weeks) may cause cardiovascular symptoms in the mother.

Improved lactation occurred in 67% of mothers with no breast milk at onset and in 100% of mothers with poor supply given metoclopramide (10 mg three times per day for 10 days) by Gupta and Gupta.<sup>61</sup> They reported that the improvement persisted when the drug was discontinued. None of the 32 women had any symptoms or side effects. This drug is a substituted benzamide, which has selective dopamine-antagonist activity.

Although growth hormone has been observed to enhance milk supply, no recommended protocol

exists for its clinical use.<sup>60</sup> In one study, 20 healthy mothers with insufficient milk who delivered between 26 and 34 weeks were given growth hormone, 0.2 international units/kg/day subcutaneously for 7 days. A group of 10 mothers received a placebo. Milk volume increased in the treated mothers. No change was noted in plasma growth hormone levels, but an increase was seen in insulin-like growth factor. No other changes were noted during this short-term therapy.<sup>60</sup>

Other drugs have been noted to enhance milk production. Domperidone (Motilium) is currently unavailable in the United States because the FDA banned its distribution. It is widely available in Canada, Europe, and Australia. It is fully discussed in Chapter 12. A dosage of 10 mg three times per day is reported to increase milk supply in some women. The drug is not without side effects, however. Other galactagogues are discussed in Chapter 12.

## Breastfeeding Twins and Triplets

Many case reports support that a mother can nurse twins and triplets. It has been documented for centuries that an individual mother can provide adequate nourishment for more than one infant. In seventeenth-century France, wet nurses were allowed to nurse up to six infants at one time. Foundling homes provided wet nurses for every three to six infants.

The key deterrent to nursing twins is not usually the milk supply but time. If a mother can nurse both infants simultaneously, the time factor is reduced (Figure 14-3). Many tricks have been suggested to achieve this. As the infants become larger and more active, it may be difficult to keep them simultaneously nursing with only two hands to cope. However, twins trained from birth to nurse simultaneously will often continue to nurse in a position that allows both to nurse when they are older, even if the other is not nursing at the moment. If a

mother has help at home to assist with feedings, breastfeeding can be accomplished. The first year of life for a mother of a set of twins is an extremely busy one and really requires additional help, particularly if the mother is going to breastfeed. She will need time for adequate rest and nourishment. She often benefits from suggestions from other mothers of twins. The incidence of prematurity with twins is 3 in 10, with triplets 9 of 10, and with singletons just 1 in 10 pregnancies.

The challenge of breastfeeding twins was investigated by questionnaire of mothers who were members of the Mothers of Twins Clubs of Southern California, a national organization that offers help and advice to mothers of twins. No other socioeconomic information was available. Of the respondents, 41 mothers (23.7%) breastfed from birth, although 30% of the infants were premature. Of those who did not breastfeed, 9% were told not to do so by their physician, 11% did not think it was possible, and 11% did not think they would have enough milk for two. Of multiparas who had breastfed their first child, an equal number breastfed and bottle fed. Of the mothers who breastfed, 39 breastfed more than 1 month and 12 breastfed more than 6 months.

Eight healthy women who were breastfeeding twins and one breastfeeding triplets participated in a study by Saint et al.<sup>128</sup> to determine the yield and nutrient content of their milk at 2, 3, 6, 9, and 12 months postpartum. At 6 months, they fed an average 15 feeds per day. Fully breastfeeding women produced 0.84 to 2.16 kg of milk in 24 hours. Those partially breastfeeding produced 0.420 to 1.392 kg in 24 hours. The mother feeding triplets at 2½ months produced 3.08 kg/day, and the three infants were fed a total of 27 times per day. At 6 months the twins received 64% to 100% of total energy from breastfeeding and at 12 months received 6% to 13%. This further demonstrates that breasts are capable of responding to nutritional demands.

**Figure 14-3.** Premature twins nursing simultaneously, resting on a nursing pillow.

Guidelines for success in breastfeeding twins reported by Hattori and Hattori<sup>66</sup> admit that many obstacles exist but suggest that health care professionals should provide extended support to mothers of multiples to promote successful breastfeeding.<sup>66</sup> An extra pair of helpful hands provide significant assistance and relieve some of the fatigue. The initiation and duration of breast milk feedings by mothers of multiples compared with mothers of singletons were studied by a mailed questionnaire to 555 women.<sup>57</sup> The 358 mothers with multiples who answered were older, had higher incomes, were married, and were less likely to return to work by 6 months postpartum. Initiation of breastfeeding was comparable between mothers of multiples and singletons, but mothers of multiples provided milk for a shorter period of time, and mothers of preterm multiples breastfed the shortest period of time. At 6 months, 33% of mothers of term singletons were breastfeeding partially compared with 37% of mothers of term multiples. For preterm singletons, 31% were breastfed compared with 16% of preterm multiples.<sup>57</sup>

The medical literature on nursing twins or triplets or multiples in general is lean. It is well established that mothers can make enough milk. On the other hand, books, pamphlets, and websites supply personal stories and advice for mothers, fathers, and families. LaLeche League International, mothers of twins, [pregnancytoday.com](http://pregnancytoday.com), [parentingweb.com](http://parentingweb.com), [multiplebirthsfamilies.com](http://multiplebirthsfamilies.com), and others have copious commentaries for mothers. Coping strategies can be helpful. Wisdom from Gromada<sup>59</sup> is shared with mothers in her book *Mothering Multiples, Breastfeeding and Caring for Twins or More*. A case of a mother successfully nursing quadruplets is reported by Berlin.<sup>23</sup> A helpful device is the "breastfeeding pillow," which is a pillow that wraps around the mother as she sits to nurse. The two infants can be supported by the pillow.

## Full-Term Infants with Medical Problems

Infants who have self-limited acute illnesses, such as fever, upper respiratory infection, colds, diarrhea, or contagious diseases such as chickenpox, do best if breastfeeding is maintained. Because of breast milk's low solute load, an infant can be kept well hydrated despite fever or other increased fluid losses. If respiratory symptoms are significant, an infant seems to nurse well at the breast and poorly with a bottle. This observation has been documented many times when nursing mothers have roomed-in with their sick infants in the hospital. The studies of Johnson and Salisbury<sup>82</sup> on the

synchrony of respirations in breastfeeding in contrast to the periodic breathing or gasping apnea pattern of the normal bottle-fed infant may well provide the underlying explanation for the phenomenon of an acutely ill infant continuing to nurse at the breast.

In addition to the appropriateness of human milk for a sick infant, nursing and closeness with the mother provide comfort. If an infant is suddenly weaned, psychologic trauma is added to the stress of the illness.<sup>8</sup> The American Academy of Pediatrics (AAP) Committee on Nutrition has reversed its recommendation and does not recommend replacing breastfeeding in a sick child.

It may be difficult to distinguish the effect of trauma of acute weaning from the symptoms of the primary illness, such as poor feeding or lethargy, if the acutely weaned infant fails to respond to adequate treatment. Returning to breastfeeding may be the treatment because the stress of acute weaning will be removed.

It is not appropriate to give a mother medicine intended to treat the infant, especially antibiotics. This has been tried to the detriment of the child because variable amounts of the drug reach the infant depending on the dose, dosage schedule, and amount of milk consumed. Maternal drugs<sup>76</sup> can produce symptoms in an infant in some cases, and thus maternal history of ingestants is important in assessing symptoms in a breastfed infant (see Chapter 12).

## BUCCAL SMEARS IN BREASTFEEDING INFANTS

Guidelines for buccal smear collection in breastfed infants should be followed when genetic review is indicated. A buccal smear is a noninvasive, fast, and relatively inexpensive diagnostic method for collecting genetic material. It is used for sex determination as well as aneuploidy, microdeletion syndromes, and a variety of polymerase chain reaction-based molecular genetic tests. Maternal cells can contaminate smears taken from breastfed infants. The recommendation is to wait at least 1 hour after a feeding. Buccal mucosa should be cleansed thoroughly with a cotton swab applicator. These procedures apply to both neonates and older nursing children.<sup>16</sup>

## GASTROINTESTINAL DISEASE

Bouts of diarrhea and intestinal tract disease are less common in breastfed infants than in bottle-fed infants, but when they occur, the infant should be maintained on the breast if possible.<sup>8,130</sup> Human milk is a physiologic solution that normally causes neither dehydration nor hypernatremia. Occasionally, an

infant will have diarrhea or an intestinal upset because of something in the mother's diet. It is usually self-limited, and the best treatment is to continue to nurse at the breast. If a mother has been taking a laxative that is absorbed or has been eating laxative foods, such as fruits, in excess, she should adjust her diet. Intractable diarrhea should be evaluated as it would be in any infant. Allergy to mother's milk is extremely rare and would require substantial evidence to support the diagnosis. Allergy to a foreign protein passed into the milk, such as bovine  $\beta$ -globulin, as in cow milk, however, can cause severe allergic symptoms in an infant (see Chapter 17).

## COLITIS WHILE BREASTFEEDING

Severe colitis in a totally breastfed infant, usually with onset in the neonatal period, suggests an intrinsic metabolic disorder in the infant or an exquisite intolerance to something in mother's milk, such as cow milk protein.<sup>89</sup> Six infants with protein-induced enterocolitis presenting in the first month of life with severe bloody diarrhea responded to weaning and use of hydrolyzed protein formula. Other cases have been reported, requiring long periods of hyperalimentation and utilization of special formulas such as Nutramigen.

Induced colitis in infants is usually caused by some dietary insult, such as exposure to cow milk.<sup>89,135</sup> It has been reported in breastfed infants, most of whom responded to removal of cow milk from the maternal diet. Several had been given formula at birth, which is believed to have sensitized them. The symptoms included bloody diarrhea, and sigmoidoscopy revealed focal ulcerations, edema, and increased friability of the intestinal mucosa. On relief of symptoms by dietary change, the intestinal tract biopsy returns to normal. Removal of all bovine protein, not just cow milk, from the mother's diet may be required to ensure recovery while returning to breastfeeding. It may take 10 to 14 days to clear the bovine protein from the mother's milk.

A prospective study examined 35 consecutive infants who had fresh blood mixed with stools at approximately 4 weeks of age.<sup>96</sup> The infants were otherwise asymptomatic and had no infection, bleeding diathesis, or necrotizing enterocolitis (NEC); 31 had histopathologic evidence of colitis characterized by marked eosinophilic infiltrate (more than 20 eosinophils per high-power field) compared with control subjects and low mean serum albumin. Ten of these 31 were exclusively breastfed, nine were fed cow milk formula, nine soy formula, two mixed breast milk and formula, and one Nutramigen. The low serum albumin and high peripheral eosinophil count suggested the diagnosis of allergic colitis. All cases cleared with

dietary change. The breastfed infants were weaned, unfortunately, and not managed by dietary adjustment in the mother in this series.<sup>96</sup>

Protein-induced colitis can follow a benign course with proper treatment. Israel et al.<sup>75</sup> studied 13 infants with blood from the rectum, negative stool cultures, and colonoscopic and histologic evidence of colitis. The infants were all less than 3½ months of age, and six were breastfed and five had been supplemented. All were gaining weight well. The mothers of the breastfed infants restricted cow milk in their diet, and the infants were able to return to exclusively breastfeeding. All recovered.

Dietary protein-induced proctocolitis in exclusively breastfed infants should be taken into consideration as a cause of rectal bleeding or blood-streaked stool in the neonatal period and early infancy (hematochezia). Benign eosinophilic proctocolitis diagnosed by colonoscopy is best treated by the exclusion of the allergen from the mother's diet. Resolution has taken place within 72 to 96 hours of elimination of the offending protein so temporarily stopping breastfeeding may not be necessary in some cases.<sup>122</sup>

An 8-week-old infant boy presented with irritability and projectile vomiting for an ultrasound to rule out pyloric stenosis. The ultrasound revealed colitis, and further history revealed bloody stools. He responded to removing bovine protein from his mother's diet and continuing to breastfeed.<sup>115</sup>

Harmon et al.<sup>65</sup> described a case of perforated pseudomembranous colitis in a breastfed infant. Other cases had been associated with giving antibiotics to an infant. The infant's stool was *Clostridium difficile* toxin positive, and the child required bowel resection for abscess and perforation. The mother had taken ciprofloxacin without consulting a physician for days before the infant's admission.

The Lactation Study Center has been notified of other cases of bloody diarrhea with a diagnosis of colitis that did appear to respond to maternal dietary restrictions. One infant showed brief improvement when all cow milk products were removed from the mother's diet and then had a relapse. Removing all bovine (both meat and milk) products from the maternal diet resulted in recovery without relapse with exclusive breastfeeding. In retrospect the mother recalled switching from a vegetarian diet to high meat, especially beef, intake throughout pregnancy.

A case of fucose intolerance is reported in a breastfed infant who was not intolerant of lactose but of the by-product of the oligosaccharides in human milk, passing large amounts of fucose in the stool.<sup>18</sup> The infant tolerated Pregestimil and then was weaned to regular formula.

It has been recommended by Haight<sup>63</sup> that severe cases of allergic colitis and also severe GI

colic can be alleviated by treating the mother with pancreatic enzymes, 25 mg three times per day. It is safe for the mother and often dramatic for the infant. This is especially effective when eliminating cow protein has not solved the problem.

A formal study of this therapy was reported by Repucci<sup>124</sup> who described four term infants who were exclusively breastfeeding between 1 and 3 months of age who had positive family history for atopy. Elimination of bovine protein had not relieved the blood in the stools. Mothers were prescribed pancreatic enzymes (Pancrease MT4 USP units: 4000 lipase, 12,000 amylase, and 12,000 protease), two capsules with each meal and one capsule for snacks. Blood cleared within 2 days. One mother had to increase the dose to three capsules per meal and two with snacks. Mothers experienced no side effects due to this therapy. Anecdotal reports continue to confirm this therapy.

The management of protracted diarrhea in infants never breastfed is reported by many human milk banks on a case-by-case basis. Eleven of 24 children managed by MacFarlane and Miller<sup>96</sup> in a hyperalimentation referral unit recovered when fed banked human milk orally without protracted IV therapy. All the infants had been tried on all the available special formulas first. A study of oral rehydration in 26 children younger than the age of 2 years showed that the children who continued to breastfeed while receiving rehydration fluid had fewer stools and recovered more rapidly than those receiving only rehydration fluid.<sup>84</sup> The Pima Infant Feeding Study clearly showed that in less developed and more disadvantaged communities in the United States, exclusive breastfeeding protected<sup>53</sup> against severe diarrhea and other GI disorders.

## LACTOSE INTOLERANCE

Suckling milk is the defining characteristic of mammals. Lactose, the major carbohydrate in milk, is hydrolyzed by lactase-phlorhizin hydrolase, an enzyme of the small intestine. Lactase plays a critical role in the nutrition of mammalian neonates. Congenital lactase deficiency, present from birth, is extremely rare and is inherited as an autosomal recessive gene.<sup>108</sup> Most humans (except Northern Europeans) and other adult mammals do not drink milk beyond infancy; it causes indigestion and mild to severe GI symptoms because of an adult's inability to digest lactose. Low lactase levels result from injury or genetic expression of lactase. The enzyme hydrolyzes lactose, phlorhizin, and glycosyl ceramides. A decline in lactase-specific activity occurs at the time of weaning in most mammalian species. In humans it may occur as early as 3 to 5 years of age; in other species the elevated juvenile levels of lactase-specific activity persist.

The developmental patterns of lactase expression are regulated at the level of gene transcription.<sup>108</sup>

Premature infants and those recovering from severe diarrhea have transient lactose intolerance. The only treatment is a temporary lactose-free diet. Reports of lactose-hydrolyzed human milk suggest that banked human milk can be treated with lactase (Keralac), which will hydrolyze the lactose (900 enzyme activity units to 200 mL breast milk degraded 82% of the lactose).<sup>136</sup> In one case the reason for using human milk was that the infant became infection prone when he was weaned from the breast at the time the initial diagnosis was made. He showed marked improvement with treated human milk. In a breastfed infant, lactase deficiency may be manifest by chronic diarrhea and marked failure to thrive.

An additional clinical syndrome related to slow gaining or failure to thrive is excessive lactose, resulting when the fat level in the milk is low and an excessive amount of milk is consumed because of the low-calorie content. The first documented case was reported by Woolridge and Fisher.<sup>157</sup> Lactose production drives the milk-making capacity. When a feeding at one breast does not last long enough for the fat to let down, the result is low-calorie high-lactose milk. The authors recommend in such cases that an entire feeding be taken at one breast.<sup>157</sup> (For further discussion of this phenomenon, see Chapter 8.)

## CELIAC DISEASE, CROHN'S DISEASE, AND INFLAMMATORY BOWEL DISEASE

Some chronic diseases are better controlled by keeping an infant on breast milk, as symptoms usually become more severe with weaning. If an infant is weaned and does poorly on formula, relactation of the mother should be considered. With the availability of the nursing supplementer, this possibility is no longer remote (see Chapter 19).

Celiac disease or permanent gluten-sensitive enteropathy is an immunologic disease dependent on the exposure to wheat gluten or related proteins in rye and barley.<sup>77</sup>

A case-control study<sup>120</sup> was done on the effect of infant feeding on celiac disease to investigate the association between duration of breastfeeding and age at first gluten introduction into the infant diet and the incidence and age of onset of celiac disease. A significant protective effect on the incidence of celiac disease was related to the duration of breastfeeding after 2 months. It was not related to the age of first gluten in diet, although the age of first exposure did affect the age of onset of symptoms.<sup>120</sup>

The risk for celiac disease was reduced in children younger than 2 years old in a study of 2000

Swedish children if they were still being breastfed when dietary gluten was introduced. The effect was more pronounced if breastfeeding continued after gluten was introduced. The authors conclude that gradual introduction of gluten-containing foods into the diet while breastfeeding reduces the risk for ever getting celiac disease.<sup>77</sup> The declining incidence of celiac disease and transient gluten intolerance has been associated with changing feeding practices, which include later introduction of dietary gluten, the use of gluten-free foods for weaning (rice), and the increased initiation and duration of breastfeeding.<sup>29</sup>

The risk for celiac disease autoimmunity and timing of gluten introduction into the diet of infants at increased risk for the disease was determined by Norris et al.<sup>115</sup> who studied 1560 children prospectively. They had been determined to be at increased risk because they possessed either HLA-DR3 or DR4 alleles or had a first-degree relative with type 1 diabetes. Diagnosis of celiac disease was based on positive small bowel biopsy and positive for tissue transglutaminase autoantibody. Children exposed to gluten in the first 3 months of life or not until after 7 months of age developed the disease; 4 to 6 months of age appeared to be a safe period when gluten was tolerated. Breastfeeding may offer protection against the development of celiac disease. Breastfeeding during the introduction of gluten in the diet (wheat, barley, or rye) and increasing the duration of breastfeeding was associated with reduced risk for developing the disease, as reported by Akobeng et al.<sup>4</sup> who did a systematic review and meta-analysis.

The discussion is not over and the guidelines are not confirmed. It is agreed that celiac disease is an immune-mediated disease that is not uncommon. An estimated 1% of the population is affected. It negatively influences the quality of life of affected individuals. Prevention strategies focusing on early infant feeding practices (i.e., breastfeeding) and timing of introduction of gluten into the infant's diet have had conflicting results. Large multiple country prospective studies are underway. Although breastfeeding in multiple smaller studies has shown to be protective, there may prove to be limitations to that. Because risk can be anticipated by family history and testing for HLA-DQ2 or HLA-DQ8, dietary management appears to at least postpone the onset of symptoms if not prevent it.

A window of opportunity has been suggested to reduce the risk of celiac disease by introducing gluten no sooner than 4 months and no later than seven months of age and exclusive breastfeeding until 12 months of age but not beyond. In progress is a multicentered, randomized, double blind, placebo controlled dietary intervention study involving 944 HLA positive children; the

Norwegian mother and child cohort study of 324 cases out of a cohort of 82,167, and a systematic review of available data from a large randomized controlled trial in 10 European countries.

The current consensus is that gluten should be added to the diet between 4 and 7 months and breastfeeding should continue until 12 months in at-risk infants. The AAP states that breastfeeding reduces the risk of celiac disease by 52%.

A family with two sons at ages 33 months and 8 months came to the attention of the Lactation Study Center. Both were breastfed. They developed an inability to sleep comfortably after having slept well previously. They cried and thrashed about, needing constant attention and motion around the clock. At age 27 months, the older son had x-rays, biopsies, and genetic testing. Endoscopy was inconclusive with moderate inflammation and smoothing. He was positive for one of the three genetic markers for celiac disease. He had been weaned at 18 months and was started on a gluten-free diet, which "cured" him. At the center, the mother was recommended a gluten-free diet while she continued to breastfeed the 8-month-old child. In 48 hours he was remarkably improved and is now symptom free, breastfeeding, and eating gluten-free solids. With the availability of gluten-free foods in supermarkets, the diet for mothers is more accessible. The public interest in gluten-free food has increased and many are trying it at random.

The development of Crohn's disease later in life has increased in recent decades. Because it has been suggested that breast milk is essential for the development of the normal immunologic competence of the intestinal mucosa, investigators have studied the association between breastfeeding and later Crohn's disease. Bergstrand and Hellers<sup>21</sup> studied 826 patients who developed Crohn's disease between 1955 and 1974 and their matched control subjects. Mean length of breastfeeding was 4.59 months among patients and 5.76 among control subjects ( $p < 0.01$ ). Patients with Crohn's disease were overrepresented among those with no, or short, periods of breastfeeding. The role of infant feeding practices in the development of Crohn's disease in childhood was reported by Koletzko et al.<sup>87</sup> in a study of 145 families with similar results. Although Crohn's disease may develop in genetically susceptible people as a result of an immunologic response to unidentified antigen in the mucosa, early feeding practices are significant.

Early determinants of inflammatory bowel disease have pointed toward infectious diseases in childhood, especially measles, and even in utero infections as possible causative factors.<sup>19</sup> It has become a major disease of adults in Europe with 5.12 cases per 1000 individuals older than 43 years

(National Survey of Health and Development of 1946) and 2.02 to 2.54 cases per 1000 adults by age 33 years (1958 National Child Development Study). In examining early determinants, these cohorts did not show a protective effect of breastfeeding. The authors comment, however, that the study recorded "ever breastfed" with no distinction for length of breastfeeding.<sup>143</sup>

A systematic review with meta-analysis of breastfeeding and risk for inflammatory bowel disease was conducted by Klement et al.<sup>86</sup> who concluded that breastfeeding is associated with lower risks of Crohn's disease and ulcerative colitis. The reports that were included were published between 1961 and 2000. A report was published in 2005 of a pediatric case-control study of inflammatory bowel disease and 60 cases of ulcerative colitis in children younger than 17 years of age. The results did not support a protective effect of breastfeeding and suggested an association with the disease.<sup>81</sup> When these data were included in the meta-analysis by Klement,<sup>86</sup> however, the results still showed a protective effect of breastfeeding for these two bowel diseases.<sup>85</sup>

Breastfeeding is associated with a 31% reduction for childhood inflammatory bowel disease according to the AAP. It is thought that the reduction results from the interaction of the immunomodulating effect of human milk and the underlying genetic susceptibility of the infant. The abnormal colonization of the gut in formula-fed infants may increase risk.

The severity of GI infection is attenuated if not prevented in breastfeeding infants according to the AAP. Infections due to enteric pathogens such as *Rotavirus*, *Giardia*, *Shigella*, *Campylobacter* and entero toxicigenic *Escherichia coli*. The risk of these illnesses is reduced by 64% for infants who are breastfeeding.

## RESPIRATORY ILLNESS AND OTITIS MEDIA

Infants who develop respiratory illnesses should be maintained at the breast. The added advantages of antibodies and antiinfective properties are valuable to infants. Sick infants can nurse more easily than they can cope with a bottle. Furthermore, the comfort of having the mother nearby is important whenever the infant has a crisis; weaning during illness may be devastating to infants.

Wheezing and lower respiratory tract disease and other respiratory illnesses are lower in frequency and duration when the infant is breastfed. Recovery is accelerated if breastfeeding is maintained. The AHRQ reported a 72% reduction in the risk of hospitalization for respiratory infections

in children under a year of age who were exclusively breastfed for at least 4 months.

Otitis media in infants occurs less frequently in breastfed infants because of the infection protection properties of human milk and the protective effect of suckling at the breast. Recurrent otitis media is associated with bottle feeding in a study of 237 children, in contrast to prolonged breastfeeding, which had a long-term protective effect up to 3 years of age.<sup>126</sup>

A regional birth cohort of 5356 children was followed prospectively regarding the occurrence of infectious disease in the first year of life.<sup>83</sup> One third developed otitis media. Median age of onset was 8 months, and 10% had had three episodes by 1 year of age. Breastfeeding for 9 months or longer had a significant impact on otitis, as did the number of siblings and daycare. Otitis media in 3- to 8-year-old children in Greenland was studied as a national concern for the incidence and associated deafness. Children who were breastfed were spared, especially if nursed a long time.<sup>117</sup>

A protective effect of breastfeeding in otitis media was shown in a large prospective study. The AHRQ reported that exclusive breastfeeding for 3 to 6 months provided a 50% reduction in otitis media compared to formula feeding even when controlling for socioeconomic status, parental smoking, and the presence of siblings.

Young infants who have older siblings may well be exposed to some virulent viruses and bacteria. Developing croup, for instance, may make an infant seriously ill. Hydration can be maintained by frequent, short breastfeedings. Studies have shown that respirations are maintained more easily when feeding on human milk than on cow milk, even from a bottle. Nursing at the breast permits regular respirations, whereas bottle feeding is associated with a more gasping pattern. Thus breastfed infants should continue to nurse when they are ill. If an infant is hospitalized, every effort should be made to maintain breastfeeding or to provide expressed breast milk if the infant can be fed at all. Staff should provide rooming-in for the mother if a care-by-parent ward is not available.

Colostrum and milk contain large amounts of IgA antibody, some of which is respiratory syncytial virus (RSV) specific. Breastfed but not bottle-fed infants have IgA in their nasal secretions. Neutralizing inhibitors to RSV have been demonstrated in the whey of most samples of human milk tested.<sup>144</sup> IgG anti-RSV antibodies are present in milk and in reactive T-lymphocytes. Breastfeeding-induced resistance to RSV was associated with the presence of interferon and virus-specific lymphocyte transformation activity, suggesting that breastfeeding has unique mechanisms for modulating the immune response of infants to RSV infection.<sup>32</sup> Clinical studies

indicating a relative protection from RSV in breastfed infants were clouded by other factors.<sup>145</sup> The populations were unequal because of socioeconomic factors and smoking (i.e., bottle-feeding mothers were in lower socioeconomic groups and smoked more). In general, if breastfed infants become ill, they have less severe illness.<sup>144,145</sup> Although breastfeeding protects, parental smoking and daycare are important negative factors in the incidence of respiratory infection. Respiratory illness in either infant or mother should be treated symptomatically and breastfeeding continued. If the infant has nasal congestion, nasal aspiration and saline nose drops just before a feed are helpful.

## GALACTOSEMIA

Galactosemia, caused by deficiency of galactose-1-phosphate uridyltransferase, is a rare circumstance in which an infant is unable to metabolize galactose and must be placed on a galactose-free diet. The disease can be rapidly fatal in the severe form. The infant may have severe and persistent jaundice, vomiting, diarrhea, electrolyte imbalances, cerebral signs, and weight loss. This is a medical emergency. This does necessitate weaning from the breast to a special formula because human milk, as with all mammalian milks, contains high levels of lactose, which is a disaccharide that splits into glucose and galactose. The condition is suspected when reducing substances are found in the urine in the newborn, and the diagnosis is confirmed by measuring the enzyme uridyltransferase in the red and white blood cells. The several forms can be distinguished by genetic testing, but except for the mild form, the infant must be weaned to a lactose-free diet. An infection with *E. coli* in the newborn period may be the trigger that precipitates serious symptoms associated with this or other metabolic disorders. Galactosemia is screened for in most states in the United States along with phenylketonuria (PKU) and other metabolic disorders.

When the diagnosis is made, genetic testing should be done. The Duarte variant of the disease is mild; some enzyme is available. Breastfeeding is permitted but the infant should be followed closely initially. Some infants can only be partially breastfed, with some lactose-free formula in addition for necessary calories. An endocrinologist should make the decision for the exact balance of milks. Classic galactose-1-phosphate uridyltransferase deficiency makes breastfeeding contraindicated.

## INBORN ERRORS OF METABOLISM

Other metabolic deficiency syndromes are usually only apparent as mild failure-to-thrive syndrome

until the infant is weaned from the breast and the symptoms become severe. This particularly applies to inborn errors of metabolism caused by an inability to handle one or more of the essential amino acids that are in higher concentration in cow milk than human milk. Infection is often a complication early in the lives of these infants, with inborn errors most commonly due to *E. coli* bacteria. While the acute infection is being treated, the infant may be weaned from the breast, and the metabolic disorder then becomes apparent precipitously.

Certain amino acids, including phenylalanine, methionine, leucine, isoleucine, and others associated with metabolic disorders, have significantly lower levels in human milk than in cow milk. Management of an amino acid metabolic disorder while breastfeeding depends on careful monitoring of blood and urine levels of the specific amino acids involved. Because these are essential amino acids, a certain amount is necessary in the diet of all infants, including those with disease. An appropriate combination of breastfeeding and milk free of the offending amino acid should be developed. The care of such infants should be in consultation with a pediatric endocrinologist. Transient neonatal tyrosinemia, which has been reported to occur in a high percentage (up to 80%) of neonates fed cow milk, is associated with blood tyrosine levels 10 times those of adults. Wong et al.<sup>156</sup> have associated severe cases with learning disabilities in later years. Tyrosine appears in human milk at low levels. Tyrosinemia type I is an inherited autosomal recessive trait. Symptoms are caused by accumulation of tyrosine and its metabolites in the liver. It is treated by dietary control consisting of low protein with limited phenylalanine and tyrosine. Some breastfeeding is possible combined with protein-free supplements. 2-(2-Nitro-4-trifluoromethylbenzyl)-1,3-cyclohexanedione reduces the production of toxic metabolites. Liver failure is common. Dietary restrictions are lifelong.

Screening programs that test all newborns have identified many victims early. Almost all programs test for PKU, galactosemia, and hypothyroidism, and increasingly maple syrup urine disease, homocystinuria, biotinidase deficiency, tyrosinemia, and now cystic fibrosis are included. Most cases can be managed with continued breastfeeding and diet modification. Congenital adrenal hyperplasia requires corticosteroids but the feeding can be breast milk. If it is the salt wasting variety, an infant must have added salt.

## PHENYLKETONURIA

The most common of the amino acid metabolic disorders is PKU, in which the amino acid accumulates for lack of an enzyme. The treatment has

been phenylalanine-free formula, available from Abbott Laboratories and Bristol-Myers, combined with added standard formula or breast milk to provide a little phenylalanine because every infant needs a small amount. If an infant is breastfed, the mother is usually willing to continue on an adjusted schedule. An infant may supplement the Lofenalac or Analog XP with breast milk. With careful monitoring of the blood levels and control of the amount of breastfeeding, a balance can be struck that permits optimal phenylalanine levels and breastfeeding. The infant will require some phenylalanine-free formula to provide enough calories and nutrients. A detailed outline of management called *Guide to Breast Feeding the Infant with PKU*, prepared by Ernest et al.,<sup>50a</sup> is available from the Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402.

Literature values for phenylalanine range from 29 to 64 mg/dL in human milk. The amount for Lofenalac or Analog XP and human milk for a given baby is calculated by weight, age, blood levels, and needs for growth. As an example, a 3-week-old baby weighing 3.7 kg whose blood level was 52.5 mg/dL when he was ingesting an estimated 570 mL of breast milk would receive 240 mL Lofenalac and 360 mL breast milk (four breastfeedings per day with before and after weighing). The details of every step of management are available in the guide to assist a physician in planning treatment.<sup>48</sup> Test weighing, which is now a simple home procedure with a digital scale, greatly facilitates the accuracy of this management.

As soon as the diagnosis is made, an infant should be placed on a low-phenylalanine formula to reduce the levels in the plasma promptly. The mother should pump her breasts to maintain her milk supply. Human milk has less phenylalanine than formula, but it exceeds the tolerance of most infants with PKU. The breastfed infant is offered a small volume of special formula (10 to 30 mL) first and then completes the feeding at the breast. As long as the blood phenylalanine levels can be maintained between 120 and 300 mmol/L, exact intake need not be measured. Initially, weight checks to ensure adequate growth are essential because poor intake leading to a catabolic state will interfere with control. Because human milk is low in phenylalanine, the offending amino acid, more than half the diet can be breast milk.

Another protocol for breastfeeding an infant with PKU was studied by van Rijn et al. The feeding schedule was based on alternating breastfeeding and phenylalanine-free formula by bottle. Each child had a separate schedule convenient for the mother-baby dyad depending on tolerance and age. At the beginning of treatment, the mother breastfed once daily allowing the infant to feed

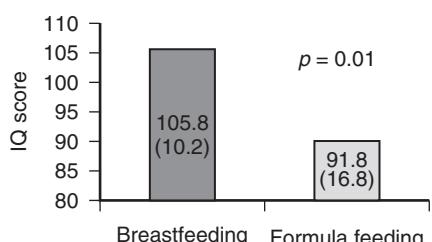

until satiated, and the mother pumped the rest of the day. Breastfeedings were increased while monitoring phenylalanine plasma levels. Ultimately breast and bottle feeding were alternated and equal. At all feedings, the infant drank until satisfied. The breastfed infants did well on this protocol and plasma levels were stable. An essential member of the management team is a board certified licensed lactation consultant to assist the mother in managing her milk supply.

The weaning of this special infant should be similar to that of other infants. Adding solid foods can be initiated at 6 months.<sup>34</sup> The liquid part of the diet continues as before, that is, two feeding components of low-phenylalanine formula and breastfeeding plus solids with little or no phenylalanine (fruits, vegetables, low-protein foods). Rice and wheat contain too much phenylalanine. When the decision is made to wean from the breast, solid foods can be used to replace the phenylalanine in the breast milk as needed. Growth should be followed closely. When weaning is complete, the infant should be given other less bulky sources of protein free of phenylalanine. This stage will be carefully orchestrated by the endocrinologist and nutritionist. Because infants with PKU are more prone to thrush infection, the mother should be alerted to watch for symptoms in the infant and the onset of sore nipples that could be caused by *Candida albicans*. Treatment is nystatin for both the mother and baby initially. (See discussion in Chapter 16.)

The other benefits of human milk make the effort to breastfeed valuable for the infant and for the mother, who usually wants to continue to contribute to her infant's nurturing and nourishment. The prognosis for intellectual development is excellent if treatment is initiated early and the blood levels maintained at less than 10 mg/dL phenylalanine (120 to 300 mmol/L).

A retrospective study of 26 school-age children who had been breastfed or formula fed for 20 to 40 days before dietary intervention was conducted by Riva et al.<sup>125</sup> The children who had been breastfed had a 14-point IQ advantage, which persisted at 12.9 points when corrected for maternal social and educational status. The age of treatment onset for PKU was not related to IQ scores. This study strongly supports the belief that breastfeeding in the prediagnostic stage has an impact on the long-range neurodevelopmental performance of patients with PKU (Figure 14-4).

Nutrition management of infants with organic acidemias involves limiting the intake of the offending amino acid(s) to the minimum necessary for normal growth and development and suppressing amino acid degradation during catabolic periods by providing alternative fuels such as glucose. In some disorders, including isovaleric

**Figure 14-4.** Intellectual quotient (IQ) in patients with phenylketonuria, evaluated by Wechsler Intelligence Scale for Children score, in relation to the type of feeding in the first weeks of life. (From Giovannini M, Verduci E, Salvatici E, et al: Phenylketonuria: dietary and therapeutic challenges, *J Inher Metab Dis* 30:145–152, 2007.)

acidemia, specific treatment is included to increase the excretion of toxic metabolites by enhancing the body's capacity to make isovalerylglycine, an acylcarnitine translocase. As more specific amino acid-free formulas are made available, a recipe for combining breastfeeding with the special formula can be engineered to specific infants' needs. The endocrinologist and the nutritionist can provide such a recipe. Dietary precautions for the mother of a breastfeeding child with PKU are to avoid the artificial sweetener aspartame (NutraSweet), which metabolizes to phenylalanine.

## Other Metabolic Disorders

Pompe disease (acid maltase deficiency or glycogen storage disease type II) is an inborn error of metabolism caused by a complete or partial deficiency of the enzyme acid  $\alpha$ -glucosidase that normally breaks down lysosomal glycogen into glucose. Glycogen accumulates in the tissues, especially muscles. The disease takes various forms. Infantile onset has a poor prognosis and treatment is supportive. Because of the frequency of respiratory infection and difficulty feeding, breastfeeding would be palliative because liver disease is rapidly progressive.

Ornithine transcarbamylase deficiency is a rare life-threatening genetic disorder. It is one of six urea cycle disorders named for the specific enzyme deficiency present.

A lack of enzyme results in excessive and symptomatic accumulation of ammonia in the blood (hyperammonemia). Symptoms vary but can occur within 72 hours of birth and include poor suck, irritability, vomiting, and progressive lethargy followed, if untreated, by hypotonia, seizures, respiratory distress, and coma. Infant onset disease is more common in males. Treatment involves limiting nitrogen intake and assisting nitrogen excretion with phenylbutyrate (Buphenyl). Infants can be breastfed and receive nonprotein caloric supplement. The advantage of human milk is not only

dietary but the infection protection and immune protective qualities. An essential amino acid formula is available for those not breastfeeding.

There are many other variations of these enzyme deficiency diseases. Without treatment, they all lead to deterioration, mental retardation, and often organ failure, especially liver failure.<sup>155</sup> The National Organization for Rare Disorders Inc. (NORD) provides information for professionals, the lay public, and support groups regarding more than 1000 rare diseases. It lobbies for development of specific treatments (orphan drugs). (Specific treatment information is available at their website, <http://www.rarediseases.org>.)

## CYSTIC FIBROSIS

Cystic fibrosis is an autosome recessive disease caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. The CFTR protein is in the epithelia of tissues including lung, sweat glands, pancreas, and GI tract.

Screening tests for cystic fibrosis (CF) have been initiated in many state-mandated metabolic screening programs for newborns, so a greater number will be identified early. Meconium plug, especially large plugs and full-blown meconium ileus, have a high correlation with pancreatic enzyme deficiency and CF. As clinicians are alerted to meconium plugs, early tests for CF can be carried out and management adjusted. Breastfeeding is optimal not only for the nutrition but for the presence of enzymes to facilitate digestion and absorption of nutrients. Because infection is a significant morbidity in these children, the infection protection properties of human milk make a critical impact. A study of infants exclusively breastfed or formula fed showed that breastfeeding does not compromise growth and is associated with fewer infections and respiratory problems in infants with CF.<sup>79</sup>

The first symptom in infants with CF is often failure to thrive. If an infant is breastfed, the mother may be forced to wean, yet the infant feeds even less well and has no weight gain on formula. Infants do better if placed back on the breast. Pumping to increase the mother's milk supply will help the child's hunger. In a study of CF centers, 77% recommended breastfeeding either alone or with pancreatic enzyme supplements.<sup>93</sup> The recommended breastfeeding duration was 3 to 6 months by 43% of the centers (Tables 14-1–14-3A and 14-3B). If supplementation is required, hydrolyzed formula is recommended. Generic and name-brand enzymes are not biologically equal, and some formulas were more frequently associated with greasy stools and abdominal cramping. Use of enzymes may be a way to improve tolerance and weight gain

in these special breastfed infants rather than weaning to formula.<sup>28</sup> Prescribing pancreatic enzymes for a mother while breastfeeding, as described earlier, is also a consideration.<sup>63</sup>

## ALPHA<sub>1</sub>-ANTITRYPSIN DEFICIENCY

Alpha<sub>1</sub>-antitrypsin is a serum protease inhibitor that inactivates a number of proteases. More than 24 genetic variants of this disease are designated B through Z, with the M variant being most

common. Children with  $\alpha_1$ -antitrypsin deficiency are at increased risk for liver disease, which occurs most often during infancy and often progresses to cirrhosis and death. Udall et al.<sup>147</sup> investigated the relationship between early feedings and the onset of liver disease. Severe liver disease was present in eight (40%) of the bottle-fed and one (8%) of the breastfed infants (breastfed for only 5 weeks). Of the 32 infants, 24 were still alive at the end of the study; 12 had been breastfed and 12 bottle fed during their first month of life. All eight of the deceased children had been bottle fed; small-for-gestational-age (SGA) and preterm infants had been excluded from the study so that all infants were equally stable at birth and capable of breastfeeding. A bottle-fed infant was seven times more likely to develop liver disease.

With the increasing early diagnosis of  $\alpha_1$ -antitrypsin deficiency, encouraging a mother to breastfeed if her infant is affected would appear to have a significant impact on reducing the chance of long-range liver disease in her infant.

## ACRODERMATITIS ENTEROPATHICA (DANBOLT-CLOSS SYNDROME)

Acrodermatitis enteropathica is a rare and unique disease in which feeding an infant with human milk may be lifesaving. It is an autosomal recessive disorder with an onset as early as 3 weeks old.<sup>132</sup> It is inherited as an autosomal recessive trait and is characterized by a symmetric rash around the mouth, genitalia, and periphery of the extremities. The rash is an acute vesicobullous and eczematous eruption often secondarily infected with *C. albicans*. It may be seen by the third week of life or not until late in infancy and has been associated with weaning from the breast. Failure to thrive, hair loss, irritability, and chronic severe intractable diarrhea are often life threatening. The disease has been associated with extremely low plasma zinc levels. Oral zinc sulfate has produced remission of the syndrome. Zinc deficiency was seen frequently in premature infants on peripheral alimentation until zinc was added to the solution.

Human milk contains less zinc than does bovine milk, with zinc concentrations of both decreasing throughout lactation. Eckert et al.<sup>47</sup> studied the zinc binding in human and cow milk and noted that the low-molecular-weight binding ligand isolated from human milk may enhance absorption of zinc in these patients. Gel chromatography indicated that most of the zinc in cow milk was associated with high-molecular-weight fractions, whereas zinc in human milk was associated with low-molecular-weight fractions. The copper/zinc ratio may also be of significance because the ratio is lower in cow milk.

The zinc-binding ligand from human milk was further identified as prostaglandin E by chromatography, ultrafiltration, and infrared spectroscopy by Evans and Johnson.<sup>51</sup> Patients also have low arachidonic acid levels. Arachidonic acid is a precursor of prostaglandin. The efficacy of human milk in the treatment of acrodermatitis enteropathica results from the presence of the zinc-prostaglandin complex. The primary deficiency in an infant is an inability to absorb zinc except in this complex form.

The clinical significance of the relationship of human milk to onset of the disease and its treatment is in developing lactation in the mother of such an infant, rare as the disease may be. Delayed lactation or relactation is possible and should be offered as an option to the mother of such an infant (see Chapter 19).

Several reports of isolated cases of zinc deficiency during breastfeeding have appeared in the literature.<sup>2,3</sup> In some cases, zinc levels in the milk were low; in others, they were not measured.<sup>158</sup> One child had a classic "zinc-deficient" rash that

responded to oral zinc therapy. One should keep in mind that any deficiency is possible and consider intake deficiency when symptoms occur in a breastfed infant. The basic defect is presumed to be related to GI malabsorption of zinc.

The treatment of choice is oral administration of zinc in the sulfate or gluconate form. It is usually well tolerated, safe, inexpensive, effective, and expedient. When zinc deficiency occurs in a breastfed infant, the possibility of zinc deficiency in the milk, although a rare disorder, should be considered.<sup>132</sup> Treating the mother would be the appropriate therapy in such a case.

Premature infants have a negative zinc balance associated with inadequate mineral stores and high requirement associated with rapid growth.<sup>35</sup> Transient zinc deficiency in breastfed infants has been described as manifest by the classic zinc deficiency rash and was treated by oral zinc to the infant because milk levels are normal in the mother.

The regulation of iron, zinc, and copper in breast milk and the transport of these minerals across the mammary gland epithelium is poorly understood. Milk values at 9 months postpartum were not associated with maternal mineral status.<sup>45</sup> This suggests an active transport mechanism according to the investigators.<sup>45</sup> Milk zinc levels increase at weaning time while iron levels decrease.

## NEUROLOGICALLY IMPAIRED INFANTS

In addition to infants who have been neurologically impaired by perinatal hypoxia or asphyxia and low Apgars, a rare infant may have an inherited neurologic problem as in a trisomy or a congenital abnormality such as spina bifida. These infants can be breastfed in most cases but it requires patience and perseverance. Holding the infant in a flexed position is an essential element of breastfeeding. A sling works well.

Down syndrome is one of the more common syndromes, occurring in 1 of 800 to 1000 births. Hypotonia is a major feature that, along with small mouth and large tongue, make breastfeeding a challenge. At first, the infant may quickly drift off to sleep at the breast and weight gain is slow. The mother learns to hold her breast in place as the infant's grasp is not strong enough to overcome gravity. The sling works also to hold the infant in place and free both the mother's hands to hold both the breast and infant jaw.

When the suckling is weak initially, mother should pump between feedings to stimulate production of milk. If supplements are required, it is best to provide them with a Lact-Aid or a cup as the infant with Down syndrome is easily confused.

## DOWN SYNDROME

Infants with Down syndrome or other trisomies may be difficult to feed. When they are breastfed, mothers need patience to teach the infants to suck with sufficient vigor to initiate the let-down reflex and to stimulate adequate production of milk. Using manual expression to start flow and holding the breast firmly for the infant so that the nipple does not drop out of the mouth when the infant stops sucking will assist the process.

Initially however, an infant with Down syndrome may have surprisingly good tone and may even suck well at the breast, only to develop problems after mother and infant have been discharged home. Providing support for the head, the jaw, and the general body hypotonia will require considerable coordination by the mother. Propping the baby firmly with a pillow in the mother's lap or supporting the infant in a sling frees a much-needed hand for steadyng the jaw and breast (see [Figure 14-2](#)).<sup>103</sup>

A nurse clinician in the hospital who is knowledgeable and experienced in dealing with neurologically impaired infants should be available to the parents. The initial goals for the mother-infant pair are developing confidence in handling the infant, adjusting to the infant's problem, and dealing with the parental grief and sense of loss—loss of the normal infant that was expected. If the mother has breastfed other children, the emphasis on breastfeeding modifications are more successful, and milk supply usually responds to manual expression and pumping. Initiating sufficient stimulus to the breast to increase milk production is critical in the first few days to induce good prolactin response, especially in primiparas. Renting an electric breast pump is a good investment, justifiable for reimbursement from health insurance by physician prescription.

With ultrasound and amniocentesis, the diagnosis is often known before birth so that the family can be prepared. In developing a discharge plan for an infant with Down syndrome, a pediatrician will need to coordinate a team to avoid the fragmented care that develops with a multiproblem situation, which may require the consultation of a geneticist, genetic counselor, cardiologist, and other medical experts to deal with the problems. Ideally a pediatrician and an office nurse practitioner can provide the additional support and counsel necessary. Many families prefer to leave the hospital early to retreat to the comfort and privacy of their home and the health care provider they selected. Home visits by the pediatrician's staff can provide the necessary monitoring of weight gain and nutrition and counseling by someone capable of handling all the problems that arise,

including breastfeeding. No referrals should be made without the pediatrician's knowledge and agreement. The pediatrician or family physician has the advantage of knowing both the family and the child.

In a study of 59 breastfed infants with Down syndrome, Aumonier and Cunningham<sup>14</sup> reported that 31 had no sucking difficulty, 12 were successfully nursing within a week, and 16 required tube feeding initially, which was associated with other medical problems, including low birth weight (LBW), cardiac lesions, and jaundice. Hyperbilirubinemia is common in trisomy and was seen in 49% of the infants in this study. Eighteen babies had multiple medical conditions, and 11 of them sucked poorly. The authors<sup>14</sup> point out that the initial sucking ability of the infants did not appear to be a major cause for nonmaintenance of breastfeeding; 10 of the 13 mothers who discontinued breastfeeding cited insufficient milk as a contributing cause, which might have been prevented by early pumping of the breasts between feedings. With amniocentesis, genetic testing, and screening in older mothers (older than 35 years), many are diagnosed prenatally. Parents are then partly prepared before birth.

The birth of an infant with a major genetic abnormality is a shock, even to the strongest parents. If the mother wants to breastfeed, she should be offered all the encouragement and support necessary. Usually she needs to talk with someone to express her anguish about the infant, not the feeding per se. A sympathetic nurse practitioner in the pediatric office can be invaluable in providing support and the expertise to help with the various management problems. If the mother chooses not to breastfeed, appropriate support can also be provided without disrupting treatment continuity.

It is especially important that these infants be breastfed if possible because they are particularly prone to infection, especially otitis media. Before the advent of antibiotics, they often died of overwhelming infection and rarely survived past 20 years of age. These infants and most other infants with developmental disorders do better with stimulation and affection, so the body contact and communication while at the breast are especially important. Those who have associated cardiac lesions not only can suckle, swallow, and breathe with less effort at the breast, but also can receive a fluid more physiologic for their needs. Breastfed or bottle fed, these infants gain poorly; thus switching to a bottle does not solve the problem. The recommendation that children with Down syndrome receive extra vitamins was tested in a controlled study in children 5 to 13 years of age, and no sustained improvement in the children's appearance, growth, behavior, or development was seen with added vitamins.<sup>20</sup>

Growth charts from birth to 18 years illustrate the deficient growth through the growing periods. In infancy they fall behind, so this observation should not be used to discontinue breastfeeding. Breastfed infants remain healthier. Children with Down syndrome are usually overweight throughout life, beginning in infancy.<sup>38</sup>

Down syndrome is a lifelong condition. Having a support system is important for a family. Support groups of other families in the community serve as vital peer support.

## HYPOTHYROIDISM

Bode et al.<sup>25</sup> reported that an infant with congenital cretinism was spared the severe effects of the disease because he was breastfed. This was attributed to significant quantities of thyroid hormone in the milk. In a prospective study of 12 cases of hypothyroidism in breastfed infants, however, no protective effect against the disease was found, nor was the onset of the disease delayed. Anthropometric measurements, biochemical values, and psychologic testing at 1 year of age did not differ from those in the 33 bottle-fed hypothyroid infants. Abbassi and Steinour<sup>1</sup> also reported successful diagnosis of congenital hypothyroidism in four breastfed neonates.

Sack et al.<sup>127</sup> measured thyroxine ( $T_4$ ) concentrations in human milk and found it to be present in significant amounts. Varma et al.<sup>149</sup> studied  $T_4$ , triiodothyronine ( $T_3$ ), and reverse  $T_3$  concentrations in human milk in 77 healthy euthyroid mothers from the day of delivery to 148 days postpartum. From their data, they calculated that if infants received 900 to 1200 mL of milk per day, they would receive 2.1 to 2.6 mg of  $T_4$  per day, based on 238.1 ng/dL of milk after the first week. This amount of  $T_4$  is much less than the recommended dose for the treatment of hypothyroidism (18.8 to 25 mg/day of levo- $T_3$ ).  $T_4$  was essentially immeasurable in the milk sampled. In another study, however, comparing 22 breastfed and 25 formula-fed infants who were 2 to 3 weeks old, the levels of  $T_3$  and  $T_4$  were significantly higher in the breastfed infants.<sup>62</sup> No definite relationship between the levels of  $T_3$  and reverse  $T_3$  could be found.

A 6-week-old girl was diagnosed to have congenital hypothyroidism by routine neonatal screening when  $T_4$  was reported at 3 mg/dL (normal greater than 7 mg/dL).<sup>40</sup> The mother gave a history of multiple applications of povidone-iodine during pregnancy and continuing during lactation. Further testing revealed thyroid-stimulating hormone levels of 0.9 mU/mL (normal 0.8 to 5  $\mu$ M/L). Iodine treatment was stopped and breastfeeding continued

while treatment of thyroid replacement was begun. At 1 year, growth and development were normal. It is, therefore, suggested that neonatal screening for thyroid disease may be even more urgent if the clinical symptoms are apt to be masked in a breastfed infant. No contraindication exists to breastfeeding when the infant is hypothyroid, and it would be beneficial.<sup>95</sup> Appropriate therapy should also be instituted promptly. Mandatory screening for hypothyroidism is available to newborns in developed countries. Many infants that screen positive do not have at birth the characteristic signs and symptoms associated with cretinism, but therapy is just as urgent. Breastfeeding is ideal for these infants as well.

## ADRENAL HYPERPLASIA

In an analysis of 32 infants with salt-losing congenital adrenal hyperplasia who were in adrenal crisis, eight had been breastfed, five had been breastfed with formula supplements, and 19 had been formula fed. Infants who were breastfed were admitted to the hospital later than the formula-fed infants, although the breastfed infants had lower serum sodium levels on admission. The breastfed infants did not vomit and remained stable longer, although they had severe failure to thrive.<sup>39</sup> Weaning initiated vomiting and precipitated crises in the breastfed infants. The authors suggest that congenital adrenal hyperplasia should be considered in a breastfed infant with failure to thrive. Electrolytes should be obtained before weaning to make the diagnosis and avoid precipitating a crisis by weaning. Then breastfeeding can continue as treatment is initiated.

## HYPERNATREMIC DEHYDRATION ASSOCIATED WITH BREASTFEEDING

The consequences of inadequate intake of breast milk range from hyperbilirubinemia, infant hunger, and low weight gain to life-threatening dehydration and starvation. The number of reported cases of hypernatremic dehydration has significantly increased because more infants have been breastfed and more infants are managed outside the hospital by lactation experts without pediatric oversight.<sup>136</sup> Term breastfed infants with serum sodium levels of 150 mEq/L or higher were found to be 4.1% of the 4136 term infants hospitalized and reviewed by Unal et al.<sup>148</sup> in the Children's Research Hospital in Ankara, Turkey. These children had lost 15.9% birth weight (range 5.4% to 32.7%). The presenting symptom in 47.3% of cases was hyperbilirubinemia and poor suck in 29.6%. Other complications

included acute renal failure in 82.8%, elevated liver enzymes in 20.7%, disseminated intracranial hemorrhage in 3.6%, and thromboses in 1.8%. Ten patients developed seizures and two died. In another study, 60 term infants were readmitted to the hospital with ketoacidosis with plasma serum sodium levels greater than 145 mmol/L. The hospital had recently upgraded its newborn discharge policy to include weights by trained midwives at 72 to 96 hours and at 7 to 10 days of age. Voiding, stooling, and breastfeeding were also checked, and infants who lost more than 10% of birth weight were sent to the hospital. The incidence of hypernatremia with plasma serum sodium levels greater than 145 mmol/L was 7.4 and 5.0 per 10,000 live births before and after the new policy, respectively, but the percentages of cases with plasma serum sodium levels greater than 150 mmol/L was 56.5% versus 18.9%. It was concluded that weighing and lactation support resulted in less dehydration and less severe hypernatremia and better breastfeeding rates.<sup>78</sup> Hypernatremic dehydration in neonates due to inadequate breastfeeding is serious, a well-recognized cause of permanent neurologic abnormality, and life threatening. Sodium levels in breast milk vary, and highly elevated levels impair lactogenesis and cause failure to breastfeed. The etiology can be associated initially with poor milk production. As milk decreases in volume in the normal weaning process the sodium level increases. With lactation failure the sodium level is usually elevated. When levels in the infant reach 145 mEq/L urgent therapy is required. Serum osmolarity is also elevated, urine output is low, and the specific gravity elevated. Sodium levels in early milk are 300 to 400 mEq/L, and as volume increases the levels drop to 120 to 250 mEq/L. The problem is seen more commonly in primiparas. Loss of weight of over 10% deserves evaluation. It is recommended that these dyads be seen by the pediatrician within 2 days of hospital discharge. Treatment not only includes aggressive rehydration of the infant but skilled intense establishment of a full milk supply. Follow-up of infants with proper medical care by pediatricians is essential.

### **NEONATAL BREASTS AND NIPPLE DISCHARGE**

A newborn may have swelling of the breasts for the first few days of life, whether male or female; this is unrelated to being breastfed. If the infant's breast is squeezed, milk can be obtained. This has been called *witch's milk*. The constituents of neonatal milk were studied in the milk of 18 normal newborns and infants with sepsis, adrenal hyperplasia, CF, and meconium ileus.<sup>22</sup> Electrolyte values were similar

to those in adult women in all infants except one with mastitis in whom the sodium level was elevated and the potassium decreased. Total protein and lactose were also similar to those in adult women. The fat was different, increasing with postnatal age and being higher in short-chain fatty acids. It was indeed true milk.

Two infants, one female and one male, were reported to have bilateral bloody discharge from the nipples at 6 weeks of age. Cultures and smears were unrevealing.<sup>22</sup> No biopsy was done. The female infant's swelling and discharge cleared after 5 months; the male infant's was present at 10 weeks when he was lost to follow-up. Galactorrhea or persistent neonatal milk has been reported in association with neonatal hyperthyroidism. In another report, a 21-day-old female infant was seen because of a goiter and galactorrhea. The infant had 50% 24-hour<sup>105</sup> I uptake and elevated prolactin levels, which slowly responded to Lugol solution treatment for hyperthyroidism.<sup>94</sup>

### **NEONATAL MASTITIS**

Neonatal mastitis occurs infrequently, although it was a common event in the 1940s and 1950s, when staphylococcal disease was rampant in nurseries. It occurs in full-term infants 1 to 5 weeks of age and in as many girls as boys, usually unilaterally.<sup>151</sup> It is unrelated to maternal mastitis and usually occurs in bottle-fed infants. Before IV antibiotic therapy, surgical incision and drainage were common. Prognosis for cure is excellent. In recent years the rare cases that occur are seen in conjunction with manipulation of the neonatal breast to express the natural secretion when the newborn breast is engorged (*witch's milk*). In some primitive cultures expressing milk from swollen newborn breasts is done and often leads to mastitis.

### **HYPERBILIRUBINEMIA AND JAUNDICE**

Jaundice in newborns has become a source of considerable misinformation, confusion, and anxiety. Incidence of jaundice is higher in full-term infants than a decade ago. From 1994 to 2002 11.9% of newborns were hospitalized for hyperbilirubinemia; rates rose to 20.0% in 2003 to 2005. The incidence of kernicterus dropped from 5.8 per 100,000 live births to 1.6 per 100,000 live births as a result of aggressive preventive measures in these years according to Burke et al.<sup>27</sup> More physicians are paying attention to the development of hyperbilirubinemia in newborns. These two factors serve to increase the frequency of the question of the role of breastfeeding in the development of hyperbilirubinemia.

Some of the confusion and inconsistencies associated with the management can be attributed to indecisive terminology. This discussion attempts to clarify the issues and outlines the causes and effects of hyperbilirubinemia.

## Why the Concern about Jaundice?

Bilirubin is a cell toxin, as can be demonstrated dramatically by adding a little bilirubin to a tissue culture, which will be quickly destroyed. Excessive bilirubin causes concern because when free, unbound, unconjugated bilirubin is in the system, it can be deposited in various tissues, ultimately causing necrosis of the cells. The brain and brain cells, if destroyed by bilirubin deposits, do not regenerate.<sup>64</sup> The full-blown end result is bilirubin encephalopathy, or kernicterus, which is essentially a pathologic diagnosis that depends on identifying the yellow pigmentation and necrosis in the brain, especially in the basal ganglion, hippocampal cortex, and subthalamic nuclei. At autopsy, 50% of infants with kernicterus also have other lesions caused by bilirubin toxicity. Necrosis of renal tubular cells, intestinal mucosa, or pancreatic cells or associated GI hemorrhage may be seen.

The classic clinical manifestations of bilirubin encephalopathy are characterized by progressive lethargy, rigidity, opisthotonus, high-pitched cry, fever, and convulsions. The mortality rate is 50%. Survivors usually have choreoathetoid cerebral palsy, asymmetric spasticity, paresis of upward gaze, high-frequency deafness, and mental retardation.<sup>42</sup> Premature infants are particularly susceptible to bilirubin-related brain damage and may have kernicterus at autopsy without the typical clinical syndrome. A significant correlation exists between level of bilirubin and hearing impairment in newborns when other risk factors are present. Classic full-blown kernicterus rarely occurs today, but mild effects on the brain may be manifested clinically in later life in the form of lack of coordination, hypertonicity, and mental retardation or learning disabilities, symptoms sometimes collectively called minimal brain damage.<sup>64</sup> Bilirubin encephalopathy is the appropriate term for conditions in which bilirubin is thought to be the cause of brain toxicity.

## Mechanism of Bilirubin Production in the Neonate

A normal full-term infant has a hematocrit in utero of 50% to 65%. Because of the low oxygen tension delivered to the fetus via the placenta, the fetus requires more hemoglobin (Hb) to carry the oxygen. As soon as an infant is born and begins to

breathe room air, the need is gone. The infant bone marrow does not make more cells, and excess cells are destroyed and not replaced. The life span of a fetal red blood cell (RBC) is 70 to 90 days instead of an adult's 120 days. Normally, when RBCs are destroyed, the released Hb is broken down to heme in the reticuloendothelial system. The reticuloendothelial system cells contain a microsomal enzyme, heme oxygenase, which is capable of oxidizing the  $\alpha$ -methene bridge carbon of the heme molecule after the loss of the iron and the globin to form biliverdin, a green pigment. Biliverdin is water soluble and is rapidly degraded to bilirubin. A gram of hemoglobin will produce 34 mg of bilirubin.

The reticuloendothelial cell releases the bilirubin into the circulation, where it is rapidly bound to albumin. Indirect bilirubin is essentially insoluble (less than 0.01 mg% soluble) and is a yellow pigment. Adult albumin can bind two molecules of bilirubin, the first more tightly than the second. Newborn albumin has reduced molar binding capacities that vary with maturity and other factors, such as pH, infection, and hypoglycemia.

Unconjugated bilirubin is removed from the circulation by the hepatocyte, which converts it by conjugation of each molecule of bilirubin with two molecules of glucuronic acid into direct bilirubin. Direct bilirubin is water soluble and is excreted via the bile to the stools. The balance between hepatic cell uptake of bilirubin and the rate of bilirubin production determines the serum unconjugated bilirubin concentration. Laboratory measurements include both bound and unbound indirect bilirubin. The amount of unconjugated bilirubin that exceeds the binding capacity of an infant's albumen is the unbound unconjugated bilirubin available to deposit in the brain.

## Evaluation and Management

Normal full-term newborns have serial bilirubin tests to determine the range of values. The cord bilirubin level may be as high as 2 mg% and rise in the first 72 hours to 5 to 6 mg%, which is barely in the visible range, and gradually taper off, assuming normal adult levels of 1 mg% after 10 days. Less than 50% of normal infants are visibly jaundiced in the first week of life. This would suggest that visible jaundice is idiopathic, not physiologic. The level of bilirubin that is acceptable depends on a number of factors. In some premature infants, even bilirubin levels under 10 mg/dL may be of concern because of the limited albumen binding sites in premature infants.

**Factors That Influence Significance.** For a given level of bilirubin, several associated factors may

need to be considered. If an infant has acidosis, anoxia, asphyxia, hypothermia, hypoglycemia, or infection, even lower levels of bilirubin may have significant risk for causing deposition of bilirubin in the brain cells. The most important factor is prematurity, which affects liver and brain metabolism and albumin binding sites. An increased incidence of elevated bilirubin levels occurs in certain races and populations. Asian populations, including Chinese, Japanese, and Korean, and Native Americans may have bilirubin levels averaging 10 to 14 mg%. A higher incidence of autopsy-identified kernicterus also is seen in these populations. Glucose-6-phosphate dehydrogenase deficiency, a genetic disorder, is also common in these groups. Infants who carry the 211 and 388 variants, respectively, in the *UGT1A1* and *OATP2* genes and are breastfed were found to be at high risk to develop severe hyperbilirubinemia according to Huang et al.,<sup>71</sup> who investigated infants born in Cathay Hospital in Taipei, Taiwan, where glucose-6-phosphate dehydrogenase is prevalent. They also noted that glucose-6-phosphate dehydrogenase is the most common genetic defect and urge more frequent screening. Infants with these genetic variants who were not breastfed had hyperbilirubinemia that was less responsive to phototherapy; thus it is recommended that breastfeeding not be discontinued.<sup>71</sup>

## Determination of Cause of Jaundice

Following the chain of events from the destruction of RBCs in newborns through the final excretion of conjugated bilirubin in the stools simplifies understanding the cause of a specific case of jaundice. Causes include (1) increased destruction of RBCs, (2) decreased conjugation in the glucuronidase system, (3) decreased albumin binding, and (4) increased reabsorption from the GI tract and decreased excretion. To be excreted from the body, unconjugated bilirubin has to be conjugated with glucuronic acid in the hepatocyte, which becomes water-soluble bilirubin glucuronide. The enzyme involved is a specific hepatic enzyme isoform (1A1) belonging to the uridine diphosphoglucuronate glucuronosyltransferase (UGT) family of enzymes. Much has been learned about these enzymes and their relationship to bilirubin metabolism.<sup>83</sup> UGTs catalyze the conjugation of not only bilirubin but steroids, bile acids, drugs, and other xenobiotics. The two separate families of genes, *UGT1* and *UGT2*, have different actions. Gilbert syndrome, an uncommon genetic anemia associated with persistent hyperbilirubinemia in neonates, is associated with a mutation in the coding area of the *UGT1A1* gene. Similar genetic variations are present in Crigler-Najjar syndrome. These

genetic variations are probably the cause of most persistent hyperbilirubinemia.

Ethnic background, risk factors, previous infants with hyperbilirubinemia, and family history of anemia and jaundice are important to the correct diagnosis and management, the preservation of breastfeeding, and the safety of the infant.

When albumin binding is altered, the visibility of the jaundice is not affected. The bilirubin level may not be very high, but the substance is not bound to albumin and is available at lower levels to pass into the brain cells.<sup>99</sup> Premature infants have much lower albumin levels and thus have fewer binding sites. Drugs that also bind to albumin (e.g., aspirin, sulfadiazine) compete for the same binding sites. A lower level of bilirubin puts infants who have these medications in their system at risk because the bilirubin is unbound and available to enter tissue cells, including brain cells.

Reabsorption of bilirubin from stool in the GI tract can increase the bilirubin level. This occurs when the conjugated bilirubin that was excreted into the colon and the stool is slow to pass. It is unconjugated by the action of intestinal bacteria and reabsorbed, which happens when stools are decreased or slowed in passage. Poor feedings, pyloric stenosis, and other forms of intestinal obstruction are common causes of this type of jaundice. Some bacteria are more likely than others to unconjugate conjugated bilirubin.

Sepsis, on the other hand, was not found in more than 300 infants readmitted for hyperbilirubinemia while healthy and breastfeeding. Lower total bilirubin and direct bilirubin levels greater than 2.0 mg% in a sick baby have a high correlation with sepsis.

**Safe Levels of Bilirubin.** Safe levels of bilirubin depend on a number of factors, including acidosis, hypoxia or anoxia, and sepsis. A handy rule of thumb is the correlation of birth weight in a premature infant and the indirect bilirubin level, using a value 2 to 3 mg lower when an infant has multiple problems. The risk for elevated bilirubin is related to the availability of albumin to bind the indirect bilirubin and prevent it from entering the brain cells. The amount of albumin is related to the degree of prematurity, and thus the rule of thumb is based on birth weight and/or gestational age. When an infant is sick, fewer albumin-binding sites are available, and the bilirubin level of concern is even lower.

Any value of 20 mg/dL or greater warrants consideration of aggressive treatment. Jaundice visible when an infant is younger than 24 hours of age is of special concern because it is usually associated with an incompatibility or infection. Rapidly rising bilirubin levels are also of concern, and a 0.5-mg/dL rise per hour is an indication for treatment.

The AAP has published a practice parameter for the management of hyperbilirubinemia in healthy term newborns.<sup>139</sup> Term infants who are visibly jaundiced at or before 24 hours of life are not considered healthy and require a diagnostic work up regardless of feeding method.

The AAP also addresses jaundice associated with breastfeeding in healthy term infants. The AAP discourages the interruption of breastfeeding in healthy term newborns and encourages continued and frequent breastfeeding (at least 8 to 10 times every 24 hours). Supplementing nursing with water or dextrose water does not lower the bilirubin level in jaundiced, healthy, breastfeeding infants.<sup>134</sup>

**Early Jaundice while Breastfeeding.** Many studies of bilirubin levels in normal newborn nurseries have been conducted that look at method of feeding. Unfortunately, few have detailed frequency of feeds, supplementation, and stool pattern.<sup>98</sup> A review summarizing results in 13 studies covering more than 20,000 infants showed a relationship between breastfeeding and jaundice. A pooled analysis of 12 studies showed 514 of 3997 breastfed infants to have total serum bilirubin (TSB) levels of 12 mg/dL or higher versus 172 of 4255 bottle-fed infants. In a smaller group of studies, 54 of 2655 breastfed infants had bilirubin levels of 15 mg/dL or greater versus 10 of 3002 bottle-fed infants. Eleven of 13 studies reported that breastfed infants had higher mean bilirubin levels. In a series of more than 12,000 infants, the risk for a breastfed infant becoming jaundiced was 1:8. The risk for becoming jaundiced for a premature infant was 3:6; for an infant of Asian race, 3:56; and with prolonged rupture of membranes, 1:91.<sup>139</sup>

**Relationship of Bilirubin Level to Passage of Stools.** There are 450 mg of bilirubin in the intestinal tract meconium of an average newborn infant. Passing this meconium is critical to avoid the deconjugation and reabsorption of unconjugated bilirubin from the gut into the serum. Failure to pass meconium is correlated with elevated serum bilirubin. Time of first stool is also correlated with level of serum bilirubin. Bottle-fed infants excrete more stool (82 g) and more bilirubin (23.8 mg) in the first 3 days than breastfed infants, who excreted 58 g of stool and 15.7 mg bilirubin. The serum bilirubin levels were 6.8 mg/dL in bottle-fed and 9.5 mg/dL in breastfed infants. Furthermore, when the breastfed infants excreted more stools and more bilirubin, they had lower bilirubin levels. This relationship has been confirmed in multiple studies.

## Clinical Risk Factors in Hyperbilirubinemia

Clinical examination by visual assessment of jaundice in newborns is not reliable in a study comparing visual estimates with laboratory values by Moyer et al.<sup>111</sup> They suggested bilirubin testing should be based on risk factors. Clinical risk factors significantly improve prediction of hyperbilirubinemia compared with the use of early total bilirubin levels, as reported by Newman et al.<sup>114</sup> based on a study of almost 54,000 infants older than 36-weeks' gestational age and at least 2000 g birth weight. From this group, 207 cases were found with elevated bilirubins drawn before 48-hour discharge. The authors found the risk index was the best predictor of elevated bilirubin (Table 14-4). Clearly, prematurity carries the greatest risk. The TSB before 48 hours was an accurate predictor of reaching a bilirubin of 20 mg/dL (Figure 14-5).

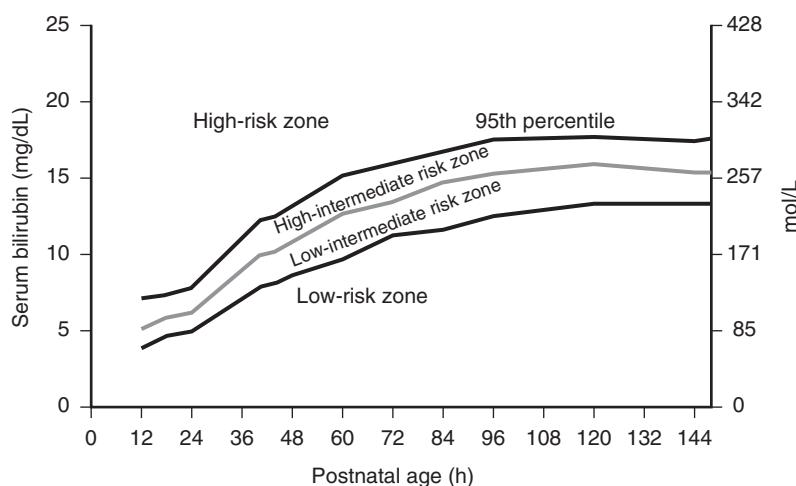

When the number of feedings at the breast in the first 3 days of life is related to bilirubin levels, there is a significant relationship. The greater the number of breastfeedings, the lower the bilirubin. Infants with more than eight feedings per day were not significantly jaundiced. Water and dextrose supplements were associated with higher bilirubin levels. Sugar-water intake in the first 3 days negatively affects the volume of breast milk available on the fourth day. The infants with high glucose intake have higher bilirubin levels.

**Caloric Deprivation and Starvation.** Elevated bilirubin does not impede sucking ability. Reduced caloric intake or starvation has been associated with hyperbilirubinemia in adult humans and in many animals. The association between starvation and early

**TABLE 14-4** Modified Risk Index for Predicting Hyperbilirubinemia in Infants Who Do Not Have Early Jaundice

Variable	Points
Exclusive breastfeeding at hospital discharge	6

Modified from Newman TB, Liljestrand P, Escobar GJ: Combining clinical risk factors with serum bilirubin levels to predict hyperbilirubinemia in newborns, *Arch Pediatr Adolesc Med* 159:113, 2005.

**Figure 14-5.** Nomogram for designation of risk in 2840 well newborns of at least 36 weeks' gestational age with birth weight of 2000 g or greater or of at least 35 weeks' gestational age with birth weight of 2500 g or greater based on the hour-specific serum bilirubin values. The serum bilirubin level was obtained before discharge, and the zone in which the value fell predicted the likelihood of a subsequent bilirubin level exceeding the 95th percentile (high-risk zone). (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.)

neonatal jaundice has been described. Gartner<sup>54</sup> has postulated that starvation may increase bilirubin production, shift bilirubin pools, reduce hepatic bilirubin uptake, diminish hepatic bilirubin conjugation, or increase enteric bilirubin reabsorption. Adequate caloric intake may simply diminish intestinal bilirubin absorption. Infants with intestinal obstruction (pyloric stenosis) at birth or in the early weeks of life are often jaundiced.

**Treatment of Early Hyperbilirubinemia.** Serum bilirubin levels in newborns and the relationship to breastfeeding were measured, and 8 of 10 infants with serum bilirubin greater than 12.9 mg/dL were breastfed.<sup>99</sup> It is the process of altered nourishment that is the cause of relative starvation. The amount of stress for a mother generated by separation from her infant for phototherapy was measured by urine cortisol levels and compared with levels in mothers who roomed-in with their jaundiced infants during phototherapy. The separated mothers were more stressed and were more likely to discontinue breastfeeding than those who remained with their infants.<sup>50</sup>

In a controlled trial of four interventions,<sup>114</sup> 125 of 1685 infants in the birth cohort whose bilirubin levels reached 17 mg/dL (291 mmol/L) were randomly assigned to treatment. The four interventions were (1) continue breastfeeding and observe; (2) discontinue breastfeeding and substitute formula; (3) discontinue breastfeeding, substitute formula, and use phototherapy; and (4) continue breastfeeding and use phototherapy. The bilirubin reached

20 mg/dL (342 mmol/L) in 24% of group 1, 19% of group 2, 3% of group 3, and 14% of group 4. Phototherapy clearly adds to the decline in bilirubin, and the authors<sup>114</sup> suggest that the parents can be offered the management of their choice. Newman and Maisels recommend that because jaundiced infants are rarely sick, the only laboratory work necessary is a blood type and Coombs test; only when jaundice is excessive should bilirubin levels be followed closely. Infants with incompatibilities should be treated aggressively.

An evaluation of the transcutaneous bilirubinometer demonstrated that it correlated well with TSBs done in the laboratory.<sup>97</sup> The correlation in black infants was not as close but levels erred on the high side so that underdiagnosing is not a risk. Multiple checks with the meter are easily done to establish trends so that a breastfed infant can be followed closely without painful sticks. Blood levels are essential if phototherapy is needed and after it is initiated.<sup>97</sup>

Hyperbilirubinemia results from unphysiologic management of breastfeeding, expressed largely through insufficient frequency of breastfeeding. To treat the actual cause, that is, failed breastfeeding or inadequate stooling or underfeeding, breastfeeding should be reviewed for frequency, length of sucking, and apparent supply of milk, adjusting the breastfeeding to improve any deficits. If stooling is the problem, an infant should be stimulated to stool. If starvation is the problem, the infant should receive additional calories (formula) while the milk supply is being increased by better breastfeeding techniques.

The same would apply to bottle-feeding jaundice (i.e., any infant with idiopathic jaundice who is being bottle fed and has a bilirubin level greater than 12.9 mg/dL). Stooling, frequency of feeds, and kilocalories would be improved. **Box 14-1** provides a management schema for preventing or treating jaundice in the breastfed infant. All infants must have the appropriate laboratory studies performed.<sup>98</sup>

Guidelines for the management of hyperbilirubinemia of a newborn who is at least 35 weeks' gestational age have been developed by the Subcommittee on Hyperbilirubinemia of the AAP (see **Box 14-1**).<sup>139</sup> The key elements of their recommendations appear in **Table 14-5**. The nomogram for designation of risk for jaundice is illustrated in **Figure 14-5**. Guidelines for phototherapies are illustrated in **Figure 14-6**.

The Academy of Breastfeeding Medicine developed a protocol for hyperbilirubinemia which is on its website: <http://www.AcademyofMedicine.com>. Jaundice in LVBW infants at less than 35 weeks' gestation also results from increased bilirubin production, decreased hepatic conjugation in an immature liver, and inadequate excretion via the stool. Hyperbilirubinemia in preterm infants is more prevalent, more severe, and more protracted. The risk for kernicterus is greater as well. Its management is the purview of a neonatologist.<sup>153</sup> In most cases, if human milk is provided it is maintained. Maisels et al.<sup>98</sup> add the following recommendations: management and follow-up plans should be based on gestational age, predischarge bilirubins, and risk factors for subsequent hyperbilirubinemia (**Box 14-2**). They begin with suggesting lactation evaluation and support for all breastfeeding mothers. They also recommend that timing of repeat bilirubin measurements after discharge depend on age at time of measurement and on degree the level is above the

#### **BOX 14-1. Management Outline for Early Jaundice while Breastfeeding**

1. Monitor all infants for initial stooling. Stimulate stool if no stool in 24 hours.
2. Initiate breastfeeding early and frequently. Frequent short feeding is more effective than infrequent prolonged feeding, although total time may be the same.
3. Discourage water, dextrose water, or formula supplements.
4. Monitor weight, voidings, and stooling in association with breastfeeding pattern.
5. When bilirubin level approaches 15 mg/dL, stimulate stooling, augment feeds, stimulate breast milk production with pumping, and, if this aggressive approach fails and bilirubin approaches 20 mg/dL, use phototherapy.

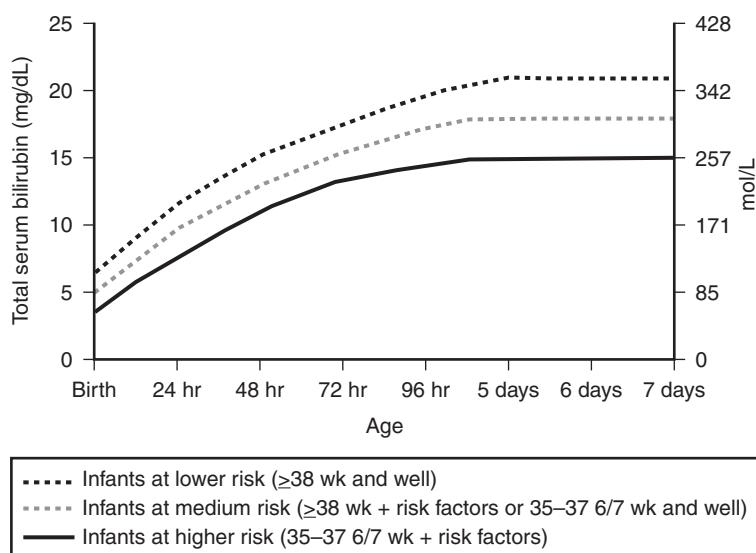

<b>TABLE 14-5</b>	Risk Factors for Development of Severe Hyperbilirubinemia in Infants of 35 Weeks' Gestation or Older (in Approximate Order of Importance)
<b>Major risk factors</b>	
Predischarge TSB or TcB level in the high-risk zone	
Jaundice observed in the first 24 hours	
Blood group incompatibility with positive direct antiglobulin test, other known hemolytic disease (e.g., glucose-6-phosphate dehydrogenase deficiency), elevated ETCOC	
Gestational age 35 to 36 weeks	
Previous sibling received phototherapy	
Cephalohematoma or significant bruising	
Exclusive breastfeeding, particularly if nursing is not going well and weight loss is excessive	
East Asian race*	
<b>Minor risk factors</b>	
Predischarge TSB or TcB level in the high intermediate-risk zone	
Gestational age 37 to 38 weeks	
Jaundice observed before discharge	
Previous sibling with jaundice	
Macrosomic infant of a mother with diabetes	
Maternal age 25 years or older	
Male sex	
<b>Decreased risk</b>	
(These factors are associated with decreased risk for significant jaundice, listed in order of decreasing importance.)	
TSB or TcB level in the low-risk zone	
Gestational age 41 weeks or more	
Exclusive bottle feeding	
Black race*	
Discharge from hospital after 72 hours	

ETCOC, End tidal carbon monoxide corrected for ambient air; TcB, transcutaneous bilirubin; TSB, total serum bilirubin.

\*Race as defined by mother's description.

From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.

95th percentile. Follow-up recommendations can be modified according to the level of risk. Infants should have a predischarge bilirubin, which has been the recommendation to improve the chances of preventing kernicterus. Universal predischarge bilirubin screening using TSB or transcutaneous bilirubin (TcB) measurements, which help to assess the risk of subsequent severe hyperbilirubinemia, is recommended. A more structured approach to management and follow-up according to the predischarge TSB/TcB, gestational age, and other risk factors for hyperbilirubinemia are essential.

- Use total bilirubin. Do not subtract direct reacting or conjugated bilirubin.
- Risk factors = isoimmune hemolytic disease, G6PD deficiency, asphyxia, significant lethargy, temperature instability, sepsis, acidosis, or albumin <3.0 g/dL (if measured).
- For well infants 35–37 6/7 wk can adjust TSB levels for intervention around the medium risk line. It is an option to intervene at lower TSB levels for infants closer to 35 wk and at higher TSB levels for those closer to 37 6/7 wk.
- It is an option to provide conventional phototherapy in hospital or at home at TSB levels 2–3 mg/dL (35–50 mmol/L) below those shown but home phototherapy should not be used in any infant with risk factors.

**Figure 14-6.** Guidelines for phototherapy in hospitalized infants of at least 35 weeks' gestation. Note: These guidelines are based on limited evidence and the levels shown are approximations. The guidelines refer to the use of intensive phototherapy, which should be used when the total serum bilirubin exceeds the line indicated for each category. Infants are designated as "higher risk" because of the potential negative effects of the conditions listed on albumin binding of bilirubin, the blood-brain barrier, and the susceptibility of the brain cells to damage by bilirubin. (From American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation, *Pediatrics* 114:297, 2004.)

### Kernicterus in Late Preterm Infants Cared for as Term Healthy Infants

Late prematurity (34 6/7 to 36 6/7 weeks' gestational age) has not been recognized as a risk factor for hazardous hyperbilirubinemia by practitioners according to Bhutani and Johnson,<sup>24</sup> who report cases of acute and chronic posticteric sequelae. Large-for-gestational-age and late preterm infants are disproportionately represented in the group with kernicterus. Unsuccessful and suboptimal lactation experience was the most frequent associated factor. The authors urge attention to early bilirubin values, additional risk factors, and the success of breastfeeding in these infants. These infants require close monitoring by the pediatrician.

**Breast Milk Jaundice.** Apart from the frequent but low level (usually less than 12 mg/dL) hyperbilirubinemia, breastfeeding rarely is associated with delayed but prolonged hyperbilirubinemia, which,

if unchecked, may exceed 20 mg/dL. This syndrome has been called breast milk jaundice, late-onset jaundice, and breast milk jaundice syndrome.<sup>54</sup> It occurs in less than 1 in 200 births; the numbers are imprecise because not all mothers breastfeed. This syndrome is associated with the milk of a particular mother and will occur with each pregnancy in varying degrees, depending on each infant's ability to conjugate bilirubin (i.e., a premature sibling might be more severely affected).<sup>54</sup> Early-onset jaundice is related to the process of breastfeeding, not the milk itself. It is essential to rule out other causes of prolonged or excessive jaundice, especially hemolytic disease, hypothyroidism, glucose-6-phosphate dehydrogenase deficiency, inherited hepatic glucuronyl transferase deficiency (Gilbert syndrome, etc.), and intestinal obstruction.

The pattern of this jaundice is distinctly different. Normally, idiopathic jaundice peaks on the third day and then begins to drop. Breast milk jaundice, however, becomes apparent or continues to

**BOX 14-2. Key Elements to Hyperbilirubinemia Management**

1. Promote and support successful breastfeeding.
2. Establish nursery protocols for the identification and evaluation of hyperbilirubinemia.
3. Measure the total serum bilirubin or transcutaneous bilirubin level in infants jaundiced in the first 24 hours.
4. Recognize that visual estimation of the degree of jaundice can lead to errors, particularly in darkly pigmented infants.
5. Interpret all bilirubin levels according to an infant's age in hours.
6. Recognize that infants born at less than 38 weeks' gestation, particularly those who are breastfed, are at higher risk for developing hyperbilirubinemia and require closer surveillance and monitoring.
7. Perform a systematic assessment on all infants before discharge for the risk of severe hyperbilirubinemia.
8. Provide parents with written and verbal information about newborn jaundice.
9. Provide appropriate follow-up based on the time of discharge and the risk assessment.
10. Treat newborns, when indicated, with phototherapy or exchange transfusion.

rise after the third day, and bilirubin levels may peak any time from the seventh to the tenth day, with untreated cases being reported to peak as late as the fifteenth day. Values have ranged from 10 to 27 mg/dL during this time. No correlation exists with weight loss or gain, and stools are normal.

The syndrome of breast milk jaundice was attributed by Arias et al.<sup>12</sup> to a substance in the milk of some mothers that inhibits the hepatic enzyme glucuronyl transferase, preventing the conjugation of bilirubin. The substance has been identified as 5 $\beta$ -pregnane-3 $\alpha$ ,20 $\alpha$ -diol, a breakdown product of progesterone and an isomer of pregnanediol that is not usually found in milk but occurs normally in 10% of the lactating population. Although this substance had also been isolated from the milk and serum of mothers whose infants were not jaundiced, this work has not been duplicated.

In a definitive study of breast milk  $\beta$ -glucuronidase, Wilson et al. examined 55 mother-infant pairs. No correlation was found between serum bilirubin levels and breast milk  $\beta$ -glucuronidase between days 3 and 6 postpartum.

The role of lipoprotein lipase and bile salt-stimulated lipase in breast milk jaundice continues under investigation. The role of free fatty acids and the possibility of abnormal lipases are unresolved. The undisputed cause of breast milk jaundice continues to elude investigators.

As in early jaundice associated with breastfeeding, jaundiced infants at 3 weeks do not produce more bilirubin than their unjaundiced breastfed peers or bottle-fed infants.

Diagnosis depends on circumstantial evidence, because no easy, rapid laboratory test exists. All other causes, including infection, should be ruled out in the usual manner and a thorough history taken, including medications and family history and ethnic background. If the mother has nursed other infants, were they jaundiced? Usually 70% of the previous children of a given mother whose infant has breast milk jaundice have been jaundiced. The difference may be related to the greater maturity of the liver of a given infant who then is able to handle the increased demands on the glucuronyl transferase system. Genetic variations in *UGTIA1* and *OATP2* genes may hold answers. To establish the diagnosis firmly, and this is necessary when the bilirubin level is greater than 16 mg/dL for more than 24 hours, a bilirubin reading should be obtained 2 hours after a breastfeeding and then breastfeeding discontinued for at least 12 hours.<sup>113</sup> The infant must be fed fluids and calories. The infant's mother should be assisted in pumping her breasts to maintain her supply. Even more urgent is providing the mother with a sympathetic explanation of the problem and the process. After at least 12 hours without mother's milk, the bilirubin level should be measured. If a significant drop of more than 2 mg/dL occurs, it is diagnostic. When the level is less than 15 mg/dL, the infant can be put to the breast. Bilirubin levels should be obtained to determine if the bilirubin rises again and, if so, how much. In most cases, in the time not breastfeeding, the infant's body equilibrates the levels sufficiently, so only a slight increase in bilirubin occurs on return to breastfeeding followed by a slow but steady drop. If that is the case, breastfeeding can continue. The bilirubin level should be checked at 10 to 14 days to be certain the bilirubin is truly clearing.

If the bilirubin has not dropped significantly after 12 hours without breast milk, the time off the breast should be extended to 18 to 24 hours, measuring bilirubin levels every 6 hours. If the bilirubin rises while the infant is off the breast, the cause of jaundice is clearly not the breast milk; breastfeeding should be resumed and other causes for the jaundice reevaluated.

**Phototherapy and Breast Milk Jaundice.** If the bilirubin is substantially greater than 20 mg/dL in a full-term infant (or proportionately lower in a preterm infant), it is important to lower the bilirubin promptly; thus phototherapy should be initiated as soon as the blood work is drawn (Figure 14-7). The relationship to breastfeeding can be established later. Often IV fluids are also necessary.

**Figure 14-7.** Phototherapy for a premature infant with two overhead banks of lights while lying on a fiberoptic blanket.

If one is attempting to establish the diagnosis of breast milk jaundice, phototherapy should not be used while breast milk is being discontinued. If establishing the diagnosis is not necessary (perhaps because of the same diagnosis in older siblings), phototherapy can be used to bring the values to a more acceptable range (i.e., less than 12 mg/dL). When phototherapy is discontinued, it is most important to establish that no rebound hyperbilirubinemia occurs. In addition, it is important to follow the infant at home after discharge through at least 14 days of life or longer if the values are not less than 12 mg/dL. It should not be assumed that the diagnosis is breast milk jaundice when breastfeeding has been stopped and phototherapy initiated simultaneously.

### Late Diagnosis of Breast Milk Jaundice

With the frequency of early discharge from the hospital, especially for families enjoying the birthing center concept, breastfed infants are often discharged before jaundice for any reason has developed. Because breast milk jaundice is likely to be delayed to the fourth or fifth day, peaking at 10 to 14 days of age, most normal infants are already home. Occasionally, an infant is observed in a pediatrician's office at 10 days of age or older with a bilirubin level greater than 20 mg/dL, often 23 to 25 mg/dL. This necessitates the immediate admission of the infant to the hospital for a complete bilirubin work up. It is important to recognize that other causes of hyperbilirubinemia must be ruled out, including blood-type incompatibilities. At this age, it is also necessary to rule out biliary obstruction and hepatitis, which might have a high direct or conjugated bilirubin level.

Phototherapy is used for 4 to 6 hours to establish whether this therapy will be effective in dropping the level sufficiently. When bilirubin is substantially greater than 20 mg/dL and if a possible association with breast milk exists, it is necessary to stop

breastfeeding temporarily and start phototherapy immediately on admission while the diagnostic work up is being performed. Otherwise, breastfeeding may continue even though IV fluids may also be necessary.

The Agency for Health Care Research and Quality, through its Evidence-Based Practice Centers, published a report on management of neonatal hyperbilirubinemia in 2003 after an extensive review of more than 4560 abstracts from which 241 articles were examined and 138 included in the report.<sup>74</sup> In contrast, Chou et al.<sup>33</sup> proposed a management of hyperbilirubinemia using a benchmarking model in a 3-year prospective cohort study. They found association of high bilirubin with lower gestational age, older mother, and exclusive or partial breastfeeding. The authors recommend assessing breastfeeding and promoting breastfeeding, supplementing if necessary but never with water, in combination with phototherapy as most efficacious.<sup>33</sup> The natural history of jaundice in predominantly breastfed infants is described by Maisels et al. They point out after measuring TcBs in 1044 breastfed infants of at least 35 weeks' gestation, that 20% to 30% of predominantly breastfed infants will be jaundiced by transcutaneous measurement at 3 to 4 weeks. Levels of 5 mg/dL or more will be found in 30% to 40%. When drawn, a TcB of zero was highly predictive that the bilirubin was less than 12.9 mg/dL and could be used for screening purposes at 1 month.

Infants discharged early (less than 30 hours of age) were more likely to be rehospitalized for hyperbilirubinemia within 7 days of discharge in a study of 310,000 newborns in the State of Washington, when compared to children discharged from 30 to 78 hours after birth. Of the children readmitted, 94% were breastfed.<sup>58</sup> Bilirubins at discharge are recommended. Prolonged breast milk jaundice has not been studied in follow-up when the association of the bilirubin elevation has been made with breast milk. A pediatric practice may see only a few in a lifetime. The safe level for chronic indirect bilirubin has not been established. The lactation study center recommends greater than or equal to 10 mg/dL. Others allow a level of 12 mg/dL. This is accomplished most easily with phototherapy; usually having an infant sleep under phototherapy 12 hours per day, utilizing home devices such as the "bilirubin blanket," will control the levels. This is not a casual arrangement. The eyes must be protected and the bilirubin monitored. As the liver matures, the problem disappears and phototherapy can be discontinued. The infant must be under the care of an experienced pediatrician. In some cases, the bilirubin can be controlled with partial breastfeeding with the addition of formula in sufficient amounts to maintain the

bilirubin at less than 10 mg/dL. Children with Gilbert syndrome, Crigler-Najjar syndrome, glucose-6-phosphate dehydrogenase, and other genetic variations must be managed individually by a genetic specialist and the pediatrician. These children have chronic hyperbilirubinemia and usually need to sleep under phototherapy.

## SUCKLING PROBLEMS RELATED TO ANATOMY AND NEURAL DISORDERS

Most problems with latch-on during breastfeeding can be solved with adjustment of position and approach, but a few cannot because an infant has an anatomic variation of the mouth or a neurodevelopmental problem. A thorough examination is required to evaluate the mouth and cheek for potential associated lesions and syndromes. Premature infants are more often identified with suckling problems because they not only are immature but also have been suctioned, intubated, and perhaps ventilated. Much has been put in their mouths. They may also have a high arched or grooved palate from the endotracheal tube used to ventilate.

When the mouth is carefully examined, an infant may have cysts on the dental ridge or under the tongue, the tongue may have limited range of motion, or the palate may be abnormal. A number of observations are being reported in the literature, such as "bubble palate" or variation in infant palatal structure. Schneider et al.<sup>132</sup> recommend alternative positioning and repatterning oral behavior to increase the transfer of milk and reduce the trauma to the maternal nipple. Breastfeeding in the supine position with the infant prone encourages the infant's tongue to fall down and forward and keeps the nipple from being abraded by "the bubble." Marmet and Shell<sup>101</sup> describe a bubble palate as a concavity in the hard palate, usually about  $\frac{3}{8}$  to  $\frac{3}{4}$  inch (1 to 2 cm) in diameter and  $\frac{1}{4}$  inch (0.5 cm) deep. Similar adjustments to positioning would be appropriate for high arched palates.

Macroglossia presents a problem of too much tongue for the oral cavity. These infants do better at the breast than with a bottle. The main problem is to have the infant bring the tongue forward to avoid gagging.

Abnormal oral motor patterns are more common in premature infants and those who have been asphyxiated at birth. These movements include exaggerated tongue thrust (often from bottle feeding and nipple confusion), tonic bite, jaw thrust, jaw clenching, and lip pursing. Some of these behaviors are associated with postural muscle tone abnormalities.<sup>152</sup> Normal muscle tone and strength throughout breastfeeding, especially alignment of the head and neck, are required to form a stable base to anchor the oral and pharyngeal musculature. Hypertonic

and hypotonic infants may pose problems. Hypertonic infants are usually overflexed or overextended and have hypertonic mouths with tonic bite, jaw thrusting, and clenching. Inducing relaxation, minimizing handling, and using gentle strokes to calm the infant can be effective. If the infant is extended, flexion may be achieved with a pleat-seat carrier (see Figure 14-2) or pillows. Flexed position in these infants relaxes the jaw and mouth and allows latching to take place. Finger feeding may help train these infants. If done just before a feed, the infant can be transferred to the breast smoothly.

Oral tactile hypersensitivity is often seen in infants who have had oral tubes, especially feeding tubes. Touching around the mouth causes feeding rejection. Decreased oral awareness may result in drooling and poor suckling. These infants may respond to stroking the oral area gently. Most infants have a strong arching reflex, which is elicited by touching or applying pressure on the back of the head, causing the infant to arch back away from the breast. Positions that require the mother to hold the head (e.g., "football hold") may trigger this reflex. Infants prefer to be swaddled but always respond better to a firm supportive hold of the body, slightly flexing the arms, legs, and trunk. Pillows can be used for support of the baby or the mother's arms.

The development of an infant's oral motor and feeding skills parallels general physical development, especially gross and fine motor skills. When an infant is having persistent feeding problems, the infant needs total neuromotor assessment. Minor problems may be solved by the firm supportive hold of a swaddled infant who is gently handled and encouraged.

Illingworth and Lister<sup>73</sup> first put forth the concept of a critical or sensitive period for the development of a skill. Conditioned dysphagia is a learned disorder, acquired and maintained through a behavioral conditioning process that occurs when a noxious stimulus is paired with the act of swallowing.<sup>44</sup> This is noted with suctioning of the mouth or nasopharynx and nasogastric feeding tubes in a NICU.

An infant with a true feeding disorder requires an assessment with a neonatal oral-motor review by a trained physical therapist. Training the infant to suckle will be required. These infants ultimately do best if sucking is limited to the breast. Cup feedings are more effective than bottle feeding.

## *Infants with Problems Requiring Surgery*

Human milk should be the food of choice for surgical infants, in other words, all newborns who undergo surgery early in life. Their own mother's

**TABLE 14-6**

Comparison of Early and Late Jaundice Associated with Hyperbilirubinemia while Breastfeeding

Early Jaundice	Late Jaundice
Occurs 2-5 days of age	Occurs 5-10 days of age
Transient: 10 days	Persists >1 month
More common in primiparas	All children of a given mother
Infrequent feeds	Milk volume not a problem May have abundant milk
Stools delayed and infrequent	Normal stooling
Receiving water or dextrose water	No supplements
Bilirubin peaks ≤15 mg/dL	Bilirubin may be >20 mg/dL
Treatment: None or phototherapy	Treatment: Phototherapy Discontinue breastfeeding temporarily Rarely: Exchange transfusion
Associations: Low Apgar scores, water or dextrose water supplement, prematurity	Associations: None identified

milk is the best option, a donor milk program is the first alternative.<sup>13,129,138</sup> The UNICEF 10 steps can be modified and adopted for a neonatal surgical unit as recommended by Salvatori (Table 14-6).

## IMMEDIATE NEONATAL PERIOD

### First-Arch Disorders

Feeding of any sort may be greatly hindered by abnormalities of the jaw, nose, and mouth. A receding chin may seem to be a minor problem and require only positioning the jaw forward. It is essential to establish that the jaw is not dislocated (Figure 14-8). A mother can hook the angle of the jaw with her finger and draw it forward. If the tongue is too large for the jaw, the infant will actually nurse better at the breast than at the bottle because the human nipple fits into the mouth with less bulk. Infants with first-arch abnormalities usually require considerable help in feeding. A cleft palate may also be present. If choanal atresia is present, because infants are obligatory nose breathers it may be necessary to insert semipermanent nasal tubes so that the infant can be fed orally until older; definitive surgery may be necessary later. Once the nasal tubes are in place, the infant can manage at the breast. Feeding by any technique, however, is never easy.

**Figure 14-8.** Demonstration of a significantly receding chin. (From Biancuzzo M: *Breastfeeding the newborn, clinical strategies for nurses*, ed 2, St. Louis, 2003, Mosby.)

### CLEFT LIP

A solitary cleft lip is usually repaired in the first few weeks of life. Before surgery, an infant will need some help, but the infant can nurse at the breast if a seal around the areola can be developed. Actually the breast may fill the defect, and suckling will go well. The mother may be able to put her thumb in the cleft to create a seal as she holds the breast to the infant's mouth. It is important to encourage the infant to suck to strengthen the tongue and jaw muscles. If all else fails, a breast shield can be tried, affixing a special cleft lip nipple to the shield. The mother will need to pump after feedings to increase milk supply. In some cases, the mother may have to express or pump milk and offer it by dropper or other means if sucking is ineffective. The pediatrician, plastic surgeon, and parents should work together as a team from the time of birth to determine a coordinated plan of treatment. Some surgeons have special protocols before and after surgery to ensure optimal healing. It is important to make all plans for feeding around the surgical plan. The literature reports individual mothers' experiences nursing infants with lip defects. The major caution in sharing these experiences is to consider that the supportive surgical approach may differ from those reported in the literature.<sup>68</sup> In these cases, a plastic surgeon is the captain of the team, working with the pediatrician and support staff. As breastfeeding has increased, lactation consultants have joined the surgical repair team, working directly with the surgeon. Ideally this lactation consultant is a skilled nurse.

### CLEFT PALATE

The prognosis for successful feeding of an infant with a cleft palate depends on the size and position of the defect (soft palate, hard palate) as well as the associated lesions. Masera et al.<sup>102</sup> and Reid et al.<sup>123</sup> recommend the application of an orthopedic

appliance to the neonatal maxilla to close the gap, thus aiding nursing, stimulating orofacial development, developing the palatal shelves, preventing tongue distortions, preventing nasal septum irritation, and decreasing the number of ear infections. This will make it easier for the plastic surgeon and help the mother psychologically as well. A cleft involving the secondary palate can interfere with normal nursing. For the infant to suckle, the nose must be sealed off from the mouth, creating a negative pressure in the oral cavity. The milk may also run out the nose. The absence of palatal tissue can prevent expulsion of milk from the nipple. The orthodontic appliance prosthetically restores the anatomy of the palate, permitting normal suckling.

Because the purpose of the negative pressure in the mouth is to hold the nipple and areola in place and not to extract milk from the breast, a seal is needed to keep the pressure. A mother may be able to perform the positioning task by holding the breast to her infant's mouth firmly between two fingers, as shown in Figures 8-13, 14-1, 14-2, and 14-9. The infant is then able to milk the areola and nipple with the tongue pressing it against the roof of the mouth, even with the cleft. The breast must be held in position just as a bottle must be held throughout the feeding.

An infant's ability to generate negative intraoral pressure and to move the tongue against the nipple is important to effective feeding techniques. These findings were summarized in relation to the possibility of breastfeeding (Table 14-7). Normal children with a cleft can swallow normally. A defect in the bony structure of the palate, however, creates a hole that is difficult to plug; thus these children are more difficult to feed by any method.<sup>116</sup>

Problems with intraoral muscular movements are associated with bilateral cleft lip, which causes severe anterior projection of the premaxilla that

precludes stabilizing the nipple, with wide palatal clefts, which offer no back guard for tongue movements, and retroplaced tongues that cannot compress the nipple effectively. When neurologic problems are causing dysrhythmic tongue movements, a weak tongue, or grinding of the gum on the nipple, it is more than a simple anatomic problem and is usually part of a syndrome (e.g., first-arch syndrome). These children usually have swallowing problems as well (e.g., Pierre Robin syndrome).

Feeding procedures for each infant vary.<sup>102,123</sup> Early assessment of infant and mother can usually lead to successful feeding within 1 to 2 days. The infant should not go hungry, and the mother should not spend hours struggling with a system that is not successful for her child. The Lact-Aid or the lactation supplementer can be helpful because the mother can control the flow by squeezing the reservoir, and the infant can have some suckling experience, which will strengthen the oral structure and avoid the trauma of invasive devices. The mother will need to pump to increase her milk supply.

Weatherley-White et al.<sup>154</sup> reported a program of early repair in breastfeeding infants with cleft lip. Repair has been initiated earlier and earlier, but these authors present 100 consecutive repairs: 51 infants were older than 3 weeks, and 49 were younger, of whom 26 underwent surgery at age 1 week or less. No increase in complication rate and no increase in need for revision of repair was observed. Sixty mothers were offered the opportunity to breastfeed immediately postoperatively; 38 began within hours. Of these, 16 infants breastfed more than 6 weeks, 22 converted by 6 weeks, and 22 were fed by cup or syringe. Breastfed infants gained more weight, and hospital stay was a day shorter. A prospective randomized

**TABLE 14-7** Assessment of Sucking and Feeding Techniques for Infants with Clefts of Lip and Palate

Condition	Assessment		
	Generation of Negative Pressure	Ability to Make Mechanical Movements	Feeding Techniques
Cleft lip and palate	—	±	Breastfeeding is unlikely. Deliver milk into infant's mouth.
Cleft palate only	±	+	Breastfeeding sometimes succeeds. Soft artificial nipples with large openings are effective. Infant may need delivery of milk into the mouth.
Cleft of soft palate	±	+	Breastfeeding or normal bottle feeding usually works well.
Pierre Robin syndrome	±	—	Breastfeeding is unlikely. Nipple position is critical. Many infants need delivery of milk into mouth.
Cleft lip only	±	+	Breastfeeding works well. Artificial nipple with large base works well.

+, Present; —, absent; ±, partial.

From Claren SK, Anderson B, Wolf LS: Feeding infants with cleft lip, cleft palate, or cleft lip and palate, *Cleft Palate J* 24:244, 1987.

trial of 40 infants showed that early postoperative breastfeeding after cleft lip repair is safe and results in more weight gain by 6 weeks after surgery when compared with infants randomized to be spoon-fed postoperatively.<sup>41</sup>

A position that is particularly effective is to have the infant straddle the mother's leg so he is directly facing the breast. If mother leans back slightly and the infant has to lean forward, structures fall in place to facilitate suckling. The breast needs to be held throughout the feeding.

Similar experience with early surgery and breastfeeding is confirmed by Fisher,<sup>52</sup> who reported performing reconstructive surgery in the Third World, where breastfeeding is undisputed and is very successful. He also reported greater success rate with breastfeeding but noted that it requires the conviction not only of the surgeon and pediatrician but also of the nurse, nutritionist, mother, and grandmother. It takes the presence of all these elements for success, but the absence of only one for failure.

As noted previously, breastfed infants have fewer bouts with otitis media, which has been attributed to the position of the infant while feeding at the breast and the antiinfective properties of the milk. This is an important consideration in infants with cleft palates, who have been identified as having more ear infections in general than other infants.<sup>44</sup>

Children with cleft palates may also fail to thrive, not only as a function of their feeding difficulty but also because they may have an underlying increased metabolic need. In a study of 37 children with cleft palates and no other anomalies, the median birth weight was at the 30th percentile.<sup>15</sup> By 1 to 2 months, weights had dropped to the

20th percentile and did not recover to the 30th until 6 months of age.

It is important to have a plastic surgeon involved promptly after birth so that management plans can be developed with the family immediately. This also avoids conflicting information from others.

The Academy of Breastfeeding Medicine has developed protocol No. 17, Guidelines for Breastfeeding Infants with cleft lip, cleft palate, or cleft lip and palate.

### Oral Defects: Feeding Recommendations

Feeding infants with oral defects requires extra effort. Each infant is slightly different. Usually mothers learn to feed their own infants more effectively, even when bottle feeding, than the skilled professional can advise them. This amplifies that it requires a special patience and knack. Breastfeeding can be successful. Infants with cleft lip or palate should be managed as normal infants. Cupping of the infant's jaw and filling the defect with the mother's thumb while supporting the breast in place for suckling will allow effective breastfeeding in the infant with cleft lip. This has been referred to as the "dancer hold" (see Figure 14-1).<sup>100</sup> As with any infant, the infant should be taken to the mother to feed and for rooming-in. Reinforcing that the infant is normal and merely needs some reconstructive surgery is important in helping parents adjust. Parent-to-parent programs are most helpful. The primary care physician coordinates care with the specialist and the rest of the health care team.

Pediatric reconstructive surgeons usually have a team of professionals, including otolaryngologists, audiologists and affiliated therapists, social

workers, and nurses who are familiar and experienced with these first-arch problems. Parent support groups have often been developed through these sources. Most reconstructive surgeons will see an infant in the first 24 to 48 hours and reassure the parents while designing a plan of action. Usually a member of the nursing staff of the surgeon's practice will also visit and provide practical advice about feeding, especially if the mother chooses to breastfeed.<sup>42</sup>

Other syndromes may be associated with feeding difficulties because of an anatomic variation that interferes. High arched palate is seen in trisomies, in Turner syndrome, and in small premature infants who have been intubated, which causes a characteristic groove in the palate. In one study, 10 infants younger than 29 months of age with Turner syndrome had difficulty feeding from birth when compared with normal children.<sup>97</sup> Breastfeeding was less successful and terminated early. The infants were noted to have marked hypertonia of the cheeks and lips, dysfunctional tongue movements, and poor chewing skills later. The infants had difficulty latching on and had a slow, weak suck. The study infants did not demand food and had not developed a diurnal cycle of hunger and satiety. No efforts were reported to remedy these problems. Referral to a physiotherapist skilled in feeding disorders is the best place to start. A specially trained lactation consultant can provide breastfeeding adaptations.

## Intestinal Tract Disorders

Infants with anomalies of the GI tract that cause obstruction develop symptoms that are a function of the location of the problem in the GI tract.

**Tracheoesophageal Fistula.** Tracheoesophageal fistula is apparent early and, depending on the exact anatomy of the lesions, results in respiratory symptoms and signs of intestinal obstruction. This is a surgical emergency. If no feedings have been given or no milk has been aspirated, surgery can be done as soon as possible. If pneumonia develops, the course is protracted and the infant may have to be maintained on peripheral venous alimentation until healing takes place and surgery can be done.

A mother who wants to breastfeed an infant with a tracheoesophageal fistula can manually express milk or pump, saving all samples in the freezer until the infant can take oral milk feedings. If the infant has a gastrostomy tube in place, small feedings may be started fairly early postoperatively, and human milk is ideal if available because of its easy digestibility and antiinfective properties. If supplementing the milk partially with IV fluids is needed initially, the fluids can be calculated to make up

the difference between needs and nutrients supplied by breast milk taken by tube. As nutrition progresses, if supply does not keep up with requirements, feedings can be supplemented with other nutrients. When ready for oral feedings, a full-term or large premature infant can nurse at the breast. Unless the mother is able to spend most of the day and night at the hospital, the infant will have to receive bottle or cup feedings as well (Figure 14-10). If the mother has been able to store up enough milk, the infant may be able to fulfill needs from breast milk or from donor milk.<sup>54</sup> After the infant is discharged and begins to nurse at the breast every feeding for a few days, the supply will increase immediately. If concern exists about nutritional lag between needs and production, the Lact-Aid or lactation supplementer device can be used briefly to stimulate the breast without starving and exhausting the infant (see Chapter 19).

**Gastroesophageal Reflux.** Gastroesophageal reflux (GER)—persistent nonprojectile, postprandial vomiting or regurgitation—is being diagnosed with increasing frequency. Part of this increase is occurring in graduates of NICUs who have been tube fed or perhaps intubated. Previously compromised infants are more frequently bottle fed; thus the increase in bottle feeding associated with this diagnosis is to be expected. Little is written about GER in breastfed infants because it usually does not occur or is asymptomatic. The position for feeding is more upright than for bottle feeding, and the suckling motion of the tongue, which triggers peristaltic waves from tongue to

**Figure 14-10.** When an infant must be fed but cannot be breastfed (e.g., when mother is ill), the infant can be fed using a small, soft medicine cup. Infant is swaddled and held semiupright, and liquid is given inside lower lip.

GI tract and an automatic swallow, provides some protection for breastfed infants.

GER is defined by the Society for Pediatric Gastroenterology as the passage of gastric contents into the esophagus and is a normal physiologic process that occurs throughout the day in healthy infants, children, and adults. GER disease (GERD) is when symptoms or complications occur including regurgitation, vomiting, poor weight gain, pain, esophagitis, or respiratory problems, such as apnea, especially in newborns.<sup>24</sup>

The "happy spitter" requires no work up. Positioning may help. This usually resolves by age 2 years. Vomiting and poor weight gain requires an upper GI series, electrolyte panel, and blood urea nitrogen (BUN). If normal, positioning is the first step, then medication if necessary after consultation with a pediatric gastroenterologist. Apnea is more common in premature infants and requires careful monitoring in the hospital and aggressive management, including medications.

The effect of milk type on physiologic GER was evaluated in 37 breastfed and 37 bottle-fed healthy term infants at 2 to 8 days of life by Bhatia et al.<sup>23a</sup> The GER episodes in breastfed infants were less frequent and shorter than those in bottle-fed infants. Breastfed infants had more quiet sleep than active sleep. No difference in volume consumed was apparent. The pH of breast milk was initially slightly higher than formula; a significantly lower pH was found for refluxes in the breastfed infants. The researchers did not test whether the differences were caused by the variations in human milk and formula or the differences in suckling at the breast, a physiologic process, or sucking a bottle. If reflux is symptomatic in a breastfed infant, breastfeeding should be done with the infant semiupright, and the infant should be placed in an inclined seat after a feed. In rare cases, medication is necessary.

**Pyloric Stenosis.** Pyloric stenosis occurs in about 2 to 5 of 1000 live births. A family tendency exists, but the disease is more common in first-born boys. Usually it occurs between the second and sixth weeks of life, although it can occur any time after birth. Vomiting is characteristic, is intermittent at first and progresses to include every feeding, and is often projectile. These infants are eager feeders and go back for more milk until the weight loss and dehydration make them anxious and irritable.

The risk of pyloric stenosis has decreased from 9 per 10,000 births in 2003 to 5 in 10,000 in 2009, just 6 years later. During that time, the incidence of breastfeeding has increased. Two major reviews of the relationship of pyloric stenosis to bottle feeding (i.e., formula based on bovine milk) have been published. One was from the Danish National Birth Cohort involving 101,000 births

from 1996 to 2002. Of that number, 70,000 were singleton births among which there were 65 infants with the diagnosis of pyloric stenosis requiring surgery. The second study, from Seattle, Wash., USA, involved records from January 2003 to December 31, 2009 of 825 infants with a diagnosis. Both reports showed bottle feeding to be associated with an increased risk of the diagnosis. The risk was 4.6 times greater for the bottle-fed infants in the Danish study. It is noteworthy that the diagnosis of breastfeeding was taken from the birth records in the Seattle study. All the authors noted the risks of bottle feeding and questioned the mechanism of the disease.

The Danish study noted a sixfold risk of stenosis in never breastfeeding and a fivefold risk of stenosis when switched to the bottle from the breast. Male predominance was striking but the protective factor of breastfeeding was the most consistent finding.

In the investigation of vomiting, it is important to keep in mind that overfeeding can cause spitting and vomiting, even projectile vomiting, but it is not associated with weight loss, decreased urine and stools, and dehydration. Therapy consists of pyromyotomy after correction of the dehydration and associated electrolyte abnormalities. If the procedure is uncomplicated (i.e., intestinal lumen was not entered), the infant can go back to the breast in 6 to 8 hours.<sup>55</sup> The mother should pump every 3 hours until the infant can be fed. The breastfed infant may be discharged in 24 hours if nursing has gone well. If the duodenum is entered at the time of surgery, gastric decompression and IV fluids will be necessary and oral feeding delayed several days until signs of healing occur. A breastfed infant may resume nursing earlier than a bottle-fed infant returns to formula because of the rapid emptying time of the stomach and the zero curd tension of the breast milk.<sup>55</sup>

**Disorders of the Small Intestine.** Disorders such as duodenal obstruction, malrotation, jejunal obstruction, and duplications require surgery. Depending on the extent of the lesion, whether the bowel wall is opened, whether bowel segments are removed, and whether associated lesions such as annular pancreas are present, an infant will need postoperative maintenance on IV fluids and possibly alimentation. In a study of early postoperative feeding in infants with duodenal atresia ( $n=10$ ), malrotation ( $n=6$ ), and jejunal atresia ( $n=1$ ), enteral feeding was started by postoperative day 2 in 14 cases. Breast milk was the most common nutrient (numbers and amounts not given). Thirteen infants were discharged (one died of sepsis).<sup>141</sup> The mother who chooses to breastfeed may or may not have ever nursed the infant before surgery, depending on the time of onset of symptoms and

their severity. The mother should be counseled about the prognosis and encouraged to express milk manually and by pump to provide her milk for her infant postoperatively. The decision should be made among the parents, surgeon, neonatologist, and pediatrician. Frequently, infants with atresias are also small or premature and have protracted recovery periods because of the removal of considerable intestinal tract. If the infant will be breastfed, breast milk can be introduced earlier than formula. Short gut syndrome requires special management, but human milk is usually tolerated and donor milk should be obtained if the mother is unable to lactate.

**Disorders of the Colon.** Disorders of the colon occur more often in full-term infants. Hirschsprung's disease, or congenital aganglionic megacolon, is the most common lesion. Passage of meconium is usually delayed; however, only 10% to 15% of all children with delayed passage of meconium have Hirschsprung's disease. Constipation and abdominal distention are the most frequent initial symptoms. They may begin during the first few days of life and gradually progress to include bilious vomiting. The clinical picture may be indistinguishable from meconium ileus, ileal atresia, or large bowel obstruction. In any infant with perforation of the colon, ileum, or appendix, Hirschsprung's disease should be considered. A breastfed infant may have milder symptoms and delayed onset of real stress because the breast milk stools are normally loose and seedy and easily passed.<sup>79</sup> The pH and flora of the intestinal tract are also different, leading to less distention. Enterocolitis may occur at any age and is the major cause of death.

No data have been found to distinguish the incidence of this complication in breastfed and bottle-fed infants, although an argument could be mounted regarding the projected value of secretory

IgA and intestinal flora of the breastfed infant. The treatment depends on the symptoms, x-ray findings, and biopsy results for the identification of the aganglionic segment. Colostomy is usually done at the time of diagnosis, with definitive surgery later in the first year of life. Feedings can be resumed as soon as the infant is stable, after the colostomy has healed sufficiently to permit bowel activity. Human milk has the same advantages for early postoperative feeding in this disease as well because of its antiinfective properties and easy digestibility.

**Meconium Plug Syndrome and Mec-o-nium Ileus.** Meconium plug syndrome and meconium ileus are less common and less severe in breastfed infants who have received a full measure of colostrum, which has a cathartic effect and stimulates the passage of meconium. If either disorder is diagnosed, an infant should continue to nurse in addition to any other treatment, which should include an assessment for CF and pancreatic insufficiency.

**Congenital Chylothorax.** Congenital chylothorax, although uncommon, is the most common cause of pleural effusion in the newborn period. It affects the respiratory, nutritional, and immunologic systems and is potentially life-threatening. Most cases are single abnormalities, but may be associated with other anomalies, lymphangiectasia, or neuroblastoma. Management is controversial. Parenteral nutrition and mechanical ventilation have improved the outcome. If diagnosed prenatally, transabdominal thoracocentesis can be done and delivery initiated after 32 weeks. The chest can be tapped or put to continuous drainage (Tables 14-8A and 14-8B).

Nutrition starts with total parenteral nutrition (TPN). Enteral feedings are started as soon as

**TABLE 14-8A** Clinical Summary of Infants with Chylothorax

Total volume (mL)	100 $\pm$ 1	95 $\pm$ 1

SD, Standard deviation.

possible (5 to 7 days) using breast milk or regular formula. If the chylothorax worsens, oral feeds are stopped for another 3 to 7 days and then restarted with special medium-chain triglyceride-rich formula (e.g., Pregestimil) and then in 2 to 4 weeks breast milk or regular formula. In a retrospective study by Al-Tawil et al.,<sup>5</sup> 19 infants were reviewed; 18 were followed for 7 years and were successfully managed after 7 weeks with breastfeeding or regular formula. In another study, infants managed with TPN ( $n=9$ ) recovered more rapidly (mean 10 days) than those treated with medium-chain triglycerides ( $n=8$ ; mean 23 days). TPN treatment permitted progression to earlier oral feeds and earlier breastfeeding.<sup>6</sup> Iatrogenic chylothorax management is not as simple and may take weeks of TPN and then the use of defatted breast milk. Defatted human milk was used in seven infants with chylous pleural effusion.<sup>30</sup> Mother's milk was placed in a clear 240-mL container and centrifuged at 3000 rotations per minute for 15 minutes at 2°C in a Beckman J2-21 High Speed Floor Model Centrifuge. The solidified-fat top layer was separated from the liquid portion. The liquid portion was poured into clean cups and frozen for later use. Before and after samples were tested for fat, sodium, potassium, calcium, and zinc. Mean fat removal was 5 g/dL. The infants started on the milk after a month of age for an average of 16 days (7 to 34 days). No reaccumulation of the chylous pleural effusion was observed.<sup>30</sup>

Intensivists and neonatologists have recognized the value of human milk and have reported the practice of defatting human milk for infants with congenital as well as iatrogenic chylothorax.<sup>31</sup> One of the first reports described spinning the breast milk at 3000 rpm for 15 minutes using a cold centrifuge. The milk was successfully used in seven infants. Children's Hospital of Philadelphia (CHOP) opened a Human Milk Management Center.<sup>137</sup> Skim milk is prepared by their milk technicians utilizing a cold centrifuge (Thermo Fisher Scientific 1 ST 16). Milk is spun at 4000 rpm for 20 minutes. They report 29 infants in 23 months of use. Chylothorax was due to congenital

diaphragmatic hernia and congenital cardiac defects that were repaired surgically. Skim milk was used an average of 16 days (range 1 to 85 days). All milk used had a hematocrit of less than 1%. It was concluded that a standard skim milk protocol allowed infants to continue the additional benefits of their mother's own milk.

**Necrotizing Enterocolitis.** Although NEC has been known for 100 years, only since 1960 has it been identified with any frequency, which suggests an iatrogenic component. It is most common in premature infants and infants compromised by asphyxia. It has been associated with umbilical catheters, exchange transfusions, polycythemia, hyperosmolar feedings, and infection. Its cause is not clear. Work with animals has suggested that human breast milk, specifically colostrum, provides protection against the disease. A "dose or two" of human milk may not be enough. Reported cases of NEC have occurred so early in life that no feedings had been given. Present regimens of treatment call for cessation of all oral feedings and use of oral and systemic antibiotics, gastric decompression, plasma or blood transfusions, and rigorous monitoring for progression or perforation with serial x-ray studies as well as a septic work up. The organisms generally associated with NEC are gram-negative organisms such as *bacteroides*, *E. coli*, and especially *Klebsiella*. Eighty-nine percent of infants with NEC had received cow milk formulas, and gram-negative bacteria and endotoxins were present in the stool. Colonization of breastfed infants with *Klebsiella* does not usually occur, and *Lactobacillus bifidus* predominates. The rare occurrence of NEC in Helsinki, at the University of Helsinki Children's Hospital intensive care nursery, is significant. All the premature infants are routinely fed colostrum and breast milk in Helsinki.

The role of bacterial colonization in NEC was further explored by Newburg and Walker,<sup>113</sup> who suggest that the beneficial effects of suppression of colonization of harmful bacteria and the stimulation of bifidobacterial growth with human milk is a valuable approach to the prevention and treatment of NEC. In a systemic review of the question of the value of donor milk versus formula for preventing NEC, the authors suggest that donor milk reduces the incidence of NEC in preterm or LBW infants.<sup>113</sup> Continued discussion of NEC appears in Chapter 15 on prematures.

**Imperforate Anus.** Defects in the rectum and anal sphincter are usually diagnosed in the first few hours of life on physical examination. When the blind pouch is more generous, diagnosis may depend on the evaluation of failure to pass stool. Depending on associated lesions and fistulas to the bladder or vagina, surgical decompression can

be performed. Until this time, oral feedings are withheld. High lesions require an immediate colostomy with later final repair, whereas low lesions may be repaired at the primary procedure through a perineal approach. Infants may be breastfed as soon as any bowel activity can be permitted, often 2 to 3 days postoperatively.

**Gastrointestinal Bleeding.** The most common cause of vomiting blood or passing blood via the rectum in a breastfed infant is a bleeding nipple in the mother, which may or may not be painful. Any time fresh blood is found in the vomitus or stool of any newborn, the blood should be tested for adult or fetal Hb. If adult Hb, it indicates the source is maternal. This is done by a qualitative test, the Apt test.

Mix red blood with 2 to 3 mL normal saline solution, and add this mixture to 3 mL of 10% NaOH (0.25 M). Mix gently. Observe for color change. Fetal Hb is stable in alkali and will remain pink, whereas adult Hb turns brown. Use a known adult sample as a color control. If the blood is adult Hb in a breastfed infant, the possibility of a cracked and bleeding nipple should be ruled out by examining the sample of expressed milk for color and guaiac, and inspection of the maternal breast (see Chapter 8).

If the blood is fetal Hb, the differential diagnosis for bleeding in any neonate should be followed. Breastfeeding can be maintained, unless a lesion requiring surgery is identified. More than 50% of cases of GI bleeding in the neonate go undiagnosed. Anorectal fissure is an uncommon cause in breastfed infants. Allergy to human milk itself has been reported as a cause of intestinal bleeding.<sup>118</sup> The distribution of causes of intestinal bleeding in the neonate, without selection for type of feeding, follows: idiopathic, 50%; hemorrhagic disorders, 20%; swallowed maternal blood, 10%; anorectal fissures, 10%; intestinal ischemia, 5%; and colitis, 5%. When the bleeding occurs beyond the newborn period, colitis (see previous discussion) becomes a more frequent cause, as does Meckel's diverticulum. Sullivan<sup>140</sup> has reviewed the subject of cow milk-induced intestinal bleeding in infancy.

## Otitis Media

Acute otitis media is a common affliction among young children that has increased in incidence, paralleling increasing attendance at daycare facilities.<sup>119</sup> Population density and air pollution have also been identified as factors. In a Finnish study of 471 2- to 3-year-old children, 188 had three or more attacks of otitis media, 76 had one to two attacks, and 207 had none.<sup>121</sup> Incidence was increased in those who

attended day care or had several siblings. Prolonged breastfeeding (longer than 6 months) was associated with a decreased risk.

Any breastfeeding reduces the incidence of otitis media by 23%, exclusive breastfeeding for more than 3 months reduces the risk by 50%, and exclusive breastfeeding for 6 months decreases the risk of respiratory infections and otitis by 63%.<sup>46</sup>

With daycare exposure and other environmental risk factors, it does have a measurable effect. Breastfeeding is also more comfortable for an infant with a painful otitis than bottle feeding because of the physiologic suck/swallow mechanism. If an infant is having difficulty feeding, providing a dose of acetaminophen or ibuprofen before the feeding can be helpful.

## Congenital Dislocation of Hip

When procedures or treatments need to be initiated for an infant previously thought to be normal, breastfeeding may not go smoothly. Using congenital dislocation of the hip as a prototype, Elander<sup>49</sup> looked at overall breastfeeding success. Compared with a randomly chosen control group of 113 infants, the 30 study infants who required the von Rosen splint were less successfully fed. However, a higher incidence of cesarean deliveries was seen in the study group (30% vs. 4%). The groups had equal numbers of primiparas (50% vs. 48%). After breastfeeding was established, the long-range success rate was no different. Mothers were pleased to be able to do something special for their splinted children (i.e., breastfeed). This would suggest that special support and guidance regarding breastfeeding issues may be needed, along with details on how to apply the splint and how to cope with the splint while positioning for breastfeeding.

## Malformations of Central Nervous System

Malformations of the central nervous system diagnosed at birth include the clinical spectrum from anencephaly and complete craniorachischisis to dermal sinuses. Defects of the spinal column range from complete spinal rachischisis to spina bifida occulta. A mother who had planned to breastfeed an infant with an inoperable condition or for whom breastfeeding is incompatible with life is presented with the additional problem of coping with her desire to nurse her infant. If an infant is to be given normal newborn care and the mother desires to nurse this infant, breastfeeding should be discussed by the pediatrician and parents together. It has been well demonstrated that parents grieve more physiologically if they have contact with their abnormal infant, but their imaginations are more

vicious than some abnormalities of development. A professional's personal bias for how to deal with the infant should not overshadow the discussion with the parents. If a mother wants to nurse an infant who has no life expectancy and the infant is to be fed at all by mouth, she should have that choice. This includes infants with trisomy 13 and 15.

Infants with central nervous system abnormalities requiring surgery can be breastfed until the procedure and postoperatively as soon as oral intake is permitted. When the GI tract is not involved, breastfeeding can be initiated 6 to 8 hours postoperatively at the surgeon's discretion. The risk for lung irritation from breast milk is minimal. The rapid emptying time of the stomach and presence of antiinfective factors serve as advantages in the postoperative course. The placing of a shunt for hydrocephalus is a common procedure, and breastfeeding is an ideal feeding mode for this infant.

## Surgery or Rehospitalization Beyond Neonatal Period

Anesthesia is a main concern when any patient is scheduled for surgery. Traditionally, a patient has been ordered "nothing by mouth" after midnight or 6 to 8 hours preoperatively. Young infants used to feeding every 4 hours are frantic when ready for the operating room.

Recommendations for fasting intervals preoperatively have changed with the belief that clear liquids are safe to within 2 hours of anesthesia, with similar gastric volumes and pH at 2 and 8 hours.<sup>10</sup> Children younger than 1 year had not been studied until the report by Litman et al.,<sup>92</sup> who evaluated 77 infants between 2 weeks and 1 year of age. Bottle-fed infants had no solids within 6 hours and only clear liquids up to 8 oz within 2 hours of surgery. Breastfed infants had no solids but were permitted to breastfeed to within 2 hours of surgery. After 0.02 mg/kg oral atropine 30 to 45 minutes before surgery, induction anesthesia, and tracheal intubation, gastric fluid was aspirated by a blinded researcher who measured volume and pH. The study was discontinued when an unacceptable number of infants in the breastfed group had gastric volumes greater than 1 mL/kg (7 of 24 breastfed and 2 of 46 bottle fed). The pH of the gastric contents of bottle-fed infants was less than 2.5 in 9 of 10 infants (90%) with measurable fluid, whereas pH greater than 2.5 in breastfed infants was found in three of eight (38%). Low pH is probably a greater risk than volume, but the residual in breastfed infants is much greater than with clear fluids.<sup>92</sup> Instructions to breastfeeding mothers should limit the amount

of breastfeeding after 4 hours and permit feeding on a prepumped breast (i.e., empty breast), predominantly for comfort, to 2 hours before surgery. According to the American Society of Anesthesiologists, adhering to these guidelines is essential for safety of the anesthesia.<sup>10</sup>

An infant who requires surgery or rehospitalization can and should be breastfed postoperatively in most cases. The gravity of the surgery and the length of the recovery phase will determine the time necessary for the mother to pump and manually express her milk to keep her supply available. The infant who is hospitalized is already traumatized by the separation, the strange surroundings and people, and the underlying discomfort of the disease process itself. If the infant is to be fed orally, feeding should be at the breast as often as possible. If the mother can room-in or the hospital has a care-by-parent ward, this works well. If obligations to other family members make it impossible for the mother to stay, she can pump her milk and bring it in fresh day by day or frozen if the time interval between visits is longer than a day. Freezing will destroy the cellular content, but this is not a major problem beyond the immediate neonatal period. The infant should not be subjected to the added trauma of being weaned from the breast when the infant needs the security and intimacy of nursing most, unless weaning is absolutely unavoidable.

The medical profession needs to be aware of these infants and mothers and their special needs for support. An opportunity to discuss the breastfeeding aspect of the infant's management should be offered by the physician. The pediatrician should assume the advocacy role. The parents should not have to fight for the right to maintain breastfeeding. Plans for pumping and saving milk should be discussed and provided. If the infant is recovering in an open ward or a room with other infants and their parents without adequate privacy, a separate room should be provided for the mother to nurse or pump her milk. This room should be clean, neat, adequately illuminated, and equipped with a sink for washing hands. Storerooms, broom closets, and staff dressing rooms are inappropriate. If a mechanical pump is to be used, it should be kept clean and operable with disposable tubing and attachments that come in contact with the milk or the breast. If a breast pump is not provided in the pediatric department, it should be available from the newborn or NICU.

Arrangements for providing sterile containers for collecting milk and storing it will be discussed (see Chapter 21). Occasionally a mother may become so concerned about the adequacy of her milk for her infant that she may nurse much too frequently. Actually her child will need much more

nonnutritive cuddling and holding than usual. A physician may need to reassure the mother when pointing this out. The father should also be encouraged to understand all the tubes, bandages, and appliances the infant may have attached. He is an important member of the parenting team and should provide some of the soothing and especially the nonnutritive cuddling.

### Congenital Heart Disease

When an infant who is diagnosed with congenital heart disease is already feeding at the breast, it is usually not a medical indication to interrupt the process unless surgery is imminent. Even infants with cyanotic heart disease, if they can be fed orally, can be breastfed. The "work" required to breastfeed is less than the "work" required to bottle feed. Heart and respiratory rates remain stable during feeding at the breast. The misconception that it is more work to breastfeed is incorrect. A study compared oxygen saturation levels ( $\text{SaO}_2$ ) as an indicator of cardiorespiratory effort during breast versus bottle feeding.<sup>100</sup> The  $\text{SaO}_2$  levels were higher and less variable during breastfeeding than the  $\text{SaO}_2$  levels during bottle feeding, especially when the infant had congenital heart disease. A second study compared growth patterns of breastfed and bottle-fed infants with cardiac defects. The breastfed infants gained weight more quickly and had shorter hospital stays.<sup>36</sup> Breastfeeding is less strenuous as seen in these and other studies.

If the infant is unable to generate enough sucking stimulus to the breast to increase the milk supply, an electric pump can be used between feedings to increase the mother's supply.

Not all infants with congenital heart disease are diagnosed at birth. When an infant is failing to thrive in spite of good breastfeeding, it is time to consider a work up for cardiac or renal disease.<sup>112</sup> Clinicians may focus on the breastfeeding and miss the "elephant in the room."

Cardiac surgeons frequently plan surgery for a certain weight or age. A mother can be assisted in helping the infant reach the goal. Human milk is low in sodium and easily digested, thus permitting frequent feedings. The nurse practitioner or lactation consultant should assist the mother in increasing her production and increasing fat content at each feeding. Feeding at one breast per feeding usually increases fat. In the case of a cardiac-compromised infant, using one breast also diminishes the stress of switching to the other side. The mother may need extra support and encouragement. Providing one's milk for one's sick infant may be extremely important. The breastfeeding relationship may be important for the infant as well. Research has shown that infants have important

cardiovascular responses to nutrient intake.<sup>110</sup> These responses are regulated by changes in autonomic activity to the heart and vasculature. These early life-shaping interactions that occur when the offspring is fed by the mother have been demonstrated in the animal model. Interactions between mothers and their young serve as hidden regulators of physiologic function. The program at CHOP is very successful in having mothers breastfeeding and pump their milk. Of mothers of infants with CHD, 89% initiate lactation.<sup>146</sup>

If oral intake must be restricted preoperatively or immediately postoperatively, "nonnutritive" sucking at the previously pumped breast can be calming and comforting for the infant.

### Sudden Infant Death Syndrome

SIDS is the leading cause of death in infants after 1 month of age, accounting for one third of all deaths in the first year. Healthy, full-term infants account for 85% of the deaths.

In a 3-year, multicenter, controlled study of SIDS in New Zealand reported in 1993,<sup>133</sup> the National Cot Death Prevention Programme<sup>106</sup> sought to reduce the rising incidence of infant death by determining associated factors. Sleeping prone, maternal smoking, lack of breastfeeding, and the infant sharing a bed were the four modifiable risk factors. New Zealand launched a major prevention program to educate the public about these risk factors.<sup>109</sup> The AAP launched a similar program focusing only on sleeping prone. A case-control study in the United States by Frederickson et al. analyzed births of infants weighing more than 2000 g between 1988 and 1989. The study included 7102 control infants and 499 SIDS and 584 non-SIDS deaths. Breastfeeding offered dose-response protection against SIDS across races and socioeconomic levels. For white infants, the risk for SIDS increased 19% for every month of not breastfeeding and 100% for every month of nonexclusive breastfeeding. For black infants, the risk was 19% and 113%, respectively. Whether breastfeeding reduces the risk for SIDS was explored by Vennemann et al.<sup>150</sup> in a German study of SIDS that included 333 deaths and 998 matched controls. Being exclusively breastfed and even partially breastfed in the previous month reduced the risk by 50% throughout infancy. The authors recommend breastfeeding be included in the prevention messages.<sup>150</sup>

Numerous studies have been conducted to define further the associations with SIDS. Prone sleeping position continues to be the most important correlation, and the AAP continues the "back to sleep" campaign. The protective influence of breastfeeding is actually strongest among infants

of smoking mothers. SIDS rates are higher among infants of mothers who smoke, but breastfeeding by a smoking mother lowers that to a rate equal to that of bottle-fed infants with nonsmoking mothers. An association has also been suggested with pacifier use in bottle-fed infants. Pacifiers are not known to lower SIDS rates among breastfed infants beyond normal breastfeeding rates. Should pacifiers be recommended to prevent SIDS, use should be limited to bottle feeders because pacifiers are associated with decreased duration of breastfeeding. Although some studies show a protective effect of bed sharing in breastfeeding, the AAP Task Force on SIDS has campaigned against bed sharing because of the reported risk for roll-over deaths and the need for additional studies.<sup>142</sup>

## MOUTH PROBLEMS

Alveolar lymphangiomas are elevations along the alveolar ridge that are isolated, bluish, firm cysts 3 to 10 mm in diameter. More than one may be present. They may interfere with suckling. They contain no dental tissue and gradually disappear in the first year. Breastfeeding is less influenced than bottle and pacifier sucking.

## ORAL HEALTH

Oral health risk assessment has been recommended by the Section on Pediatric Dentistry of the AAP with the establishment of a dental home by 1 year of age.<sup>9</sup> Visits are recommended to begin at 7 to 9 months. Recommendations include systematic examination and oral fluoride, elimination of simple sugars in the diet, and initiation of oral hygiene early. The infant is not colonized until the eruption of the primary teeth. Caries are associated with *Streptococcus mutans* and usually occur at the age of 2 years. High caries rates run in families, usually passed mother to child; 70% of caries occur in 20% of children. Children who sleep with the mother and nurse throughout the night are at higher risk, especially if the mother is prone to caries.

### *Nursing Bottle Caries in Breastfed Infants*

The development of rampant dental caries can occur in breastfed infants.<sup>26</sup> Usually the children have been nursed for 2 or 3 years, spending long stretches at the breast. One infant had early signs at 9 months, and by 18 months she required full mouth reconstruction.

A physician should be alert to the potential for dental decay when infants nurse frequently, especially through the night. Family history of dental

enamel problems is worth investigating. Certainly these children are candidates for fluoride treatment.

The levels of mutant streptococci in saliva and plaque are higher in children with rampant cavities than in control subjects.<sup>102</sup> All breastfed infants have mutant streptococci and lactobacilli on their teeth. Tooth susceptibility is genetically programmed. Children with a strong family history of caries may need fluoride supplements while breastfeeding.<sup>43</sup> They are at special risk if they suckle all night beyond 1 year of age. The most cariogenic solutions are soda, fruit juice, sweetened cow milk, chocolate milk, and sugar water. If a mother is prone to caries, it increases the risk to the infant, not just because of family history but by sharing cariogenic bacteria.

Ankyloglossia is a short lingual frenulum that results in restricted range of tongue movement, especially forward protrusion and lateral mobility. The incidence is estimated at between 3% and 10%. It is discussed in Chapter 8, but the concern for breastfeeding infants has precipitated controversy about the frequency of feeding difficulties, later speech problems, and concerns about swallowing. Nipple pain is the most common cause for considering frenulotomy. In addition to maternal pain, the infant may have trouble with latching and suboptimal weight gain; 24 mother-infant dyads with these symptoms received supplemental ultrasound scans of the oral cavity before and 7 days after frenulotomy.<sup>56</sup> Milk transfer, pain, latch, swallowing, shape of nipple, and comfort were recorded. Milk intake was also measured by test weighing. Significant improvement was recorded by all dyads. The infants demonstrated less compression of the nipple by ultrasound after frenulotomy. The diagnosis was confirmed by ultrasound before the surgery.

Use of the Hazelbaker Assessment Tool for Lingual Frenulum Function has been reviewed by many clinicians.<sup>67</sup> More than 3000 patients were examined by Ballard et al.,<sup>17</sup> who found 123 dyads who fit the description by Hazelbaker criteria. They received frenulotomies with latch improvement in all cases and pain reduced in most. Amir et al.<sup>11</sup> also used the Hazelbaker scoring tool and found that using part of the tool worked well in assessing 58 dyads.

## CHAPTER 15

# Premature Infants and Breastfeeding

---

### *Premature Infants*

The data are overwhelming. Even the most reluctant of neonatologists have accepted the tremendous importance of human milk to all infants large and small.

Research in the science of nutrition for low-birth-weight (LBW) infants and micropremature infants has advanced tremendously as the technology to study the important questions has improved. Neonatologists meanwhile have spent the past decades studying the physiology of respiration. Their advances have contributed to the survival of smaller and smaller infants. The edge of viability is 24 weeks and a weight of 500 g; however, infants have survived under these values. One of the key points learned retrospectively about survival, generation after generation, has been the critical impact of fluid and nutrition. Although human milk has gained prominence in these studies, the early use of unsupplemented drip milk and some donor milks produced poor growth patterns. Drip milk is low in fat and, therefore, low in calories. The protein levels in donor milk from women late in lactation (i.e., beyond 6 to 8 months, when the levels have dropped) parallel a child's decreased biologic needs with the addition of solid foods. These factors contributed to the abandonment of human milk until supplements were developed and studies of the milk of women who had delivered prematurely sparked new investigations.

This discussion highlights only the important issues; the reader is referred to reviews such as the exhaustive summary of human milk for the premature infant in the technical review of the optimal

feeding of LBW infants for the World Health Organization (WHO) by Edmond and Bahl<sup>36</sup> that was released in 2006. Policy statements from WHO, UNICEF, and other international and national organizations confirm the importance of providing a mother's own milk to preterm and small-for-gestational-age (SGA) infants. Standard practice in neonatal units is to promote mother's own milk as the food of choice for all LBW infants.<sup>130</sup> Edmond and Bahl state that their review confirms this position worldwide. *Nutritional Needs of the Preterm Infant* by Tsang et al.<sup>132</sup> is an international collaboration that involved many major premature infant centers in discussions to create unity out of a tremendous disparity of practice and various recipes for nutritional support in 1993. This collaboration also produced a consensus on individual nutrient requirements for infants of less than 1000-g birth weight, for 1000- to 1750-g infants, and for post-discharge management. In spite of these strong statements, however, neonatologists have not reached a consensus on the feeding of premature infants.<sup>69</sup> The absolute standard for evaluating the nutritional outcome of preterm infants remains undefined. A strategy to minimize mobilization of endogenous nutrient stores is moving from a focus on intrauterine-based, short-term growth and nutrient retention rates to a system that considers long-term growth achievement.<sup>102</sup> The optimal time to initiate oral feedings in the smallest and sickest preterm infants is under revision.<sup>97</sup> Prolonged exclusive parenteral nutrition is being replaced with minimal amounts of oral feedings with parenteral nutrition to preserve and maintain intestinal function. As nutritional markers shift, a preterm infant's own mother's milk may well be recognized, even by

the most skeptical clinicians, as the "gold standard" to prevent short-term morbidities and enhance long-term outcome. With this change comes the recognition that even fortified donor milk is superior to artificial feeds.

LBW has been defined by WHO as a weight at birth of less than 2500 g. The global incidence of LBW is 15.5%, which includes 20.6 million infants born each year, only 35% of which occur in developed countries. LBW infants form a heterogeneous group, some born early, some who are born at term but are SGA, and some both early and small. LBW infants account for 60% to 80% of all neonatal deaths and are at high risk for early growth retardation, infectious disease, developmental delay, and death in infancy and childhood.

A normal full-term infant can usually be breastfed with only minor adjustments, even without the support of medical expertise. When an infant cannot nurse directly at the breast, is providing mother's milk appropriate? What is the overall prognosis for ever feeding at the breast or, perhaps, for survival itself? Parents are so awed by the medical staff of special and intensive care nurseries that they are often afraid to bring up the subject of breastfeeding. In addition, the nursery staff may be so busy balancing electrolytes and adjusting ventilators and monitors that they have not thought to ask what plans the mother might have had for feeding before the infant developed a problem ([Table 15-1](#)).

The birth of an extremely LBW (ELBW) premature infant is a nutritional emergency. Even with parenteral nutrition from the first day, weight loss exceeds 10%, and it takes at least 10 days to regain birth weight. The long-term consequences of early

nutrition have a great impact on neurodevelopment and may well reduce the risk for perinatal brain lesions. Fetal and postnatal events affect gut development.

## Gastrointestinal Tract Development

The gastrointestinal (GI) tract is one of the first structures defined in the developing embryo. Gut length proceeds rapidly throughout fetal life and for the first years of life. The proton pump is present at 13 weeks of gestation. Intrinsic factor and pepsin are identifiable a few weeks later ([Figure 15-1](#)). Even in ELBW premature infants, the gastric pH can be lowered to 4.0. Digestive enzymes are capable of intraluminal digestion of fat, protein, and carbohydrates. Although pancreatic lipase and bile salts are minimal in ELBW infants, the introduction of mother's milk will stimulate maturation and also provide lipases and other digestive enzymes.

The intestinal villi and cellular differentiation occur at about 10 to 12 weeks' gestation and begin a complex interrelationship with developing epithelium and the mesoderm, according to Newell.<sup>111</sup> Lactase and other carbohydrate enzymes begin to appear. Gut motility is believed to appear first as irregular GI activity at 23 weeks progressing to organized motility at approximately 28 weeks. Most studies of nutritive sucking and swallowing are done with artificial feeding with a bottle. Suckling at the breast, which begins with peristaltic motion of the tongue and continues down the esophagus, has been initiated by breastfeeding as early as 28 weeks or sooner.

**TABLE 15-1** Risks of Neonatal Mortality According to Timing of Initiation of Breastfeeding in Singletons Who Initiated Breastfeeding and Survived to Day 2

Initiation of Breastfeeding	No. of Infants (%)	No. of Deaths (% risk) <sup>*</sup>	aOR 1 (95% CI) <sup>†</sup>	aOR 2 (95% CI) <sup>‡</sup>
Within 1 h	4763 (43)	34 (0.7)	1	1
From 1 h to end of day 1	3105 (28)	36 (1.2)	1.45 (0.90-2.35)	1.43 (0.88-2.31)
Day 2	2138 (20)	48 (2.3)	2.70 (1.70-4.30)	2.52 (1.58-4.02) <sup>\$</sup>
Day 3	797 (7.3)	21 (2.6)	3.01 (1.70-5.38)	2.84 (1.59-5.06) <sup>\$</sup>
After day 3	144 (1.3)	6 (4.2)	4.42 (1.76-11.09)	3.64 (1.43-9.30) <sup>\$</sup>
Total	10,947 (100)	145 (1.3)		
			$p_{LRT} < 0.0001$	$p_{LRT} = 0.0001$
			$p_{trend} < 0.0001$	$p_{trend} < 0.0001$

\*% risk, number of deaths/number of infants in exposure category.

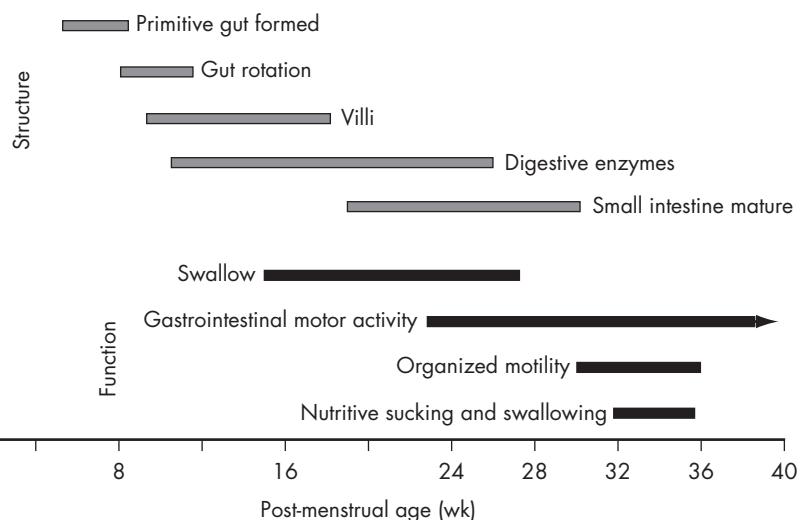

<sup>†</sup>Adjusted for sex, birth size, gestational age, presence of a congenital anomaly, health on the day of birth, health at the time of interview, mother's health at the time of delivery, age of mother, parity, educational level of mother, mother having cash income, household water supply, place of defecation, number of antenatal visits, place of birth, and birth attendant.

<sup>‡</sup>Adjusted for all factors mentioned previously plus established breastfeeding pattern.

<sup>\$</sup>The combined aOR for initiation of breastfeeding after 1 day was 2.88 (95% CI, 1.87 to 4.42).

aOR, Adjusted odds ratio; CI, confidence interval; LRT, likelihood ratio test.

Edmond KM, Zandoh C, Quigley MA, et al: Delayed breastfeeding initiation increases risk of neonatal mortality, *Pediatrics* 117:e380, 2006.

**Figure 15-1.** The ontogenetic timetable showing structural and functional gastrointestinal development. (Modified from Newell SJ: Enteral feeding of the micropremie, *Clin Perinatol* 27:221, 2000.)

#### BOX 15-1. Factors Affecting Gastric Emptying

Faster gastric emptying	No effect	Slower gastric emptying
Breast milk	Phototherapy	Prematurity
Glucose polymers	Feed temperature	Formula milk
Starch	Nonnutritive sucking	Caloric density
Medium-chain triglycerides		Fatty acids
Prone position		Dextrose concentration
		Long-chain triglycerides
		Osmolality
		Illness

Gastric emptying in premature infants is slow, generating the impression that feedings are not tolerated. Gastric emptying is enhanced by human milk and slowed by formula and increased osmolarity (Box 15-1). Half emptying time with human milk is reported to be as rapid as 20 to 40 minutes.<sup>70</sup> Ultrasound studies have assessed small volume feeds. Some premature infants show delayed antral distention after a nasogastric feeding with emptying that follows a curvilinear pattern after an initial rapid phase.

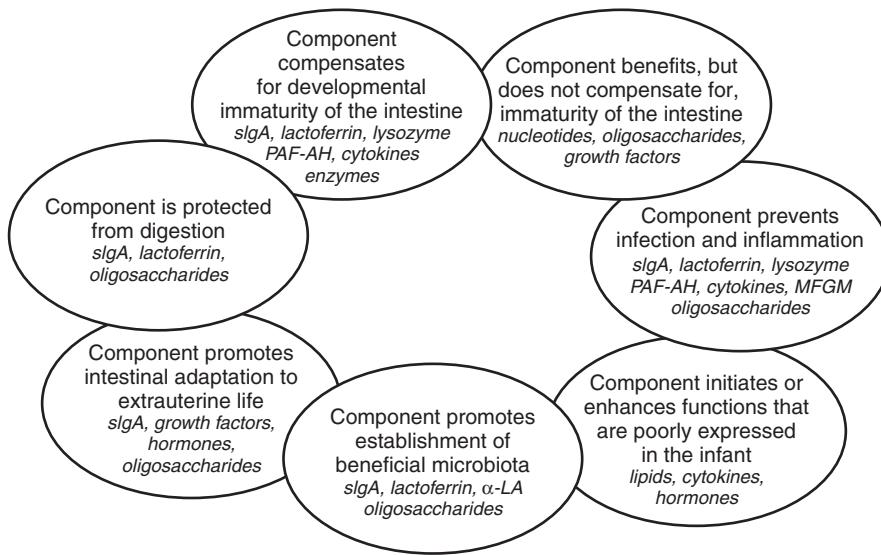

Maturation of the small intestinal motility, and hence tolerance of feeds, is enhanced by previous exposure of the gut to nutrition. Early feeding precipitates preferential maturation and thus a more mature response to feeds. Total gut transit time in premature infants varies from 1 to 5 days and is more rapid in those who have received food.<sup>12</sup> In those younger than 28 weeks, it takes 3 days to pass meconium. Breast milk feedings, however, increase motility and stool passage.

When prematurity is complicated by intrauterine growth failure, the resultant cascade of events includes decreased splanchnic circulation and oligohydramnios, poor gut perfusion, decreased growth of the small intestine and pancreas culminating in a fetal echogenic gut, and poor intestinal motility resulting in poor tolerance to milk feeds. It is not uncommon for this to result in necrotizing enterocolitis (NEC). These events require careful consideration, including the choice to use mother's milk, especially beginning with colostrum.

Although feeding regimens vary, evidence is strong and consistent that feeding mother's own milk to preterm infants at any gestation is associated with a lower incidence of infections and NEC and improved neurodevelopmental outcome compared with the use of bovine milk products.<sup>36</sup> The challenge is to increase the availability of mother's milk (Figure 15-2).

#### GI Priming

When feedings are delayed in any newborn, luminal starvation results in epithelial cell atrophy. Lung injury may aggravate this because of multiorgan system dysfunction, increasing the risk for intestinal mucosal injury and associated barrier dysfunction. The ultimate injury would be the invasion of bacteria from the gut lumen.<sup>21</sup> Initiating feeds is a delicate balance between insufficient feeds that fail to trigger gut maturation and excessive feeds that overwhelm the digestive capacity. Also, excessive feeds can result in bacterial overgrowth and injury to the brush border.<sup>21</sup> When internal nutrients are absent, the intestinal size and weight are

**Figure 15-2.** Strategies for beneficial effects of bioactive agents in human milk. Human milk contains bioactive agents with overlapping and synergic effects on intestinal development of neonates. *MFGM*, Milk fat globule membrane; *PAF-AH*, platelet-activating factor-acetylhydrolase. (Modified from Goldman AS: Modulation of the gastrointestinal tract of infants by human milk. Interface and interactions. An evolutionary perspective, *J Nutr* 130:426S, 2000.)

diminished, atrophy of the mucosa, delayed maturation of intestinal enzymes, and increased permeability and bacterial translocation may occur. Intestinal motilities, perfusion, and reactions to the usual GI trophic hormones are also affected by lack of nutrients. Trophic hormone levels in the plasma are significantly altered by starvation.

In the words of Lucas,<sup>83</sup> "It is fundamentally unphysiological to deprive an infant of any gestation of enteral feeding since the deprivation would never normally occur at any stage." This statement is based on the fact that a fetus normally makes sucking motions and swallows amniotic fluid from early gestation. This may even have a trophic effect on the gut. By the third trimester, a fetus is swallowing up to 150 mL/kg/day, which actually provides as much as 3 g/kg of protein per day. The secretion of GI hormones is believed to occur in response to the first postdelivery feedings.<sup>132</sup> In animals, after only a few days of deprivation of enteral feeds, atrophic changes take place in the gut.<sup>85</sup> In human infants who have never received enteral feedings, no gut peptide surges occur, not even those of the trophic hormones enteroglucagon, gastrin, and gastric inhibitory polypeptide. These hormones are believed to be key to the activation of the enteroinsular axis<sup>85</sup> (Box 15-2). Clinical trials of early priming in premature infants showed that infants primed in the first few days or first week had better feeding tolerance to advancing feeds and were weaned from parenteral nutrition promptly. It was also associated with lower serum alkaline phosphatase activity and significant stimulation of GI

#### BOX 15-2. Biology of the Gut in VLBW Infants

- Swallows amniotic fluid daily, up to 150 mL/kg/day
  - Potential for gut atrophy if not fed
  - All of gastrointestinal track is immature
  - Enzymes and nutrients in human milk enhance maturation
  - Higher total body water, muscle mass, growth accretion rates, and oxygen consumption
  - Higher evaporative water loss due to greater surface area
  - Prone to hyperglycemia due to poor insulin response
  - Lower brown fat reserves and glycogen stores
  - Immature thyroid control of metabolic rate
- VLBW, Very low-birth-weight.

hormones such as gastrin. It also resulted in more mature intestinal motility patterns, greater absorption of Ca and P, increased lactase activity, increased bone mineral content (BMC), and reduced intestinal permeability. Tyson and Kennedy<sup>133</sup> reviewed the studies of early priming and found shorter times to full feeding, fewer days when feedings were held, a shorter duration of hospitalization, and no increase in NEC. Many of the involved infants were actually at high risk for complications by virtue of their own morbidities, including mechanical ventilation, umbilical catheterization, and patent ductus arteriosus. Schanler<sup>123</sup> recommended that ELBW infants who are ill be

**BOX 15-3. Advantages of Gastrointestinal Priming**

- Shortened time to regain birth weight
- Improved feeding tolerance
- Reduced duration of parenteral nutrition
- Enhanced enzyme maturation
- Reduced intestinal permeability
- Improved gastrointestinal motility
- Matured hormone responses
- Improved mineral absorption, mineralization
- Lowered incidence of cholestasis
- Reduced duration of phototherapy

**BOX 15-4. Advantages of Priming with Mother's Milk**

- Earlier use of mother's milk
- Mothers begin milk expression earlier
- Infants receive more mother's milk
- Psychological advantage for mother's safety

Modified with permission from Schanler RJ, Anderson D: The low-birth weight infant in patient care. In Duggan C, Watkins JB, Walker WA, editors: *Nutrition in pediatrics*, ed 4, Hamilton, 2008, BC Decker.

given small volumes, 10 to 20 mL/kg/day, in the first few days of life to continue for 3 to 7 days before advancing the feeds. Clinical stability is required before advancing the feeds. These volumes are compatible with the volume of mother's milk of a mother of a premature infant (Boxes 15-3 and 15-4). In a randomized trial of GI priming and the tube-feeding method, bolus feeding was found to be superior, the major outcome being time required to attain full oral feedings. GI priming was not associated with adverse effects. Feeding intolerance was less and the rate of weight gain was greater. The greater the amount of human milk fed, the lower the morbidity.

Although early enteral feedings are not universally accepted, a number of randomized controlled studies support the concept. Berseth<sup>12</sup> reports that the response of the preterm infant's intestine to entire feedings at different postnatal ages showed significantly more mature motor patterns of the gut as well as higher plasma concentrations of gastrin and gastric inhibitory peptide. From a management standpoint, early-fed infants were able to tolerate full oral feeds sooner, had fewer days of feeding intolerance, and required shorter hospital stays. Studies varied from infants who were fed at less than 24 hours of age at 1 mL/h to infants who were fed full feeds starting at days 2 to 7 compared with infants on usual delayed protocols. All

showed an advantage to early feeds<sup>85</sup> (Table 15-2 and Box 15-5).

Requirements of ELBW infants begin with water, the first great need, followed by energy requirements of 120 kcal/kg/day to meet metabolic and growth rates. Protein is key because ELBW infants miss the last trimester, when protein and fat are stored. To stop catabolism and promote protein accretion, Brumberg and LaGamma<sup>21</sup> recommend 3.5 to 4 g/kg/day of protein, presuming a daily loss of 1.1 to 1.5 g/kg of stored protein per day. Protein should start early either orally or by parenteral nutrition.

Human milk is the preferred feeding for all infants, including premature and sick newborns, with rare exception according to the American Academy of Pediatrics (AAP),<sup>4</sup> WHO, and the Institute of Medicine.

Human milk is better than formula in early feeds in establishing enteral tolerance and discontinuation of parenteral nutrition, in long-term improved neurodevelopmental outcome, and in the psychological benefit to mothers. Human milk falls short after 4 to 6 weeks in the amount of protein, calcium, and phosphorus, a problem solvable with the use of a human milk fortifier. No substitute has been developed that replaces the many and varied advantages of human milk, however.

Many investigators have concluded that minimal enteral feedings with human milk can optimize growth, development, and progress for small premature infants, even if ventilator dependent.<sup>85</sup> In most studies, the incidence of NEC has been similar with and without early feeds.<sup>83</sup> The presence of an umbilical catheter has long been a contraindication to feeding because of the risk for NEC. When Davey et al.<sup>30</sup> investigated this, the incidence of NEC was comparable in infants with and without umbilical catheters.

Other advantages of early feeds include lower serum direct and indirect bilirubin and less phototherapy. Benefits from early feeds were measurable with raw maternal milk, pasteurized premature milk, and even to some extent whey-dominant infant formula (Figure 15-3).

## *Low Birth Weight (LBW) Infants*

All premature infants are not the same. Infants who are born weighing less than 2500 g are referred to as being low birth weight (LBW). If the infants are less than 37 weeks' gestation, they are premature; if they are full term and LBW, they are SGA.

Very LBW (VLBW) refers to an infant weighing less than 1500 g. The probability of survival has changed dramatically in all weight ranges. With the availability of surfactant for respiratory distress,

#### BOX 15-5. Published and Putative Effects of Early Enteral Intake of Infants Weighing Less Than 1500 g

- No change in necrotizing enterocolitis incidence
- Less cholestatic jaundice
- Less osteopenia
- Less physiologic jaundice
- Increased glucose tolerance
- Better weight gain
- Earlier tolerance of full oral nutrient intake
- Increased gut hormones: gastric inhibitory peptide, enteroglucagon, gastrin, motilin, neurotension
- Induction of digestive enzyme synthesis and release
- Improved antral-duodenal coordination of peristalsis
- Allows gut colonization (vitamin K production) and avoids germ-free gut complications
- Earlier maturation of brush border barrier qualities
- Prevents atrophy and attendant effects of starvation

**Figure 15-3.** Episodes of apnea and bradycardia before and after initiation of transpyloric tube feedings especially when limited to human milk. (From Malcolm WF, Smith PB, Mears S, et al: Transpyloric tube feeding in very low birthweight infants with suspected gastroesophageal reflux: impact on apnea and bradycardia, *J Perinatol* 29:372, 2009.)

infants between 500 and 1000 g are surviving in greater numbers. The problems of nutrition, however, pose new challenges to the neonatologist. The feedings appropriate for a 2000-g premature infant vary only in volume and frequency from full-term infants in most cases. Feedings for VLBW infants must address the advantages and disadvantages of human milk at this point in their growth

curve. The composition of mother's milk varies in some constituents with the degree of prematurity, which is advantageous (Box 15-6).

The advantages of human milk for LBW infants include the physiologic amino acid and fat profile, the digestibility and absorption of these proteins

**BOX 15-6. Milk of Mothers Who Deliver Preterm**

and fats,<sup>119</sup> and the low renal solute load. The presence of active enzymes enhances maturation and supplements the enzyme activity of this underdeveloped gut. The antiinfective properties and living cells protect immature infants from infection and protect against NEC. The psychological benefit to the mother who can participate in her infant's care by providing her milk is a less tangible but no less important advantage.

The disadvantages are the possible gaps in certain nutrients that have been estimated to be required for adequate growth, which include the volume of total protein and macrominerals, especially calcium and phosphorus.<sup>43-45</sup> Much of the attention to the shortcomings has been based on work done using pooled milk samples collected from women whose infants are full term and many months old, resulting in the impression that mother's milk is inadequate. The sources of the human milk and processing—freezing or pasteurizing—are significant to the question of nutritional adequacies. Many laboratory and clinical scientists have studied the questions posed here with new techniques and provided hundreds of reports regarding the nutrition and nurturance of LBW and VLBW infants. Only a fraction of the resources can be referenced here.<sup>13,44</sup>

### Optimal Growth for Premature Infants

Optimal growth for infants born prematurely is considered to be the growth curve they would have followed had they remained in utero<sup>45</sup> (Figure 15-4)

**Figure 15-4.** Postnatal bone mineral content (BMC) in 33- to 35-week-old appropriate-for-gestational-age or preterm infants compared with intrauterine bone mineralization curve. Regression curve and 95th percentile confidence limits for regression for BMC of infants born at different gestational ages (30 to 42 weeks' gestational age) represent intrauterine bone mineralization curve. Infants fed routine cow milk formula (solid triangles) had significantly lower BMC than infants fed standard formula supplemented with calcium and phosphorus (solid circles). In these infants, BMC was not different from intrauterine bone mineralization curve at 4 and 6 weeks' postnatal age. (From Steichen JJ, Gratton TL, Tsang RC: Osteopenia of prematurity: the cause and possible treatment, *J Pediatr* 96:528, 1980.)

and Tables 15-3 and 15-4). Achieving this goal utilizing the immature intestinal tract requires that the nutrients be digestible and absorbable and not impose a significant metabolic stress on the other immature organs, especially the kidney. Although human milk provides the ideal nutrients, it would require an inordinate nonphysiologic volume to achieve adequate amounts of some nutrients without calculated supplementation. To fill these growth needs, one can use an artificial or chemical formula or use human milk as a base, with all its advantages, and add the deficient nutrients to it.

### Special Properties of Preterm Milk

The identification of special quantitative differences in nutrients in the milk of mothers who

\*Body weight of 26-week fetus is 1000 g and of 40-week fetus is 3500 g.

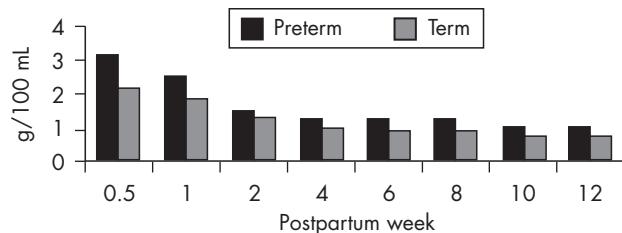

Modified from data of Widdowson from Heird WC, Anderson TL: Nutritional requirements and methods of feeding low birth weight infants. In Gluck L et al., editors: *Current problems in pediatrics*, vol. 7, no. 8, Chicago, 1977, Year Book, pp 1-4.

delivered prematurely created new interest in the use of human milk for premature infants (see **Box 15-6**). Many investigators have contributed to the pool of knowledge after the initial revelations

in 1980 by Atkinson et al.<sup>8</sup> who reported the nitrogen concentration of milk from mothers of premature infants to be greater than that of milk from mothers delivering at term.<sup>9,14</sup>

Preterm milk is higher in protein content during the first months of lactation, containing between 1.8 and 2.4 g/dL. Preterm milk contains similar fat in quality and quantity, although Anderson et al.<sup>5</sup> reported increased values for preterm milk over term milk. Lactose in preterm milk averages 5.96 g/dL and up to 6.95 g/dL at 28 days, whereas the values in term milk are 6.16 and 7.26 g/dL, respectively. Preterm milk has higher energy than term milk, 58 to 70 kcal/dL, compared with 48 to 64 kcal/dL in the first month postpartum (**Figure 15-5**).

The macronutrients calcium and phosphorus are slightly higher in preterm milk (14 to 16 mEq/L vs. 13 to 16 mEq/L calcium and 4.7 to 5.5 mL vs. 4.0 to 5.1 mL phosphorus). Neither term nor preterm milk has adequate calcium and phosphorus for the VLBW infant. Magnesium levels in preterm milk are 28 to 31 mg/L, dropping to 25 mg/L at 28 days, and term milk levels are 25 to 29 mg/L. Zinc levels are higher in preterm milk, beginning at 5.3 mg/L and dropping to 3.9 mg/L, whereas term milk begins at 5.4 mg/L and drops to 2.6 mg/L. Sodium levels in preterm milk are higher (26.6 mEq/L, dropping to 12.6 mEq/L), whereas term milk is 22.3 mEq/L, decreasing to 8.5 mEq/L at 28 days.<sup>106</sup> Chloride has a similar average (preterm 31.6 mEq/L, decreasing to 16.8 mEq/L, and term 26.9 mEq/L, decreasing to 13.1 mEq/L).

**Figure 15-5.** Protein content of human milk. (Data from Butte NF, Garza C, Johnson CA, et al: Longitudinal changes in milk composition of mothers delivering preterm and term infants, *Early Hum Dev* 9:153, 1984; Gross SJ, David RJ, Bauman L, Tomarelli RM: Nutritional composition of milk produced by mothers delivering preterm, *J Pediatr* 96:641, 1980.)

## REQUIREMENTS FOR GROWTH IN PREMATURE INFANTS

The whey protein in human milk is an advantage for all infants but especially for premature infants. It includes the nine amino acids known to be essential to humans, as well as taurine,<sup>129</sup> glycine, leucine, and cystine, which are considered essential for premature infants. Taurine is not present in cow milk and has to be manufactured and added to formula.<sup>97</sup> The premature infant lacks the necessary enzymes for metabolism and has been noted to accumulate nonphysiologic levels of methionine, tyrosine, phenylalanine, blood urea, and ammonia. When fed formula, the protein requirement for LBW infants based on intrauterine accretion rates is 2.5 g/100 kcal or 325 mg/kg of body weight per day. The metabolizable energy requirement is 109 kcal/kg/day. Further study has led to the recommendation of 3.2 to 4 g/kg/day<sup>72</sup> because VLBW infants' protein requirements have to be considered in combination with energy intake. If energy intake is deficient, protein synthesis can be depressed and protein retention reduced. Greater protein intake is risky if energy intake is limited. LBW infants fed mother's milk exclusively for 2 weeks have been found to have low protein. This has led to the need to supplement human milk when the infant has reached full tolerated volumes (150 mL/kg/day). Protein content of human milk on average is 1.09 g/dL, whereas fortified human milk is 2.2 g/dL. Fortified milk can achieve 3 to 3.5 g/kg/day; however, in some cases 4 g/kg/day may be necessary.<sup>117</sup> Although formula has more protein, it is not well absorbed.

A diurnal variation in the creamatocrits (see Chapter 21) of expressed breast milk of mothers delivering prematurely was demonstrated in 23 mothers by Lubetsky et al.<sup>80</sup> The creamatocrit was significantly higher in the evening—7.2% ± 2.0% compared with first morning samples, 5.4% ± 1.2% ( $p < 0.001$ )—regardless of gestational age or birth weight.

Fat content of mother's milk is not affected by fetal growth of the infant. Fifty-six lactating women of newborns (26 SGA and 30 AGA [appropriate-for-gestational-age]) had their creamatocrits measured on the third day postpartum and again at 7 and 14 days.<sup>34</sup> Other parameters (maternal age, body mass index, gestational age, weight gain, or parity) were similar except for birthweight for gestational age (SGA or AGA). Fat content of the milk was not affected by fetal growth status.

The requirement for fat is based on the essential fatty acid proportion as 3% of total caloric intake. Human milk has high levels of linoleic acid (9% of lipids) and adequately meets this requirement. Human milk fat is more readily absorbed in the

presence of milk lipase and other enzymes in human milk. It is reported that infants less than 1500 g absorb 90% of human milk fat and 68% of cow milk formula fats.<sup>104</sup> This phenomenon is due to the fact that human milk has a very special fat globule containing another protein coat and inner lipid core (see Chapter 4). The pattern of fatty acids (i.e., high in palmitic 16:0, oleic 18:1, linoleic 18:2 omega-6, and linolenic 18:3 omega-3), their distribution on the triglyceride molecule, and the presence of bile salt-stimulated lipase characterize the lipid system in human milk.<sup>67</sup> The presence of lipase in human milk facilitates the fat digestion and absorption. Lipase is heatable, is reduced in activity in donor milk, and does not exist in formula. So, although formula has higher levels of fat, it is not as well absorbed or metabolized.

Fat digestion is efficient in LBW infants who receive their own mother's milk fresh and untreated. Fat absorption is decreased by calcium supplementation, however, and by sterilizing the milk. If human milk is supplemented with lipids, it will change the vitamin E/polyunsaturated fatty acid (PUFA) ratio. Vitamin E may need to be added to keep the vitamin E/PUFA ratio greater than 0.6 (human milk vitamin E/PUFA is 0.9 normally).<sup>56</sup>

Special attributes of human milk for VLBW infants have been confirmed as investigators inspect the value of adding nutrients to formulas specifically for these infants.<sup>134</sup> In a study of omega-3 fatty acids on retinal function using electroretinograms, human milk was associated with the best function, followed by formula supplemented with omega-3 fatty acids. This supports the concept that omega-3 fatty acids are essential to retinal development.<sup>15</sup>

Although human milk contains 250 mg Ca and 140 mg/L P in ready absorbable form, preterm and term milk do not contain sufficient calcium and phosphorus for bone accretion in LBW infants. Rickets has developed in LBW infants who are not supplemented because the requirement for bone growth at this point in the growth curve is high. Calcium and phosphorus fetal accretion increases steadily during the last trimester of pregnancy. Magnesium accretion is unchanged in that period.

Mineral accretion is a complex phenomenon dependent on a number of variables beyond simple levels of calcium, phosphorus, magnesium, and vitamin D.<sup>1</sup> Absorption and retention are altered by the quantities of other minerals and other nutrients, including fat, protein, and carbohydrate. Although the calcium/phosphorus ratio in human milk is more physiologic than that of cow milk, the low levels of phosphorus may lead to loss of calcium in the urine if not supplemented.<sup>125</sup>

Even with optimal vitamin D and magnesium, the amount of calcium absorbed from preterm milk is not enough to meet intrauterine accretion rates without supplementation. Because human milk phosphorus levels are low, even with high intestinal absorption and high renal tubular reabsorption, compared with the needs of the premature infant, supplementation is necessary to avoid depletion or deficiency.<sup>22</sup> Intrauterine accretion rates for calcium and phosphorus were achieved when Schanler and Abrams<sup>122</sup> fed human milk supplemented with calcium gluconate and glycerophosphate to VLBW infants. In their study, supplementation with magnesium was not included. The authors concluded that greater intakes of calcium and phosphorus and not improved bioavailability were responsible for the improved net retention. Premature infants who receive only unfortified human milk never achieve intrauterine retention rates of Ca and P.<sup>123</sup>

Vitamin D requirements in this period of high skeletal development depend on maternal vitamin D status because significant correlation exists between maternal serum and preterm infant cord serum 25-hydroxyvitamin D values. Recommendations for vitamin D have changed dramatically. No longer are maternal stores considered adequate. Work by Wagner et al.<sup>137</sup> has demonstrated that average women, even with a healthy lifestyle, have low vitamin D levels and thus their infants are relatively deficient at birth, especially infants born prematurely. The milk was also low in vitamin D. The recommended daily dose of vitamin D for mothers is 1000 units. Obtaining vitamin D blood levels is simple and should be checked early in pregnancy and the dose adjusted. Because infants are no longer exposed to sunlight, dietary sources are crucial. LBW infants quickly become dependent on exogenous vitamin D because fetal storage is minimal. The recommended dietary allowance of 400 units of vitamin D appears to be appropriate for all LBW infants, regardless of feedings, as well as for term infants. The 2014 AAP Committee on Nutrition recommends 125 to 333 USP units of vitamin D for infants less than 1000 g and the same for infants more than 1000 g, varying the absolute value by the actual weight—larger infants receive the larger dose.

Other vitamin needs of LBW infants depend on body stores, intestinal absorption, bioavailability of the vitamin, and rates of utilization and excretion.<sup>46</sup> Little information suggests that major differences exist in absorption between term and LBW infants, although fat-soluble vitamins depend on bile acids for absorption. (See Chapter 9 for vitamin requirements.) It is recommended that LBW infants receive daily vitamin supplements to address the increased need and borderline levels provided in the volume of human milk they can reasonably consume (Box 15-7).

### BOX 15-7. Vitamin Supplements for Low-Birth-Weight Infants Fed Human Milk

- Vitamin B<sub>12</sub>: Only if mother's diet deficient
- Folic acid: Human milk usually adequate
- Thiamin (B<sub>1</sub>): Borderline
- Riboflavin (B<sub>2</sub>): Borderline
- Vitamin B<sub>6</sub>: Human milk usually adequate
- Niacin: Human milk usually adequate
- Vitamin A: 1000-1500 IU/day
- Vitamin C: If infant receives supplementary protein up to 60 mg/day
- Vitamin D: 400 IU/day
- Vitamin K: All infants should receive 0.5-1 mg at birth; recommended 5 mg/kg/day; human milk borderline
- Vitamin E: 25 IU/day for first month, 5 IU/day after first month; human milk adequate

IU, International units.

Intake (mg/kg/day)	242	81	5.70	246	81	5.37

\*Assuming a weight of 1000 g and 1250 g, respectively, in an infant fed human milk.

From Steichen JJ, Krug-Wispe SK, Tsang RC: Breastfeeding the low birth weight preterm infant, *Clin Perinatol* 14:131, 1987.

The mineral supplementation required for LBW infants fed human milk is based on intrauterine accretion rates, which may not actually be achieved (Table 15-5). Not all premature infants fed human milk develop rickets, which occurs infrequently in infants greater than 1500 g. VLBW infants do need supplementation, and cases of rickets are well documented in the literature for this group.<sup>122</sup> Supplements are usually not necessary while an infant is receiving fortified human milk or formula and when an infant reaches 40 weeks' postconceptional age. Hypophosphatemia is a sensitive biochemical indicator of low bone mineralization in VLBW infants fed human milk. Tsang et al.<sup>132</sup> recommend weekly measurements of serum phosphorus for the first month and biweekly until 2000 g or 40 weeks' gestation. A level less than 4 mg/dL phosphorus should

Data from Forbes GB: Nutritional adequacy of human breast milk for premature infants. In Lebenthal E, editor: *Textbook of gastroenterology and nutrition in infants*, New York, 1981, Raven, pp 321–329.

be followed by X-ray films of the wrists for osteopenia and rickets. Supplementation should be based on an infant's needs. Calcium levels should also be obtained weekly to evaluate levels greater than 11 mg/dL for too much calcium or too little phosphorus.<sup>122</sup> Supplements of calcium and phosphorus are incorporated in available human milk supplements derived from formula (Table 15-6). Now such supplementation is available from human milk products: Prolact CR, product of Prolacta (Figure 15-6 and Box 15-8) and Medolac (Box 15-9).

Trace minerals in general appear in physiologic amounts in human milk and are more bioavailable from human milk than artificial feedings. The minimum daily requirements for LBW infants are based

**Figure 15-6.** Prolact CR®. (Reproduced with permission from Prolacta Bioscience®.)

on daily accretion rates as calculated from third-trimester data and calculated obligatory losses.

Zinc is known to be readily available in human milk, although zinc deficiency syndromes from hyperalimentation are well known in the literature and in neonatal intensive care units (NICUs). Zinc requirements (1000 to 3000 mg/kg/day) are probably met by a mother's own milk, but pooled milk levels are lower because zinc levels drop from term birth through 6 months, and donor milk will need supplementation.

Copper accretion requires 59 mg/kg/day, and absorption is thought to be 50% to 70%. Copper levels also decline in milk from term to 6 months postpartum. It is recommended that VLBW infants receive an additional 30 to 40 mg/day or 120 to 150 mg/kg/day of copper for the first 3 months.<sup>132</sup>

Manganese represents an apparent deficiency because the minimum daily requirement is calculated to be 7 ng/kg/day. The provision in human milk is 0.35 ng/mL, or 0.5 mg/kg/day, but no information is available recommending supplementation.<sup>39</sup>

The selenium suggested requirement is 1.5 to 2.5 mg/kg/day (1 mg minimum). Human milk provides 1 to 2 mg/dL and is stable throughout lactation, so no supplementation has been recommended.<sup>53</sup>

Iodine levels in human milk are sufficient to meet daily requirements in LBW infants.

Chromium requirements are calculated to be 1.0 to 2.0 mg/kg/day based on an accretion rate of 0.1 to 0.2 mg/kg/day and only 10% absorption. Levels in human milk are reported to be 0.03 mg/dL, which, with 150-mL/kg/day intake, would supply 0.045 mg/kg/day. Supplementation is not usually provided, and absorption in human milk is probably greater than 10%.

Molybdenum levels in human milk are believed sufficient to meet LBW accretion rates (1 mg/kg/day).

Iron requirements are a complex issue, and intrauterine accretion rates are not appropriate values on which to base requirements.<sup>64,115</sup> Iron stores partially enlarged by hemoglobin breakdown in early life will eventually be used up if no iron is provided. Providing iron, however, interferes with the immunologic properties of human milk, especially the bacteriostatic properties of lactoferrin in the gut.

The recommendations for iron supplementation for infants receiving human milk (either own mother's or donor milk, which are similar in iron) are based on age and weight of the infant. Supplementation should begin at 2 to 3 months or when birth weight has doubled. For birth weight less than 1000 g, infants should receive 4 mg elemental iron/kg/day; infants weighing 1000 to 1500 g should receive 3 mg/kg/day.<sup>64,115</sup>

**BOX 15-8. Prolact CR® 10 mL Human Milk Caloric Fortifier (Human, Pasteurized)****PRODUCT DESCRIPTION**

- Prolact CR is pasteurized human milk cream derived from human milk. It is composed of 25% fat and provides 2.5 Cal/mL. It contains no added minerals.
- Store at: -20°C or colder until ready to thaw for preparation and use.
- Available frozen in 30 mL bottles containing 10 mL of product (four bottles per package).

**INTENDED USE**

Prolact CR is intended for use with mom's own breast milk or donor human milk to achieve a 20 Cal/fl oz feeding solution.

**DIRECTIONS FOR THAWING**

*Under no circumstances should the product be defrosted or warmed in a microwave.*

Remove bottle from the freezer and label with date and time. Thaw product using any of the following methods:

- Refrigeration: (2°C to 8°C) Place unopened bottle in refrigerator. Once thawed, must be administered within 24 hours. Do not refreeze, keep refrigerated.
- Rapid Thawing: Place bottle under lukewarm running water, or place in a water bath. Do not submerge top of bottle. Warm only until product is thawed. Continued warming, or exposure to high temperatures, could result in undesirable changes to the product. Wipe outside of bottle with appropriate disinfectant to reduce the risk of contamination. Once thawed, keep refrigerated, do not refreeze. Product must be administered within 24 hours of thawing.

**INGREDIENTS**

Human milk cream and human milk ultrafiltration permeate.

**PREPARATION INSTRUCTIONS**

Always maintain aseptic technique when preparing and handling human milk products. \*\*DO NOT ADD WATER\*\*

- Thaw mom's own or donor milk according to hospital policy.
- Measure caloric content of mom's own or donor milk.
  - If using a commercial human milk analyzer, follow the manufacturer's instructions.
  - If using a creamatocrit, ensure the milk is room temperature and follow the manufacturer's instructions.
- Thaw Prolact CR according to "Directions for Thawing." Swirl gently prior to each aliquot.
- Based on the measured caloric content of mom's own or donor milk, follow the instructions in table below to formulate 100 mL of human milk plus Prolact CR.

Cal/oz (equivalent to)	Cal/ 100 mL	Mom's own or donor milk volume	+ Add to milk
19-20	64-67.9	98 mL milk	2 mL Prolact CR
18-18.9	61-63.9	96 mL milk	4 mL Prolact CR
17-17.9	57-60.9	94 mL milk	6 mL Prolact CR
16-16.9	54-56.9	93 mL milk	7 mL Prolact CR
15-15.9	51-53.9	91 mL milk	9 mL Prolact CR
14-14.9	47-50.9	90 mL milk	10 mL Prolact CR

- Swirl gently to mix.
- Once completed, the product is ready for use, OR
- Store bottle in refrigerator (2°C to 8°C). Use within 24 hours after thawing Prolact CR.

**BOX 15-9. Medolac® Offers Commercially Sterile, Shelf-Life-Stable Human Donor Milk as Easy-to-Use as Formula**

May 4, 2015—Medolac® Laboratories, an Oregon-based human milk nutritionals start-up, announced the launch of Donormilk.com, the first direct-to-consumer offering of human milk. Medolac's Co-op Donor Milk human milk is commercially sterile, safe, tested, homogenized, and can be stored at room temperature making it easier for home use. In addition, Medolac

human donor milk is less expensive and safer than donor milk bought from online classifieds and other milk banks where testing, safety, and nutritional content cannot always be verified. This new product will make it possible for more babies to receive 100% human milk protein instead of bovine or soy protein formula.

From Medolac <http://www.medolac.com/press-releases.html>, with permission.

It is necessary also to ensure adequate vitamin C and vitamin E supplementation (4 to 5 mg/day), even though human milk normally contains 5 mg/dL vitamin C and 0.25 mg/dL vitamin E. Vitamin C levels in mother's milk can be increased by dietary increases. However, vitamin C is affected by pasteurization.

**BRAIN GROWTH AND SUBSEQUENT INTELLIGENCE**

Although physical growth and plasma levels of nutrients have been closely scrutinized by investigators following nutrition in LBW infants,<sup>63</sup> adequate measurement of brain growth is not

currently possible except indirectly in long-range studies of neurodevelopment and intelligence. A carefully controlled, long-range study of preterm infants by Lucas et al.<sup>89,90</sup> in a 10-year period has produced some remarkable results. Mothers who provide their milk have a special desire to be good parents and embrace positive health behaviors, which has been suggested as the real cause of this study's measured differences. Several points deserve attention, however. LBW infants are born at a time of rapid brain growth. In fact, term infants have considerable brain growth in the first year of life, doubling the size of the brain by 1 year of age. Several nutrients in human milk have been associated with brain tissue growth, including taurine, cholesterol, omega-3 fatty acids, and amino sugars in the free and bound forms.<sup>56</sup> Amino sugars such as *N*-acetylneurameric acid are important constituents of brain glycoproteins and gangliosides.<sup>89,90</sup>

The Lucas studies<sup>89,90</sup> included infants weighing less than 1850 g at birth delivered at multiple centers, which were entered in four parallel trials of preterm feedings from 1982 to 1985. Mothers decided whether to provide their milk; the remaining infants were assigned to receive preterm formula. All feedings were by feeding tube the first 4 weeks. At both age 18 months and age 7½ to 8 years, when the children were tested by an examiner blinded to their feeding method, the children who had received their mother's milk scored better. At 18 months, they were more advanced on the Bayley Scales of Infant Development.<sup>89</sup> In a subset of the larger study, comparison groups of infants who received preterm formula were more advanced than infants who received regular formula. At the second point, 7½ to 8 years of age, using the Wechsler Intelligence Scale for Children, the children who received their mother's milk had an 8.3-point advantage, even after adjustments for mother's education and social class ( $p < 0.0001$ ).<sup>90</sup>

A subset of this large study was reported on infants who had been randomly assigned for 30 days to receive preterm formula, unfortified donor milk, or their mother's milk (with donor milk supplements as necessary).<sup>89</sup> The infants fed donor milk or those whose mothers produced less than 50% of the diet and were supplemented with donor milk were disadvantaged by 0.25 standard deviation (SD) on the developmental scales. This was not pronounced in infants with mental growth retardation. The method of collection of milk from the donors was by drip; that is, the donor fed her baby at the breast and collected milk by drip from the other breast.<sup>89</sup> Drip milk is low in fat and fat-soluble nutrients. Donor milk actively pumped has a higher fat and calorie content. An important feature of these studies was that they focused on the first month of life, a critical time to protect the brain and facilitate its growth.<sup>88–90</sup> The infants

were all tube fed, thus removing the physical interaction of the breastfeeding mother. Impact of early diet on long-term neurodevelopment continues in multicentered studies on infants fed human milk supplemented with human milk-based supplements. Unfortified human milk has been shown to have measurable impact on neurodevelopment, but investigation of these same parameters comparing fortification of human milk with bovine-based supplements has not shown improvement over unfortified milk. Neurodevelopmental outcomes at 18 months were not affected by bovine fortification.<sup>87,90</sup> Fortification in these previous studies was with a bovine milk-based supplement.

The effect of human milk on cognitive and motor development was compared to the effect of formula in a matched cohort of premature infants. Assessment at 3, 7, and 12 months' corrected ages revealed higher motor scores at 3 and 7 months and higher cognitive scores at 12 months when adjusted for maternal vocabulary score on the Peabody Picture Vocabulary Tests. The improved development scores persisted.<sup>17</sup>

In a study of three groups of preterm infants matched for birth weight (mean 1308 g, range 640 to 1780 g), gestational age (mean 30.8 weeks, range 26 to 35 weeks), medical status, birth order, sex, parental age, and educational and socioeconomic level, grouped by (1) more than 75% breast milk intake, (2) 25% to 75% breast milk, and (3) less than 25% breast milk, the infants in group 1 scored highest, independent of whether mother's milk was given by bottle, tube, or breastfeeding. The more milk the infant received, the greater the score on the Brazelton Neonatal Behavioral Assessment Scale (NBAS). The authors concluded that human milk enhances neurodevelopment quantitatively. The mothers who provided more milk were less depressed and had better interactive affiliative care styles.<sup>38,41</sup>

Visual function is improved in premature infants fed human milk. This is believed to be a result of the long-chain polyenic fatty acids and the antioxidant activity of human milk in  $\beta$ -carotene, taurine, and vitamin E.<sup>72</sup> The diagnosis of retinopathy of prematurity was 2.3 times greater in formula-fed infants than in those fed human milk in a report by Hylander et al. Few infants fed human milk advanced to severe retinopathy, and none required cryotherapy. Results were similar in fortified and unfortified human milk feeds.

Mother's own milk has clear advantages. Mother's milk helps prevent infection, sepsis, and the most destructive NEC. The cost of these morbidities in VLBW infants add over \$15,000 to already high costs of NICU care for each morbidity. Morphometric brain imaging studies support the theory that human milk is associated with improved measures of IQ and cognitive

functioning. White matter is conspicuously more developed when the infant receives mother's milk. Healthy neural growth and white matter development were associated with improved brain development, explaining some of the earliest advantages compared to formula-fed infants. Donor milk requires pasteurization, which may destroy some valuable properties, but it is still advantageous.

## GI Characteristics of Premature Infants

The anatomic differentiation of the intestinal tract begins before 20 weeks' gestation, but the functional development is limited before 26 weeks.<sup>77</sup> Different parts of the fetal gut develop at different

times so that some nutrients are better tolerated than others (Tables 15-7 and 15-8). The present concentration of digestive enzymes determines the rate of digestion and absorption, along with the maturity of membrane carriers. (See Chapter 7 for the impact of human milk on gut maturation.) The presence of active enzymes in the gut improves the digestion and absorption of human milk. As noted earlier, the gastric emptying time in preterm infants when given human milk is biphasic, with an initial fast phase in which 50% has left the stomach in the first 20 to 25 minutes.<sup>23</sup> After 1 hour, 25 mL of human milk has left the stomach. In contrast, the formula feeding follows a linear pattern, with half emptying in 51 minutes and a total of 19 mL in 1 hour.

Gut microbiota in the health and growth of prematures is escalating rapidly partially due to metagenomics technologies that permit the measurement

of the entire microbiome, including some microbes not culturable at this time. Early gut microbiota play a major role in intestinal health and disease. The human milk glycans, especially the oligosaccharides and human microbes, are a major component of the immune system by which breastfeeding mothers protect their infants from disease, especially their microprematures.

## *Use of Human Milk for Premature Infants*

A clear distinction must be made between an infant's own mother's milk and pooled human milk for the feeding of LBW infants. The mother's premature milk has some higher levels of nutrients but never lower levels than term milk. Mothers who donate to milk banks are also feeding their own infants, who may be any age from birth to 6 months or older. Donor milk must also be prepared by sterilization. An infant's own mother's milk may be fed fresh or fresh-frozen and is rarely heat treated. [Chapter 21](#) discusses milk storage and milk banking.

When the volume of milk produced by a mother is not sufficient to meet the infant's needs each day, providing additional nourishment by donor milk is clearly needed. There are several choices for human milk supplementation.

A 2001- to 2500-g infant without complications may be weaned from the incubator to an open crib within 24 hours. Although the suck reflex may be poor, the infant can usually be breastfed. The infant is ready to breastfeed even if he or she takes a bottle poorly. If the infant can stimulate the breast briefly and obtain the rich, antibody-containing, cell-filled colostrum, the infant will be protected against infection while receiving nutrition. Inadequate stimulation of the breast by the infant will require mechanical pumping after the feeding. If the infant cannot suck and must be tube fed, any colostrum the mother can manually express or pump from the breast can be given by gavage tube along with donor milk or, if human milk is not available, the prescribed formula necessary for nourishment. [Chapter 5](#) reviews the protective value of colostrum to the infant.

Intestinal permeability is another parameter of great importance to LBW infants. The GI tract development provides an important barrier to infectious materials and a path for protective and nourishing substances. A precarious balance of intestinal permeability is required to promote infant growth and to avoid severe preterm infant diseases.<sup>131</sup> Decreasing intestinal permeability is associated with gut maturation. In a study of 62 preterm infants ( $\leq 32$  weeks' gestation), the children were

evaluated utilizing enteral lactulose and mannitol administration and urinary measurements at three points in the first month postnatally while assessing their feeding type.<sup>131</sup> Those infants receiving predominantly human milk (>75%) had significantly lower intestinal permeability compared with those receiving formula and little or no human milk. The portion of human milk received increased in importance over time, with more than 25% required by 30 days of age to see a significant advantage.

A study in Guatemala that was repeated in the special care nursery of the Rainbow Children's Hospital in Cleveland showed that the infection rate among sick and premature newborns was greatly diminished by providing 15 mL of human colostrum contributed by random donors daily.<sup>32</sup> These findings were especially dramatic in Guatemala, where the mortality rate from infection in the nursery was extremely high. It has been suggested that mixed feedings of an infant's own mother's milk and formula to necessary volume be calculated over a 24-hour period so that the infant receives some mother's milk at each feeding and a supplement of formula, in contrast to alternating feedings or using all mother's milk until it runs out and finishing the day with formula. The reasoning is based on the concept of "inoculating" every feeding with human milk to provide the enzymes and immunologic properties with each feeding. Generous levels of active enzymes in the milk will also assist in the digestion and absorption of the formula. The immunologic properties are less measurable, but the only known interference with function is the addition of iron, which blocks the effectiveness of lactoferrin. Therefore, the nutritional and infection-protective properties are also spread throughout each feeding around the clock. Now that donor milk is more readily available, it is recommended to make up the deficit in volume of mother's milk with donor milk.

The quantities of direct-acting antimicrobial factors in human milk vary according to the method of collection, processing, and storage.<sup>39</sup> The ability of donor milk to protect against infection in premature infants is being tested in multiple clinical studies.<sup>48</sup>

## *Supplementation of Mother's Own Milk or Pooled Human Milk*

No supplement to human milk is usually needed if the infant is more than 1500 g at birth.

The options for supplementing an infant's own mother's milk depend on need for additional volume or for specific nutrients, especially protein, calcium, and phosphorus, based on birth weight and growth rates.<sup>65,66</sup>

The ideal supplementation is one using human milk nutrients and is referred to as *lacto engineering*, in which nutrient concentration is increased by adding specific nutrients derived from human milk. Techniques involve use of donor milk and separating the cream and protein fractions, reducing the lactose content, and heat-treating the product with a high-temperature, short-time process of pasteurization. This completely human milk product provides higher protein and energy needs so that weight gains and nitrogen retention are similar to intrauterine rates.

Using a feeding prepared from human milk protein and medium-chain triglyceride supplementation of human milk for VLBW infants was reported by Rönnholm et al.<sup>119</sup> Forty-four infants averaging 30 weeks' gestation with birth weights ranging from 710 to 1510 g were nourished by one of four protocols: plain human milk, human milk and protein, human milk and triglycerides, or human milk and protein and triglycerides. The triglycerides did not influence weight and length, but the two groups receiving added protein gained along a curve comparable with the intrauterine growth for their birth weight, gaining faster from 4 to 6 weeks than the unplemented infants. The protein-supplemented groups also grew more in length; however, head circumference growth was similar in all groups.

Total protein is usually calculated by determining the total nitrogen content (Kjeldahl method) and multiplying the number by the protein factor (6.25). Total protein corrected for nonprotein nitrogen, which is high in human milk, is true protein.<sup>10</sup> True protein is a heterogeneous mixture of casein and whey proteins. Whey proteins include lactoferrin, immunoglobulin, and lysozyme. True protein minus those more or less indigestible proteins is called *digestible protein*. Analysis of preterm milk by Beijers et al.<sup>10</sup> demonstrated that nonprotein nitrogen was dependent on the degree of prematurity and averaged 20% to 25%, increasing during the time of lactation. Only 30% to 60% of total protein is available for synthesis. However, in absolute amounts over lactation time, it remains stable.

Schanler et al. compared plasma amino acid levels in VLBW infants (mean age 16 days, mean birth weight 1180 g, mean gestation 29 weeks) fed either human milk fortified with human milk or whey-dominant cow milk formula. The infants received continuous enteral infusions of isonitrogenous, isocaloric preparations. Taurine and cysteine were significantly higher in the infants fed human milk, and threonine, valine, methionine, and lysine were significantly higher in the infants fed formula.

Mother's own milk shows a wide variability in nutrient components when being pumped for a

#### **BOX 15-10. Steps to Preserve the Nutrient Value of Mother's Milk**

- I. Most variable component: Fat
  - A. Lost in collection and storage
  - B. Settles out on standing
  - C. In one report fat content ranged from 2.2 to 4.7 g/dL
  - D. Steps to enhance fat
    - (1) Avoid separation of fat
    - (2) Avoid continuous feeds
    - (3) Utilize intermittent bolus feeds
    - (4) Orient syringe of milk upward
    - (5) Use short length of tubing
    - (6) Empty syringe completely at end of infusion
  - E. Use hind milk preferentially if volume is adequate
- II. Protein content declines from transitional to mature milk
  - A. Nutrient needs for premature are higher
- III. Mineral content has increased bioavailability but content is lower than needs of premature infants. Vitamins A, C, and riboflavin levels decrease with collection, storage, and delivery.

hospitalized premature infant. Nutrient supplementation is necessary to maintain adequate growth and good nutritional status. According to Herman and Schanler,<sup>58</sup> extraordinary efforts should be made to use mother's own milk because the advantages of nonnutritive components in human milk are significantly diminished by storage and heat processing. The most variable constituent is fat (Box 15-10). Protein does not meet the needs of a small premature. Although levels of minerals (Ca, P) are stable, the needs of VLBW infants require supplementation. Substantial benefits of mother's own milk include reduced infection, enhanced neurodevelopmental outcome, and healthy postnatal growth. The minimum dose of mother's milk when given with various fortifications has been found to be more than 50 mL/kg/day to protect against infection, especially late-onset sepsis.<sup>47</sup> A systemic review looking at multi-nutrient fortification for human milk involved 10 trials and a total of more than 600 infants weighing less than 1800 g.<sup>73</sup> It clearly showed improvement in weight gain increments in length, head circumference, and BMC compared with unplemented milk. Neurodevelopmental outcomes were significantly improved with mother's milk. The magnitude of the effect was seen as mother's milk intake increased to 110 mL/kg/day; the developmental scales showed an increase of five points, an important gain for these ELBW infants. Preterm infants have lower energy expenditure when they are fed breast milk than when they are fed preterm infant formula.

Preterm infants with birth weights from 750 to 1250 g were randomly assigned to a cream or control group. The cream group received a human milk-derived cream supplement if the energy density of the human milk tested below 20 kcal/oz, measured using a near infrared human milk analyzer. The control group received their mother's own milk or donor human milk with donor human milk-derived fortifier. Premature infants who received human milk-derived cream as a fortifier had improved weight and length compared to the control group. Cream can be used as an adjunctive supplement to an exclusive human milk-based diet to improve growth rates (see [Figure 15-6 Prolact CR™ Human Milk Caloric Fortifier](#)).

All preterm infants should receive human milk fortified with protein, minerals, and vitamins when birth weight is less than 1500 g according to the American Academy of Pediatrics' section on breastfeeding.

## *Artificial Fortification of Human Milk*

No longer is supplementing an infant's own mother's milk with specially prepared formula supplements necessary. Available commercial preparations for such supplementation were intended to complement human milk and not to be used as an exclusive formula. When multicomponent fortified human milk product for promoting growth in preterm infants was examined in a Cochrane Review,<sup>74</sup> the authors found short-term increases in weight gain, linear growth, and head circumference. No effect was seen on serum alkaline phosphatase levels, and the effect on BMC was unclear. Nitrogen retention and blood urea levels were increased. Conclusions about long-term neurodevelopmental and growth outcomes were limited by insufficient data after 1 year. The significance of increased blood urea nitrogen and blood pH levels was unclear. Preparations are different and are used differently ([Table 15-9](#)). The powdered supplement is intended to add special nutrients to an adequate volume of mother's own milk (Enfamil human milk fortifier or Similac human milk fortifier), or it can be used to enhance pooled donor human milk. Neither fortifier contains fat. Milk fortification extends the mother's milk and provides additional nitrogen, calcium, phosphorus, and vitamins for an LBW infant. If an infant is fed the mother's milk, pooled donor milk, and a fortifier, the sum total should meet the infant's daily requirements ([Table 15-10](#)). Any addition of artificial formula interferes with the infection protection qualities and other benefits of human milk so use of formula-based supplementation should be

avoided unless human milk-based formula is not available. Preventing one case of NEC saves \$100,000.

Studies comparing fortified mother's milk with premature infant formulas have shown comparable growth in weight, length, and head circumference. This makes it possible to lose many advantages of a mother's milk, while providing the additional nutrients for appropriate accretion rates.<sup>127</sup>

When powdered fortifier was added to a mother's milk, the supplemented infants had significantly greater weight gain, linear growth, and head circumference growth than those not supplemented. The supplemented infants also had higher blood urea nitrogen levels ([Table 15-11](#)).<sup>53</sup> The loss of human milk benefits is of significant concern.

When a preterm infant's own mother's milk was fortified with protein (0.85 g/dL), calcium (90 mg/dL), and phosphorus (45 mg/dL), the rate of weight gain was greater than that of the unfortified group and comparable with that of the Similac Natural Care formula group.<sup>50-52</sup> Bone mineralization improved during the 6 weeks of the study but did not reach the intrauterine accretion rate of 150 mg/kg/day. A relative phosphorus deficiency occurred in the human milk groups, both with and without supplementation. Fortifying preterm mother's milk permits biochemically adequate growth comparable with that provided by special care formula ([Table 15-12](#)).

The effect of calcium supplementation on fatty acid balance studies in LBW infants fed human milk or formula has been shown to be significant. A decrease in total fatty acid absorption both in LBW infants fed their own mother's milk and in formula-fed infants was seen when calcium was added. Fecal output of fat and fatty acid excretion was higher in the formula-fed infants. In mother's milk-fed infants, the total fat absorption and the coefficient of absorption were higher.

Preterm milk with routine multivitamin supplementation (providing 4.1 mg of tocopherol) uniformly resulted in vitamin sufficiency in VLBW infants in a control study by Gross and Gabriel.<sup>54</sup> This was true when they received iron, as well as when they were not iron supplemented. VLBW infants were fed preterm milk, bank milk, or formula, utilizing 2 mg/day of iron. Vitamin E content of preterm milk does not differ significantly from that of term human milk from days 3 to 36.<sup>56</sup>

Jocson et al.<sup>68</sup> studied the effects of nutrient fortification and varying storage conditions on host-defense properties of human milk. Total bacterial colony counts and immunoglobulin A (IgA) were not affected by the addition of fortifier.

The effect of powdered human milk fortifiers on the antibacterial actions of human milk were

explored by Chan.<sup>24</sup> Human milk inhibited the growth of *Escherichia coli*, *Staphylococcus aureus*, *Enterobacter sakazakii*, and group B *Streptococcus* when Enfamil and Similac human milk fortifiers were mixed with human milk, along with medium-chain triglycerides and 1.09 mg ferrous sulfate (in 25 mL milk). The fortifiers containing iron and the iron alone inhibited the protective effect of human milk against the bacteria. The probable explanation is the interference of iron with the protective action of lactoferrin in human milk. The ferrous iron in the fortifier is changed to a ferric state in human milk, which readily binds with lactoferrin.

Concerns over the nutrient content of supplemented human milk have been expressed by many authors since the early work on premature infants from the Houston group.<sup>125</sup> After noting growth failure in some premature infants, it was discovered that some mother's milk was lower in calories than 20 kcal/oz. This has been reported by Prolacta Biologicals, which tests the protein and caloric content of all donations. This is a major issue for premature infants who have a restricted fluid intake in the early months of life. Preterm infants fed a commercially prepared, bovine-based human milk fortifier receive less protein than they need, according to Arslanoglu et al.<sup>7</sup> They tested the actual nutrient intakes observed in a previously reported study, with assumed nutrient intakes based on the usual assumptions about the composition of human milk. Actual protein intakes were significantly and consistently lower than the levels assumed based on the standard protein content of human milk. Actual

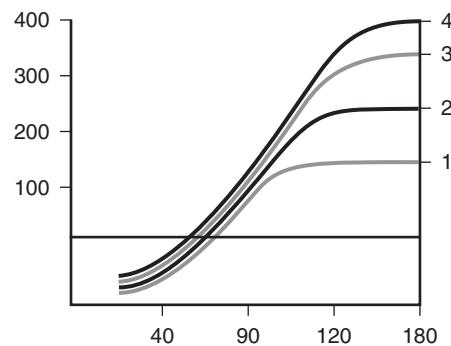

Figure 15-7. WHO technical report on optimal feeding for LBW infants.

intakes of protein by preterm infants fed bovine-fortified human milk were significantly lower, especially after 3 weeks postpartum when the mother's milk no longer had the higher protein content of the milk of a mother who delivers prematurely. Calorie content was not significantly lower (Figure 15-7).

The Committee on Nutrition of the AAP has outlined requirements for the premature infant who is less than 27 weeks' gestation and less than 1000 g at birth, regarding calcium and vitamin D. Bone mineral status should be started by 4 to 5 weeks after birth. Alkaline phosphatase above 800 to 1000 IU/L or clinical evidence of fractures require radiographic evaluation. A persistent serum phosphorus concentration less than 4 mg/dL should be monitored and supplementation with phosphorus considered. Postdischarge monitoring

**BOX 15-11. Protein Recommendations**

- Categorized by life stage and gender, because among healthy individuals, these are the two parameters responsible for variations in the body's need for protein
  - The Pediatrics Stage has been subdivided into six groupings: *infancy*, 0 to 6 months of age; *infancy*, 7 to 12 months of age; *toddlers*, 1 to 3 years of age; *early childhood*, 4 to 8 years of age; *puberty*, 9 to 13 years of age; and *adolescence*, 14 to 18 years of age
- Optimal food for full-term infants is human milk
  - Recommended that it be the sole source of nutrition for infants during the first 6 months of life
  - On average, infants to 6 months of age consume 0.78 L of milk per day
- Average value of 11.7 g/L used to calculate adequate intake for protein
- Nonprotein nitrogen component of human milk contains substantial quantities of taurine, which is virtually absent from cow milk
- Human milk proteins have a high nutritional quality and are digested and absorbed more efficiently than cow milk proteins
- Breastfed infants' protein intakes appear to satisfy the infant requirements for maintenance and growth without an amino acid or solute excess

Data from Rigo J, Senterre J: Nutritional needs of premature infants: current issues, *J Pediatr* 149:880, 2006; Kleinman RE, editor: *Pediatric nutrition*, ed 7, 2013, American Academy of Pediatrics, and World Health Organization: *Protein and amino acid requirements in human nutrition*, Geneva, 2007, World Health Organization.

is also necessary if exclusively breastfed. When the infant reaches 1500 g, vitamin D intake should be 400 IU/day minimum and up to a maximum of 1000 IU/day. A mineral intake between 100 and 166 mg/kg/day of highly absorbed calcium and 60 to 75 mg/kg/day of phosphorus is recommended to provide appropriate mineralization. Protein requirement is considered to be a matter of some debate, as human milk protein is readily absorbed, and bovine protein is less well absorbed. The revised recommendations for protein appear in **Box 15-11**. These adjustments were an effort to reduce metabolic stress from protein overload and unbalanced amino acid supply. Human milk has the ideal balance of casein and whey.

### **Fortification of Human Milk with Human Milk**

The problem of adding nutrients to mothers' milk to meet the increased nutrient needs of premature infants, especially ELBW premature infants, has

challenged neonatologists for years. The commercial products developed from a bovine milk base have been widely used and have improved the nutrient intake of these infants. The theoretical concern about the impact of bovine milk on the infection protection properties of human milk has been argued.<sup>62</sup> A minimum of 50 mL/kg/day of the mother's milk is deemed necessary to maintain the protection provided by the mother's milk. A number of investigators have explored the possibility of a fortifier made out of human milk, so the feeding would meet needs with entirely human constituents. The antibacterial activity inherent in human milk was inhibited when a bovine-based fortifier containing added iron was mixed with human milk. Chan et al.<sup>25</sup> tested the same antibacterial activity when a newly derived human milk-based product became available (Prolacta Bioscience, Monrovia, Calif.). Human milk samples from 10 fully lactating mothers were utilized to test the effect on the antimicrobial activity of human milk, milk plus bovine fortifier, and milk plus human milk fortifier against *Ent. sakazakii*, *E. coli*, *Clostridium difficile*, and *Shigella sonneii*. Human milk inhibited the growth of all the test organisms. The antibacterial activity was almost completely inhibited by the addition of the bovine-based fortifier. The activity was unaffected by the addition of human milk-based fortifier. Further studies of human milk-based fortifier ( $H^2MF$ ) have been conducted at national and international sites. The fortifier ( $H^2MF$ ) is available from Prolacta Bioscience. Preliminary results from University of Florida, Schneider's Children's Hospital, Baylor College of Medicine, and Yale-New Haven Medical Center were reported on 207 extremely premature infants whose mothers intended to provide their milk. The infants were randomized to one of three groups: mother's milk plus (HUM40) or 100 mL/kg/day (HUM100); the third group received mother's milk plus 100 mL/kg/day of the bovine-based product (**Table 15-13**). The groups had similar lengths of stay and rates of growth, chronic lung disease, and sepsis. However, significantly lower rates of NEC, surgical NEC, and combined deaths were observed with the human-based fortifier. Further results are available from other participating centers and all involved patients.

### **Long-Term Follow-Up of Growth Parameters in VLBW Infants**

Weight gain and growth in length and head circumference are similar in VLBW infants who are breastfed or given standard formula after discharge. BMC was also followed at 10, 16, and 25 postnatal

From Sullivan S, Schanler R, Abrams S, et al: Abstract at PAS 2009. #2155.1 Neonatal nutrition and follow up 5/2/09. Sullivan S, Schanler R, Abrams S, et al: *A randomized controlled trial of human versus bovine-based human milk fortifier in extremely preterm infants*, Baltimore, Md., 2009, PAS Meetings.

weeks in those graduates from the NICU who had formerly received fortified human milk. At 16 and 25 weeks, the breastfed infants had lower BMC and BMC/bone width ratio, as well as serum phosphorus concentration and higher alkaline phosphate activity than the formula-fed group. These data suggest a need to carefully monitor this select group of VLBW infants for suboptimal bone accretion while receiving their mother's milk. However, human milk-based fortifier should solve this problem.<sup>57</sup>

Reduced bone mineralization is common in preterm infants and has been associated with growth stunting at 18 months of age and dietary insufficiency of calcium and phosphorus. Bishop et al.<sup>16</sup> evaluated 54 children at a mean age of 5 years who were born prematurely and had been part of a longitudinal dietary growth study. The diets included were either banked donor milk or preterm formula as a supplement to the mothers' own milk. Increased human milk intake was strongly associated with better BMC. Those children who had the greater proportion of human milk had greater BMC than children born at term. That is, supplementing with donor milk produced a better outcome at age 5 years than supplementing with infant formula, even though the nutrient content of formula was greater. The later skeletal growth and mineralization of an infant can be calculated and feeding adjusted to add necessary mineralization with human milk-based supplements.

Iron status has also been studied in LBW infants at 6 months' chronologic age. The incidence of iron deficiency was 86% in the breastfed group of LBW

infants and only 33% in those receiving iron-fortified formula.<sup>2</sup> The breastfed group had significantly lower serum ferritin and hemoglobin values at 4 months of age. Abouelfetoh et al.<sup>1</sup> recommended that these special breastfed infants should receive iron from 2 months of age, because they were developed.

The AAP recommends that infants less than 1500 g birth weight receive 4 mg/kg/day of iron. There were no studies to test this until Taylor and Kennedy compared the effect of 2 mg/kg/day in a multivitamin on the hematocrit at 36 weeks' postmenstrual age. It was concluded that this iron therapy for infants under 1500 g at birth, in addition to dietary intake, did not improve the hematocrit or the number of transfusions required compared to the controls who received no additional iron.

The feeding of these special VLBW infants after discharge and for the next 6 to 9 months is an important consideration. Breastfeeding with added supplementation has been studied. Some important results came from a randomized, double-blind trial of the effect of supplementary standard formula feedings.<sup>84</sup> Growth and clinical status of infants receiving nutrient-enriched "postdischarge" formula were significantly affected, without vomiting, gas, or stool problems. The group receiving the enriched formula ingested volumes similar to those receiving regular formula.

A large multicenter follow-up study of more than 1000 ELBW infants who had extensive nutritional data collected was reported by Vohr et al.<sup>136</sup> Birth weight, gestational age, intraventricular

hemorrhage status, sepsis, bronchopulmonary dysplasia, and hospital stay were similar between those never receiving human milk and those for whom variables of socioeconomic status, race, ethnicity, educational attainment, and parity were adjusted. Effects of human milk intake on mental and motor development were significantly positive. The impact of receiving 110 mL/kg/day of human milk was correlated with a 5-point increase on the Bayley scales. Human milk feedings affect scores even when donor milk is used, compared with term formula.<sup>19</sup>

Infants fed breast milk were found to have faster brainstem maturation, compared to those infants who received formula. This was determined by an analysis of the rate of maturation of the BAERs (auditory evoked response). Components of human milk improved cognitive and neurological outcomes in a series of studies on VLBW infants. Lack of breastfeeding was a major predictor of poor cognitive outcome in very preterm infants, compared to low social status and cerebral lesions by ultrasound.

The association of human milk feedings with a reduction in retinopathy of prematurity among VLBW infants compared to formula-fed infants, after adjusting for confounding variables, is significant. It can be considered as available intervention.

**Box 15-12** lists recommendations modified from the work of Tsang et al.<sup>123a</sup> and Schanler and Hurst.

## Antimicrobial Properties of Preterm Breast Milk

The infection-protective properties of human milk have been considered to be a key reason to provide human milk to high-risk infants who are prone to devastating infections such as NEC, sepsis, and meningitis and viral infections such as respiratory syncytial virus and rotavirus. The antimicrobial properties of milk produced by mothers who deliver preterm have been studied by several investigators.

The antiinfective factors in preterm human colostrum were studied by Mathur et al.,<sup>95</sup> who compared the colostrum values of a comparable group of postpartum mothers. The mean concentrations of IgA, lysozyme, and lactoferrin were significantly higher than in full-term colostrum. IgG and IgM were similar in both groups. The absolute counts of total cells, macrophages, lymphocytes, and neutrophils were significantly higher in preterm colostrum. The mean percentage of IgA in the premature colostrum was also significantly higher. The degree of prematurity had no effect, although the study group ranged in gestation from

### BOX 15-12. Feeding Schedule for Human Milk in Low-Birth-Weight Infants

1. Use refrigerated milk from the preterm infant's mother when it is available and has been collected within 48 hours of feeding.
2. When fresh milk is not available, use frozen human milk from the infant's mother. This milk should be provided in the sequence that it was collected to provide the greatest nutritional benefit.
3. When the preterm infant is tolerating human milk at greater than 100 mL/kg/day, supplementation using a human milk fortifier is started.
  - a. If it requires more than 1 week to reach 100 mL/kg/day intake, fortifier is added even though volume tolerance has not been achieved.
  - b. Milk volumes should increase to 150 but not exceed 200 mL/kg/day. Weight gain is optimally 15 g/kg/day and length increment 1 cm/wk. Urinary excretion of calcium should be less than 6 mg/kg/day and phosphorus greater than 4 mg/kg/day.
  - c. If weight gain is less than 15 g/kg/day, hind milk is used if mother's milk production exceeds the infant's requirements by 30%.
4. If the mother's milk supply is inadequate to meet her infant's feeding needs, an infant formula designed for preterm feeding is used as described.
5. Fortification of human milk is recommended until the infant is taking all feedings from the breast directly or weighs 1800 to 2000 g, depending on nursery policy on infant discharge weight. During the transition from feeding human milk by gavage or bottle and nipple to feeding at the breast, only those feedings given by gavage or bottle require fortification.
6. Multivitamin supplementation is started once feeding tolerance has been established. This supplementation varies depending on the composition of human milk fortifier.
7. Iron supplementation providing 2 mg/kg/day is started by the time the infant has doubled birth weight.

28 to 36 weeks (mean  $33 \pm 2.1$  weeks), compared with the control infants, who were at 38 to 40 weeks (mean  $39.1 \pm 0.8$  weeks). The colostrum of preterm mothers had an even greater potential for preventing infection than term colostrum and are an additional reason to begin early enteral feeds with human colostrum.<sup>95</sup> **Table 15-14** lists the specific antiinfective components.

The cells of preterm milk were compared with those of term milk and found to be similar in number and in capacity to phagocytose and kill staphylococci.<sup>108</sup> The ability of the preterm cells to produce interferon on stimulation with mitogens was marginally better than that of term cells. The cells survived 24 hours refrigerated at  $4^{\circ}\text{C}$  ( $39.2^{\circ}\text{F}$ );

**TABLE 15-14** Comparison of Antiinfective Properties in Colostrum of Preterm Versus Term Mothers

	Preterm Colostrum	Term Colostrum
<b>Total protein (g/L)</b>	0.43±1.3	0.31±0.05

Macrophages	4041±1420	1597±303
Lymphocytes	1850±543	954±143
Neutrophils	842±404	512±178

Modified from Mathur NB, Dwarkadas AM, Sharma VK, et al.: Anti-infective factors in preterm human colostrum, *Acta Paediatr Scand* 79:1039, 1990.

at 48 hours, cell number, but not function, was reduced. Passing the milk through a feeding tube did not diminish the number or function of the cells. The levels of lactoferrin and lysozyme were greater in preterm milk than in term milk from the 2nd to 12th weeks postpartum.<sup>49</sup>

Secretory IgA is the predominant form of IgA, and values increased from the 6th to 12th weeks in preterm milk. The increase in IgA is not dependent on method of collection, rate of flow, or time of day, but the concentration varied inversely with the milk volume. Thus some investigators think that total production of IgA in 24 hours is comparable for the two groups.<sup>26</sup> Preterm infants (31 to 36 weeks' gestation) were fed human milk and compared with a matched group of premature infants fed infant formula. The serum levels of IgA at 9 to 13 weeks were higher in the human milk-fed infants.<sup>121</sup> Those infants who received at least 60% of their own mother's milk had higher IgA levels at 3 weeks of age than those receiving less than 30% of the feedings from their mother's milk.

Serum IgG levels were higher in the breast milk group, and serum IgM levels were similar in the two feeding groups. Samples of precolostrum collected from undelivered mothers were assayed and found to contain equal or greater amounts of IgA, IgG, IgM, lactoferrin, and lysozyme as mature colostrum.<sup>79</sup>

When the impact on actual prevention of infection among premature infants is reviewed, significantly less infection is found in infants receiving human milk compared with those receiving formula (9 of 32 receiving breast milk, 28.1%; 24 of 38 receiving formula, 63.3%). In a prospective evaluation of the antiinfective property of varying quantities of

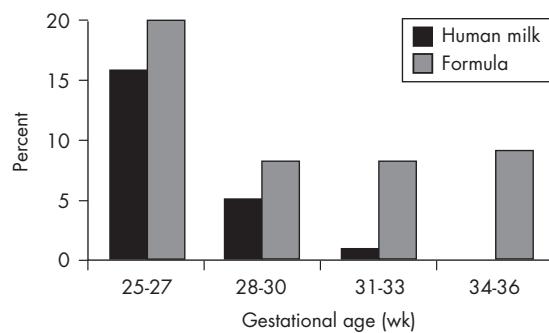

expressed human milk for high-risk LBW infants, infections were found to be significantly less frequent in the groups that received human milk.<sup>128</sup> This has been documented for decades.

NEC is a major cause of morbidity and death in preterm and other high-risk infants. The absolute cause has eluded neonatologists, although many theories have been put forth and associations suggested<sup>86</sup> (Box 15-13). When researchers investigate its prevention, the role of human milk is prominent. In a large prospective multicenter study of 926 infants, 51 infants (5.5%) developed NEC. The mortality rate was 26% (Figure 15-8). In exclusively formula-fed infants, the incidence was 6 to 10

**BOX 15-13. Issues and Risk Factors Associated with Enteral (Oral) Intake and the Causation of NEC**

- Initiation of oral fluids too early
- Excessively rapid increases in volume or concentration of oral fluids
- Nutritional and nonnutritive sucking
- Hyperosmolar fluids
- Formula compared with human breast milk
- Feeding intolerance (cannot advance, residuals)
- Transpyloric compared with gastric gavage
- Bolus compared with continuous gavage
- Malabsorption of carbohydrates (lactose)—low luminal pH and ischemia
- Malabsorption of protein—low luminal pH
- Differences in gut bacterial or viral flora (epidemic NEC)
- Labile or inadequate gut blood flow (e.g., diving reflex, apnea, asphyxia)
- Increased work of gut muscle (increased oxygen consumption) because of gut motility

NEC, necrotizing enterocolitis.

**Figure 15-8.** Effect of gestational age and human milk versus formula feeding on necrotizing enterocolitis (NEC). In infants fed formula, incidence of NEC decreases after 27 weeks and then remains the same. In infants fed human milk, incidence of NEC continues to decline. (From Lucas A, Cole TJ: Breast milk and neonatal necrotising enterocolitis, *Lancet* 336:1519, 1990.)

times more common than in those who received human milk exclusively. In those who received human milk and formula, it was three times more common than in the exclusively breastfed group. Pasteurization did not diminish the effect of human milk in these studies.<sup>86,128</sup> The comparison was more dramatic at more than 30 weeks' gestation, when formula-fed infants were 20 times more apt to develop NEC than human milk-fed infants. Early enteral feeding did not change the risk in those receiving breast milk, whereas delaying feedings of formula did lower the rate of NEC.<sup>75</sup> In a study of the prevention of NEC in LBW infants, with feedings higher in IgA and IgG, none of the infants in the study group or the breastfeeding comparison group developed NEC. Six cases developed among the 91 infants in the untreated group.<sup>37</sup>

It is notable that human milk also affects the incidence of other infections in the premature infant, including upper respiratory infections (Figure 15-9).

When stool colonization and incidence of sepsis in human milk-fed and formula-fed infants were studied in an intensive care nursery, a protective effect was seen against nosocomial sepsis, which was unrelated to GI flora. It was concluded that human milk feeding is associated with a significantly decreased incidence of nosocomially acquired sepsis that cannot be explained by the effect of human milk feeding on the GI flora. In a retrospective review of a group of premature infants fed fortified human milk, a 26% incidence of infection was seen. Those fed all formula had an infection rate of 49%.<sup>87</sup> Infants fed predominantly human milk (i.e., more than 50 mL/kg/day) had significantly less late-onset sepsis and NEC and shorter hospital stays compared with those receiving preterm formula. This dose of at least 50 mL/kg/day as protective was confirmed in another study.<sup>47</sup> The greater the dose of human milk, the greater the effect was.<sup>102</sup> A large multicenter study in Norway<sup>118</sup> reported that early feeding of extremely

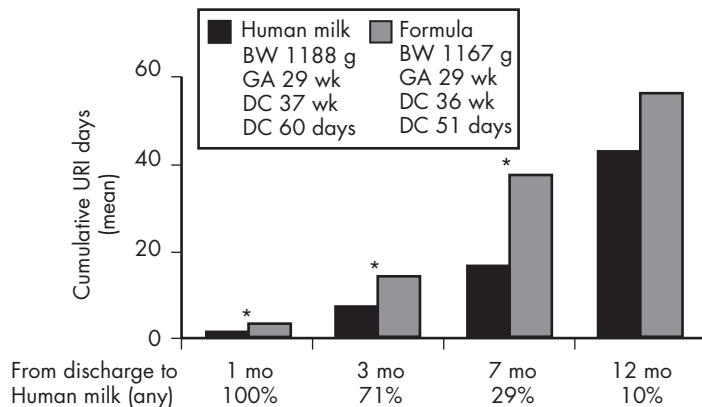

premature infants with human milk and subsequent fortified human milk was associated with significantly less late-onset sepsis and improved survival. Probiotics for the prevention of NEC in preterm infants were subjected to a Cochrane Review. Milk feeding and bacterial growth play a role. Dietary supplements containing potentially beneficial bacteria reduce the occurrence of NEC and death in premature infants under 1500 g. However, this review did not find support for probiotics in infants under 1000 g at birth.

The impact of postnatal antibiotics on the preterm intestinal microbiome was studied in a group of premature infants between 24 and 31 weeks' gestation. They received at least 50% or more of breast milk per day and had received only 2 days of antibiotics or 7 days of antibiotics. The results showed that antibiotics disturbed the acquisition of bacteria in the gut.

Dysbiosis in the first week of life is related to later onset of NEC. Neuregulin-4 (NRG4) is an ErbB4-specific ligand that has been shown to help epithelial cells survive. Epithelial cell death is a major pathologic feature of NEC. Studies of ErbB4, which is found in the developing human intestine, as well as NRG4 (its receptor), which is found in human milk, suggest that NRG4-ErbB4 signaling may be a special pathway for therapeutic intervention to prevent NEC. Perhaps this explains the role of human milk.

An exclusively human milk-based diet is associated with a lower rate of NEC than a diet of human milk and bovine milk-based product. This was demonstrated by a multicentered study involving 207 infants.<sup>130</sup> A human milk diet with human milk-based fortification allows the neonatologist to feed premature infants on totally human milk, meeting nutritional needs and preventing NEC.

NEC has historically had a variable rate in nurseries but the etiology has remained elusive. Patel et al. developed an NEC QI initiative when their NEC rates went from 4% in 2005 to 2006 to

**Figure 15-9.** Effect of human milk on upper respiratory infection symptoms in premature infants during their first year. BW, Birth weight; DC, discharge; GA, gestational age. (From Blaymore Bier J-A, Oliver T, Ferguson A, et al.: Human milk reduces outpatient upper respiratory symptoms in premature infants during their first year of life, *J Perinatol* 22:354, 2002.)

10% in 2007 to 2008. A change in feeding protocol had no effect. However, NEC rates did change significantly when nasogastric tube management was redesigned to include more frequent NG tube changes, as well as reeducation of parents about pump cleaning and storage. This project demonstrated the need for ongoing evaluation of routines and protocols.

Changing to an exclusively human milk diet for infants under 33 weeks' gestational age was tested to reduce the incidence of NEC. The diet was limited to the mother's milk and human milk-based fortifier and excluded any trace of bovine protein. It was compared to the incidence of NEC during the years that formula was used, and human milk was fortified with bovine-based supplements. It reduced the incidence of NEC from 3.4% down to 1%.<sup>59</sup>

When donor milk was compared to the mother's own milk, it provided no short-term advantage in infection rates over premature formula. The mother's own milk appears to protect the premature infant from infectious morbidity<sup>58</sup> (Table 15-15). Further investigation into pasteurization techniques is important. High-temperature short-time techniques appear to protect more infectious protection properties than the Holter technique.

In South Africa, where mothers remain with and help care for their premature babies, a study compared feeding an infant its own mother's milk with feeding pooled pasteurized breast milk. Birth weights were between 1000 and 1500 g. Babies who were not on ventilators began feedings by 96 hours of age. Weight gain was significantly greater using untreated mother's milk, both for regaining birth weight and reaching 1800 g sooner. Both SGA and AGA infants did better on their own mothers' milk. This diet decreased hospital stays and decreased hospital-acquired infection. The authors attribute the advantages to the milk being fed fresh, with early initiation of feeding at the breast, compared to the pasteurization of the bank milk.<sup>127</sup>

## Kangaroo Care and Skin-to-Skin Care

Kangaroo care and skin-to-skin care are important constituents of the support program for milk production by mothers who are pumping to produce milk, without the benefit of the infant suckling at the breast. The conduction of heat from parent to infant is sufficiently high to compensate for the increase in evaporative and conductive heat loss.

Extensive studies have been carried out to substantiate not only the safety, but also the benefits of the skin-to-skin contact for fragile prematures, including micropremates, at 24 weeks' gestation. All the reports recommend initiation directly after birth, even when the infant requires ventilator care. Stability of heart rate, respirations, and oxygen saturation during skin-to-skin care is remarkably calm.<sup>42</sup> This technique was started initially in resource-poor countries but has been so effective in calming stabilizing infants that it has become universal. It is particularly effective when the mother is initiating breastfeeding and pumping to start milk production. The Kangaroo Mother Care (KMC) method is a standardized, protocol-based system for preterm and/or LBW infants. The cardiorespiratory instability seen in separated infants during the first hours is consistent with the mammalian "protest-despair" biology and with a hyperarousal and dissociation response.<sup>11</sup> The aim is to empower the mother (and father, if possible) by gradually transferring the skills and responsibility for becoming the child's primary caregiver. It has been formally organized internationally.<sup>18,112</sup> See Boxes 15-14 and 15-15.

Skin to skin has been evaluated by utilizing a number of measurements to demonstrate the physiologic benefits of this close contact with a parent for prematures. Measurements of salivary cortisol showed that the infant's cortisol reactivity decreased in response to handling. In addition, skin to skin improves the symmetry between the mother's and the infant's salivary cortisol levels.<sup>103</sup> It also helps

**BOX 15-14. Kangaroo Mother Care**

There is sufficient evidence to make the following general statements about KMC:

- The kangaroo position provides a neutral thermal environment that provides immature infants with optimal thermal regulation, which is the same or better than provided by an incubator.
- KMC enhances bonding and attachment, universal human needs that apply to all preterm and low-birth-weight infants, their parents, and families.
- Avoiding unwarranted mother-infant separation and initiating the kangaroo position as early as possible helps repair a bonding process that is disrupted by delivering a preterm or ill infant.
- KMC helps reduce maternal postpartum depression symptoms and increases parental sensitivity to infant cues.
- Initiation of KMC as soon as possible is essential for the establishment of breastfeeding and for increasing the duration of exclusive and any breastfeeding.
- KMC has positive effects on infant/parent psychological development and the development of mutual communication, understanding, and social recognition; reduces parenting stress; and contributes to an optimal family home environment.

From Nyqvist KH, Anderson GC, Bergman N, et al.: Towards universal Kangaroo Mother Care: recommendations and report from the first European conference and Seventh International Workshop of Kangaroo Mother Care, *Acta Paediatr* 99:820, 2010.

**BOX 15-15. Kangaroo Mother Care Principles**

The following guiding principles should pervade all components in KMC protocols:

- All intrapartum and postnatal care should adhere to a paradigm of nonseparation of infants and their mothers/families.
- Preterm/low-birth-weight infants should be regarded as extero-gestational fetuses needing skin-to-skin contact to promote maturation.
- KMC should begin as soon as possible after birth and continue as often and for as long as appropriate (depending on circumstances).

KMC, Kangaroo Mother Care.

allay the father's fears of spousal relationship problems, as he feels abandoned when the mother is totally consumed by the infant's needs. Breastfeeding was more common and more exclusive in the skin-to-skin group than in the control group at 1 and 4 months (all 18 dyads vs. 16 of 19).<sup>103</sup>

**Figure 15-10.** Kangaroo care method.

**KANGAROO CARE**

Kangaroo care was first introduced in 1979 in a hospital in Bogota, Colombia, because of a shortage of incubators, high death rate from infection, and abandonment of premature infants by their mothers. Since that time, many investigators have carefully evaluated kangaroo care and found it to be beneficial to mother and infant.<sup>71</sup> Dressed only in a diaper, an infant is held skin to skin against the mother's chest between her breasts, snug inside the mother's clothing, often for hours. The father can do the same. Many advantages have been noted, including more stable respirations, heart rates, and temperatures. The infants spend less time crying and more time in a quiet, alert state and deep sleep.<sup>82</sup> Some studies suggest better weight gain and earlier discharge. Hurst et al.<sup>61</sup> also reported an increase in milk volume during pumping (Figure 15-10).

Mothers who give kangaroo care breastfeed longer and more frequently. They also report greater confidence in caring for their fragile infant than those who experience traditional care.<sup>6</sup> NICU nurseries should encourage kangaroo care. All parents should be assisted in providing it whenever they are in the nursery to benefit both the mother and the infant. This skin-to-skin contact enhances milk production, especially when the infant is too immature to suckle.

**Milk Production by Mothers of Premature Infants**

The Committee on Nutrition at the AAP<sup>28</sup> published a handbook in 2014 that included a section on nutritional needs of LBW infants. They suggest

that the mother's own milk and new special formulas for those babies who need breast milk substitutes are promising alternatives.

A joint effort of the AAP Committee on the Fetus and Newborn and the American College of Obstetricians and Gynecologists Committee on Obstetric Practice states that "human milk has a number of special features that make its use desirable in feeding preterm babies."<sup>29</sup>

The production of milk by a mother who is not actively nursing her infant, as is frequently the case in LBW infants and other neonates in NICUs, is a challenge to the resources of the NICU and the postpartum staff. Insufficient milk production is a common problem that becomes more critical as time passes. As production continues to drop, an infant's needs increase. Evaluation of various protocols has been undertaken by investigators who looked at onset of pumping postpartum, frequency of pumping, and duration in total minutes per day and length of time when no pumping occurred.

Hopkinson et al.<sup>60</sup> enrolled 32 healthy mothers, 19 of whom had no previous breastfeeding experience, into a study protocol. Their infants were 28 to 30 weeks' gestation. All of the mothers initiated pumping between days 2 and 6. The day of initiation was correlated with the volume of milk at 2 weeks, but not at 4 weeks, with mothers who had nursed previously and initiated pumping sooner. Parity, gravidity, age, and previous nursing experience were not correlated with volumes at 2 weeks. Parity and previous nursing experience were associated with milk volume at 4 weeks, with multiparas producing 60% greater volumes. The investigators found no significant relationship between 24-hour milk volume and frequency, duration, or maximal night interval. The change in milk volume from 2 to 4 weeks was correlated with frequency and duration of pumping but not to maximal night intervals. The range in number of pumpings per day was four to nine. The authors<sup>60</sup> concluded that optimal milk production occurs with at least five expressions per day and pumping durations that exceed 100 min/day.

The frequency of milk expression was evaluated by de Carvalho et al.<sup>32</sup> in a crossover design study of 25 mothers who delivered at 28 to 37 weeks' gestation. Frequent expression of milk was significantly associated with greater milk production ( $342 \pm 229$  mL) than with infrequent expression ( $221 \pm 141$  mL). They compared three or fewer pumpings per day to four or more. The mean numbers were 2.4 versus 5.7, neither equaling the frequency that a mother would usually feed her infant in the first few weeks.

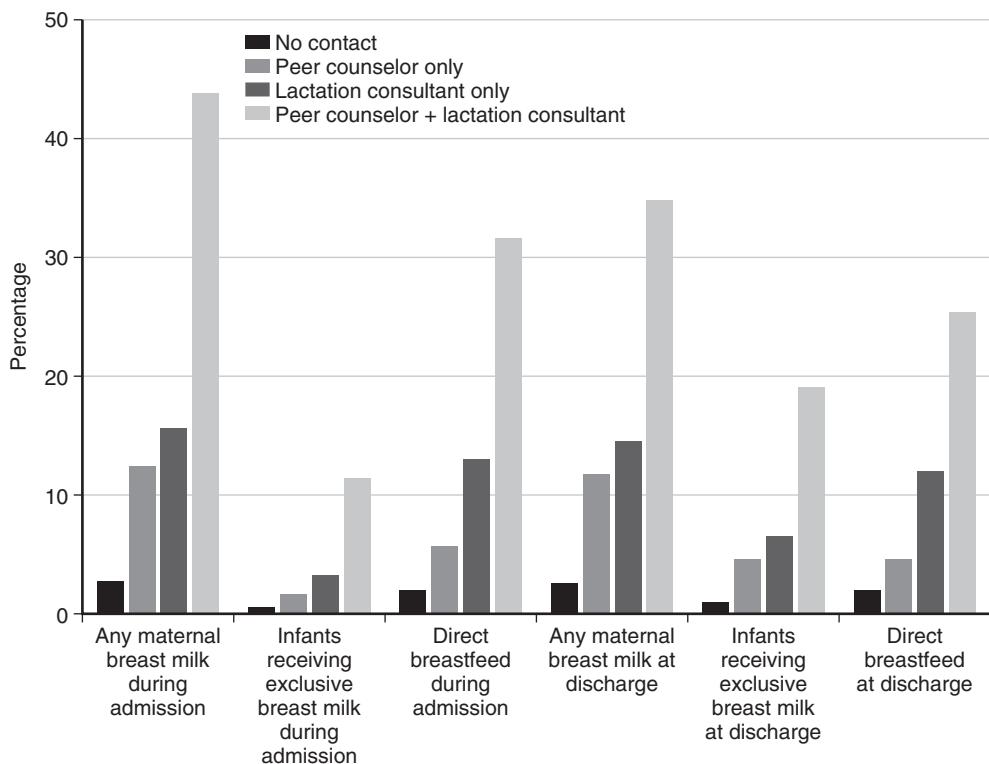

Minimum frequency and duration figures have been provided. However, it is advisable to increase

the frequency of pumping as the need to raise production increases and as the time for discharge and feeding the infant exclusively at the breast approaches. Consideration for increasing nighttime pumpings is also important as discharge approaches. Some mothers experience a dread of the pump when demands are increased for "more milk production." The management of the mother producing milk for her hospitalized infant should be coordinated by a neonatologist and a primary care physician. She should be assisted by a primary care nurse and the unit's lactation coordinator and lactation consultants to maximize support and minimize stress.

Peer counselors have become important members of the lactation support teams in the NICU, as they have been in birth centers and in the community. Peer support was originated by the LaLeche League. Anthropologist Dana Raphael coined the expression "a friend from across the street." Health departments and WIC programs have developed peer counselor programs, where women (peers) with breastfeeding experience are trained to provide support and counsel but not practice medicine.<sup>114</sup> Very successful programs have been developed in NICUs. A combination of a lactation consultant and a peer counselor provides the most effective breastfeeding support in the NICU<sup>100</sup> (see Figure 15-11 and Chapter 22).

The NICU at Rush University Medical Center developed a lactation support program that included peer counselors who were former NICU parents.<sup>120</sup> They work directly with NICU mothers and babies, in collaboration with the NICU nurses, to promote successful breastfeeding. The health care providers in a study of 17 university NICUs thought the peer counselors improved the care of the infants by empowering the mothers to provide milk and modeling good infant care for the mothers.

When the physiology of lactation is applied to the practical management of inducing milk supply without the benefit of an infant's participation, it is apparent that mimicking natural breastfeeding is more effective. The breast can be prepared with massage and manual expression. Although some women succeed with manual expression alone, it is rare, and a good pump should be recommended. None of the hand pumps can truly duplicate the milking action of the infant, and all are essentially vacuum extractors. They should be used only as a stopgap measure when the electric pump is unavailable (see Chapter 21). A pump that can be used on both breasts simultaneously saves time and generates higher levels of prolactin. These pumps also generate a greater total milk volume than pumping each breast separately for the same length of

**Figure 15-11.** Breastfeeding outcomes during hospital stay by lactation staff type.  $\chi^2$  tests for overall differences within each outcome were significant at  $p < 0.001$ . Breastfeeding outcomes were classified as any maternal breast milk (infant receiving any maternal breast milk via direct breastfeeding and/or pumping regardless of supplementation with formula), exclusive breast milk (infant receiving exclusive maternal milk via direct breastfeeding and/or pumping without any formula supplementation), and any direct breastfeeding during NICU admission and at discharge (infant fed directly at the breast for at least one feeding with or without subsequent formula supplementation) during NICU admission and at discharge. Estimates do not include exclusive donor milk. (From Oza-Frank R, Bhatia A, Smith C: Combined peer counselor and lactation consultant support increases breastfeeding in the NICU, *Breastfeed Med* 8:509, 2013.)

time.<sup>103</sup> Subsequent studies have produced variable observations. Groh-Wargo et al.<sup>52</sup> studied 32 women who were randomly assigned to single or double pumping for 6 weeks. No difference was found in prolactin levels or total volume of milk produced by these investigations, although the time-saving effect was considered important.

Jones et al.<sup>69</sup> reported a randomized, controlled trial that was designed to compare methods of milk expression after preterm delivery. It involved 36 women: 19 used simultaneous pumping and 17 used sequential pumping by random assignment. A crossover design was used to evaluate the effect of breast massage on milk volume and fat content (estimated by creatmatocrit). The authors reported that the results were unequivocal, showing that pumping both breasts simultaneously produced more milk—125.1 g with massage and 87.7 g without. This was compared with sequential volumes of 78.7 g with massage and 51.3 g without.

Pumping should be initiated as soon as a mother's condition permits. Offering this

opportunity to the mother should be part of the supportive care offered by postpartum staff. All the points of preparation for pumping should be included: comfortable position, tranquil atmosphere, preparation of the breast with gentle stroking and warmth, massage during pumping, confidence, and reassurance from the staff. The obstetrician is in an important position to initiate the offer to pump, because he or she should know whether or not the mother intends to breastfeed from conversations during the mother's prenatal care. The mother may not know it is appropriate to ask for a pump. Providing knowledgeable, accurate, consistent, and sensitive support should be the rule in every perinatal center, especially for mothers of high-risk infants who choose to breastfeed.<sup>100,103</sup> The opportunity to pump should be offered to all women, regardless of previous feeding choice. Often a mother changes her mind when her infant is high risk and would receive many additional benefits from her milk.

Providing an appropriate room for pumping after the mother has been discharged is critical to individual success and is an expression of commitment to

breastfeeding by the NICU. This room should be clean, bright, and cheerful and accommodate more than one mother and companion at a time, unless several rooms are available. It should have a sink for washing hands and storage for equipment and supplies. A nurse call button or other alarm system is also essential. Additional features are soft music, a telephone, and reading material. The hospital should have a supply of approved electric pumps and individual disposable attachment packets for each mother. A place should be available to store her properly labeled and dated milk in a freezer or refrigerator. Sterile storage containers should be readily available.

A mother should be encouraged to rent a pump for home use and around-the-clock pumping. These are available from medical supply stores, pharmacies, home care services, hospitals, and some lactation consultants. Insurance companies reimburse for the cost of the rental when the milk is prescribed for a high-risk infant. A neonatologist can provide an appropriate letter of support. The hospital support staff who are coordinating the mother's care or the NICU staff should be sure that the mother understands how to use the equipment effectively. Ideally, NICUs have at least one staff member who is a licensed, certified lactation consultant who will coordinate this effort under the direction of the obstetrician, pediatrician, and neonatologist. One lactation consultant per 15 infants in the NICU is ideal. The mother should not be subjected to pressures of pump equipment entrepreneurs and unsolicited advice. The best remedy is for the NICU to provide on-staff, up-to-date experience and support to the mother in her efforts to provide milk and breastfeed her high-risk infant. **Box 15-16** outlines key strategies for successful

#### **BOX 15-16. Guidelines for Initiating Milk Supply Without Infant Suckling**

1. Begin as soon after delivery as maternal condition permits.
2. Initiate use of electric pump while in hospital.
3. Begin slowly, increasing time over first week.
4. Pump on more regular basis as soon as engorgement is evident.
5. Pump at least five times in 24 hours.
6. Allow a rest period for uninterrupted sleep of at least 6 hours.
7. Pump a total of at least 100 min/day.
8. Use "double" pump to pump both breasts simultaneously, which can cut total time proportionately.
9. Prepare breast with warm soaks, gentle stroking, and light massage to maximize production of milk.
10. Encourage skin-to-skin care (kangaroo care).

pumping when an infant is unable to suckle the breast. All neonatal nurses should be familiar with the available pumps and their use and be supportive of mothers who are pumping.<sup>100</sup>

### **Who Produces Milk for LBW or SGA Infants?**

Nationwide, mothers who give birth to infants who are admitted to special care nurseries are less likely to initiate lactation than mothers of healthy term infants, according to Meier.<sup>97</sup> The profile of mothers who give birth to these high-risk infants includes a higher percentage of low-income, low-education, young mothers, who do not breastfeed in great numbers. Postpartum and NICU staff should work to encourage these women to initiate lactation.

Maternal choice to breastfeed or provide milk for an LBW infant is influenced by many factors beyond those that affect most feeding decisions of normal full-term infants.<sup>92</sup> Lucas et al.<sup>88,89</sup> sought to answer two major questions in a study of 925 mother-infant pairs in five hospitals. Do health care professionals in neonatal units exert a major influence on a mother's feeding preference and availability of her milk for her infant? Are there population differences between mothers who do and do not provide their milk? In this study of five centers, the demographic characteristics of the mother were important, not those of the staff. This study did not look at success rates, however.

Mothers in a study by Verronen<sup>135</sup> had delivered infants at a mean of 31 weeks' gestation; the infants weighed less than 1850 g with a mean of 1370 g. More educated mothers provided their milk (98%) than uneducated (40%). Factors of higher socioeconomic class, lower parity or fewer living children, being married, and being older than 20 years of age were associated with providing milk. Boys were more apt to receive mother's milk, as shown in other studies. Birth weight and extreme immaturity were not a determinant, nor was transfer of the infant to another center. The Rush Mother's Milk Club, which is a breastfeeding intervention for mothers of VLBW infants in Chicago, was developed and directed by Meier and colleagues.<sup>98,99</sup> In the 52-bed urban NICU, the staff provided facilitated learning. Transportation was provided for mothers from home, as well as a weekly interactive social luncheon. They employ five peer counselors and provide a 24-hour, toll-free pager information line. The peer counselors also contact mothers at home. Low milk supply is aggressively managed with record keeping, encouragement, and counseling. The lactation initiation rate among these predominantly low-income African-American women was

72.9%. Exclusive mother's milk was attained by 57.2% and some mother's milk by 72.5%.<sup>101</sup> Skin-to-skin and kangaroo care are important features of this program and many others.<sup>91</sup>

## *Feeding the Near-Term Infant (35 to 37 Weeks' Gestation) at the Breast*

Near-term infants (i.e., 35 0/7 weeks to 36 6/7 weeks) may be nursed at the breast if otherwise stable. Breastfeeding should be initiated by one hour of age if mother and infant are stable. Health care professionals should monitor to ensure that frequent ongoing feedings are occurring "on demand" at least 10-12 times a day. Communication among staff and with the parents is key to success. Involvement of lactation-trained staff who are also skilled neonatal nurses mitigates confusion and conflicting messages to the family. Particular care should be given to assist a mother in getting the infant to suckle, especially if the breast and nipples are large or engorged.<sup>107,110</sup> Weight should be followed closely to prevent excessive weight loss. Infants who receive sugar water and formula supplements lose more weight than those who are nursed frequently at the breast without supplementation. If breastfeeding is going well, the infant could be discharged with the mother from the hospital as soon as the infant begins to gain substantially, with close follow-up at home. Poor weight gain, less than 20 g/day, is usually the result of inadequate intake. Average weight gain should be 26 to 31 g/day (see Appendix J). A mother may need to pump between feedings if the infant does not stimulate the breasts adequately. The milk can be provided by cup or lactation aide device (see Appendix J and Figure 14-10). Difficulties with latch should be investigated with a careful examination of the infant's mouth and the mother's breast and nipples. Before discharge, the physician, as well as the nurse, should observe the dyad.<sup>116</sup> If a mother is a low producer, galactagogues can be considered. (See Chapter 11 and Protocol #9 in Appendix J.) Follow-up should include frequent weighings and growth measurements (length and head circumference should increase approximately 0.5 cm/wk). Home visits or office checks are crucial to monitor progress. An extensive review of practice guidelines for the care of the late preterm infant has been prepared by the National Perinatal Association.

## *Premature Infants of 28 6/7 Weeks to 32 6/7 Weeks*

Infants of gestational age more than 28 weeks but less than 35 weeks are frequently breastfed in

NICUs, because the value of human milk has been recognized by most neonatologists.

Feeding at the breast when an infant is less than 1500 g is considered too strenuous by many neonatologists, even though it has been proved that it takes less energy and less impact on vital signs to breastfeed than bottle feed.<sup>81</sup> When the feeding of infants of less than 1500 g was examined, however, the growth of those fed at the breast was comparable with that of matched control infants fed expressed human milk by bottle.<sup>69</sup> Breastfeeding was started when sucking movements were observed. Initially, they received supplementary human milk by tube plus 800 units of vitamin D and 60 mg of vitamin C daily. Unrestricted visiting of parents to the neonatal unit, an optimistic and knowledgeable attitude of the nursing staff toward breastfeeding, and the avoidance of a bottle for the infants are important to success.<sup>93,94</sup> Encouraging the expression of milk by the mothers early in the postpartum period is essential. The main deterrent to successful breastfeeding was lack of maternal interest and commitment.

Blaymore Bier et al.<sup>17</sup> undertook a clinical study of breast feeding and bottle feedings in ELBW infants (birth weight 800 g or less) when they were considered ready to bottle feed. This was at a mean age of 35 weeks since conception (corrected gestational age). One breastfeeding and one bottle feeding were monitored each day for 10 days. Prefeeding and postfeeding weights, oxygen saturation, respiratory and heart rates, and axillary temperature were recorded. Higher oxygen saturation and higher temperatures during breastfeeding and less likelihood of desaturation below 90% were noted in the breastfed infants. The weights reflecting intake were higher in the bottle-fed infants. The authors concluded that it was physiologically safe and less stressful for infants to breastfeed. The lower intake requires monitoring, however.<sup>17</sup>

The ontogenetic and temporal organization of nonnutritive sucking during active sleep was studied by Hack et al.<sup>55</sup> in preterm infants. One of the six infants studied had recognizable rhythmic sucking bursts at 28 weeks, and all had bursts by 31 to 32 weeks. The number of bursts increased and the interval between bursts decreased as the infants matured, with the earliest indications of intrinsic rhythm beginning at 30 weeks.

Nonnutritive sucking has become a subject of controversy in NICUs. Allowing premature infants to suck on a pacifier during gavage feedings was initially reported to be associated with increased weight gain and shorter hospitalization. When nutrient intake and other parameters were controlled, however, no advantages to nonnutritive sucking were observed in somatic growth, serum proteins, energy absorption, or feeding tolerance, nor was any increase in tropic hormones or growth

promoters seen.<sup>33,40,93</sup> Infants have been observed to have transcutaneous oxygen saturation measurements increase by 3% to 4% during nonnutritive sucking.<sup>32</sup> Nonnutritive sucking does not appear to carry risk for infants destined for further bottle feeding. However, it should be avoided for infants destined to breastfeed, in order to avoid interference with normal sucking. Unfortunately, most studies have been done with bottles.<sup>35</sup>

Of greater significance is the value of having these infants placed at the "emptied" breast during gavage tube feedings. When Narayanan et al.<sup>109</sup> studied this practice, they found no change in weight gain or length of hospital stay. The practice did, however, result in more successful and longer duration of breastfeeding after discharge. This technique was originally designed in our nursery to improve the mother's milk production and encourage mothers who were becoming discouraged. As the infant matures and begins swallowing with sucking, it becomes unnecessary to pump the breast "empty" before presenting it to the infant. This is because any milk provided could be suckled and swallowed. Suckling at the breast initiates a peristaltic action that also triggers swallowing and the physiologic response of the entire GI tract (see Chapter 8). Suckling the breast also improves the mother's success when pumping. Readiness to wean from tube feedings to oral feeding is poorly defined and based on observations utilizing a bottle and/or a pacifier. Stable cardiopulmonary status at 33 to 34 weeks is associated with sucking patterns that resemble term infants (i.e., rhythmic alteration of suction and expression and the positive pressure generated by compression). Mature sucking pattern is not necessary for safe, successful feeding at the breast.<sup>76</sup> Infants can feed orally without suction. The undulating motion of the tongue does trigger let-down and the swallowing of fluid. An infant's behavioral state and organization during feeding, as well as the nursery environment (especially light and sound), and a caretaker's approach to oral feeding all affect an infant's performance.<sup>76</sup> This is another point supportive of early breastfeeding. Avoidance of bottles during the establishment of breastfeeding in premature infants has been evaluated in a Cochrane Review.<sup>27</sup> Small premature infants begin with tube feedings of their mother's milk. As they mature, they have breastfeedings added. But in many nurseries, the bottle with the mother's milk is introduced. Its impact on successful breastfeeding is challenged. Five studies of 543 infants were included in a Cochrane Review by Collins et al.<sup>27</sup> Four of the studies substituted cup feeding when mother was not available to breastfeed. The cup feedings increased the probability of successful breastfeeding and continuation of breastfeeding. Cup feedings, however, prolonged hospitalizations by 10 days. Noncompliance was

an issue as well. A study in Egypt, after this review, reported 30 cup-fed premature infants compared with 30 bottle-fed infants who were breastfed on discharge because mothers did not provide their milk or breastfeed before discharge. The cup-fed infants breastfed for longer durations and in greater numbers.<sup>1</sup> The crucial role of adequate nutrition to brain growth, especially in the premature infant, is generally acknowledged. Although nutrition may not overcome all the problems of extreme prematurity and its impact on the immature brain, it does reduce infections and NEC and has immunomodulatory properties when it includes over 50% human milk. The impact of human milk constituents on the white matter and its development is remarkable. This is being attributed to the gut-immune brain axis.<sup>71</sup> The nutritional adjustments to use human milk and human milk supplements are considered safe, inexpensive, cause few side effects, and are easily implemented.

## Breastfeeding the Extremely Premature Infant

Evaluations of feeding strategies are rarely conducted or published, in spite of rigid protocols in some nurseries. Early initiation of feedings has been thought valuable and safe. In a study of 171 premature infants between 26 and 30 weeks' gestation, Schanler et al.<sup>124</sup> tested the validity of GI priming and continuous infusion, versus intermittent bolus tube feeding with human milk or preterm formula. Infants were randomized to four treatment combinations in a balanced two-way design. Investigators compared the presence or absence of GI priming for 10 days and continuous infusion versus intermittent bolus tube feeding. Time to full feeding was similar in all groups. GI priming had no adverse effects and improved calcium/phosphorus retention and shorter intestinal transit times. Bolus feeding was associated with less feeding intolerance and greater weight gain than the continuous method. The more human milk fed, the lower the morbidity rate was. The authors concluded that early GI priming with human milk and bolus feedings provided the best advantage for premature infants. Very preterm infants, born at 26 to 31 weeks' gestation, have the capacity for the early development of oral motor competence that is sufficient for establishment of full breastfeeding at a low postmenstrual age, according to Nyqvist.<sup>112</sup> Using the Preterm Infant Breastfeeding Behavior Scale (Table 15-16), designed for use by mothers and professionals to observe levels of competence in oral motor behavior during breastfeeding, the author studied 15 infants born at 26 to 31 weeks'

**TABLE 15-16** The Preterm Infant Breastfeeding Behavior Scale (PIBBS)

Scale Items	Levels of Competence
Rooting	Did not root Showed some rooting behavior (mouth opening, tongue extension, hand-to-mouth/face movements, head turning) Showed obvious rooting behavior (simultaneous mouth opening and head turning)
Areolar grasp (how much of the breast was inside the baby's mouth)	None, the mouth only touched the nipple Part of the nipple The whole nipple, not the areola The nipple and some of the areola
Latched on and fixed to the breast	Did not latch on at all so the mother felt it Latched on for <1 min Latched on for 1-15 min or more, recorded by marking a cross along a line graded 1-15 min
Sucking	No sucking or licking Licking and tasting, but no sucking Single sucks, occasional short sucking bursts (2-9 sucks) Repeated (2 or more consecutive) short sucking bursts, occasional long bursts (10 sucks or more before a pause) Repeated long sucking bursts
Longest sucking bursts	Maximum number of consecutive sucks, recorded by marking a cross along a line graded 1-30
Swallowing	Swallowing was not noticed Occasional swallowing was noticed

From Nyqvist KH: Early attainment of breastfeeding competence in very preterm infants, *Acta Paediatr* 97:776, 2008, p 778, Figure 1.

gestational age. The author made daily assessments. Semidemand feeding was utilized with a prescribed total daily income volume. Breastfeeding was initiated at 29 weeks. Rooting, efficient areolar grasp, and repeated short sucking bursts were noted at 29 weeks. At 31 weeks, long sucking bursts and repeated swallowing were observed. Sucking rates ranged from 5 to 24 with a median of 17. Full breastfeeding was reached between 32 and 38 weeks with a median of 35 weeks. Weight gain was described as adequate. Alternative techniques were described in a report from a nursery in Brazil,<sup>31</sup> in which they placed infants in groups trying techniques of relactation, translactation, and breast-ogastric tubes. They described 432 infants who, at discharge, were breastfeeding 85%, 100%, and 100% in each group, respectively. All attained good weight gain, with only 1.6% feeding-related problems. The definition of relactation and translactation resembles other nurseries' use of lactation aide devices for additional nutrition.

Transpyloric tube feeding in VLBW infants with suspected gastroesophageal reflux has been used successfully by Malcolm et al.<sup>92</sup> They described 72 VLBW infants with a median birth weight of 870 g (a range of 365 to 1435 g) and a gestational age of 26 weeks (range 23 to 31 weeks) who received transpyloric feedings. They observed a reduction in apneic episodes and a decrease in bradycardia. Five infants developed NEC, none of

whom were receiving human milk. The authors concluded that transpyloric feedings, when limited to human milk, may safely reduce episodes of apnea and bradycardia in preterm infants suspected of gastroesophageal reflux. They suggest confirmation of this work in other NICUs, with the potential of changing hospital procedures.

### SGA Infants

Infants who are below the 10th percentile (or 2 SDs) in weight for their gestational age are termed SGA. These infants may also be shorter in length and have smaller heads, depending on when in gestational life the insult to their growth occurred. The more general the growth failure is, the earlier the intrauterine effect appears. For example, rubella in the first trimester causes total growth retardation, whereas hypertension in the mother in the third trimester predominantly affects weight. The more profound the growth retardation is, the more difficult the nutritional problems are.

SGA infants are prone to be hypocalcemic; however, if they can be provided with adequate breast milk early, this complication may be avoided. This is because the calcium/phosphorus ratio is more physiologic in human milk than formula. Other problems, including hypothermia and hypoglycemia, which lead to a vicious circle of acidosis and associated problems, can be triggered by

unmonitored exposure of an infant to thermal stress in the first hours of life and failure to identify the hypoglycemia early. Hypoglycemia in an SGA infant cannot be ignored. The potential exists for significant stress to the nervous system, which can result in seizures that require aggressive therapy and a detailed diagnostic workup. SGA infants lack glycogen stores, so they cannot raise their own blood sugar level by mobilizing stores.

Using human  $\alpha$ -lactalbumin as a marker protein, Schanler et al.<sup>125</sup> demonstrated that SGA infants with intrauterine growth restriction have delayed postnatal decrease in macromolecular absorption and delayed intestinal maturation, even compared with premature infants of the same weight. Their management demands special care. The enzymes in human milk can facilitate catch-up maturation of the intestinal tract.

Thus perinatal nursery staff may appear to be obstructive to breastfeeding when they hover over this infant or even insist on transfer to the nursery. Initial breastfeeding at delivery is permissible; however, adequate external heat must be provided. Testing the blood sugar should be performed in the delivery room recovery area. The infant should be sent to the nursery if hypoglycemia or hypothermia cannot be controlled. Frequent breastfeeding can be initiated unless the blood sugar level is too low (less than 30 mg/dL) or unresponsive to oral treatment. It may not be possible for even an actively lactating multipara to sustain an SGA infant initially, but the infant should be put to breast at least every 3 hours and given intravenous glucose as well.<sup>78</sup>

Term SGA infants often have a poor suck and poor coordination with the swallow reflex. They may have considerable mucus, with gagging and spitting. A simple lavage of the stomach with a No. 8 feeding tube (or No. 5, if the infant weighs less than 2600 g) and warmed glucose water usually relieves the gagging. Once this SGA infant begins to eat, he or she will do well and will require sufficient kilocalories to meet the needs of an AGA infant. The mother may need to use a breast pump initially to stimulate lactation and increase the volume she produces.

Children born SGA are at a neurodevelopmental disadvantage. When these infants receive enriched formula, it does improve their growth, but breastfed SGA infants grew best in a series of children followed by Morley et al.<sup>104</sup> Three groups fed regular formula, enriched formula, or breast milk were followed: 147 were randomized to regular formula, 152 received enriched formula, and 175 were in the reference group of breastfeeding. The developmental scores using the Bayley Mental Development Index or the Psychomotor Development Index at 18 months were measured. No difference between formula groups was seen. The breastfeeding infants had significantly higher Psychomotor

Development Index scores and a 6-point advantage in the Bayley Mental Development Index. The authors suggested that SGA infants clearly benefited from being breastfed.<sup>104</sup>

## *Transitioning from Hospital to Home*

---

The transition from hospital to home is a stressful time for all families, but when an infant is premature and has been in the NICU for days, weeks, or months, transition can be extremely difficult. The stress can be reduced by discharge planning. The mother should spend as much time as possible with her infant, breastfeeding when present. A lactation consultant or trained staff member should observe these interactions. The presence of sucking and swallowing should be documented. If mothers have received adequate assistance in the days and weeks before discharge, then positioning and latch should be perfected by discharge.

The Committee on Fetus and Newborn of the AAP has delineated three physiologic competencies that are recognized as essential before hospital discharge of the preterm infant:

- The ability to maintain body temperature in a home environment
- Sufficiently mature respiratory control
- Oral feeding sufficient to support appropriate growth

Hospitals that have facilities to accommodate care-by-parent overnight are helpful in the transition. At minimum, parents should be given all the medications and treatments before discharge and be breastfeeding. If a mother's supply is not adequate yet, she should be instructed in the use of the lactation supplementer before discharge, with a plan for the amount and substance to be placed in the supplementer. If she has stored milk available, it can be used. If not, the neonatologist will have to order donor milk, preferably from a milk bank. If not, a special care formula or special human milk supplementer, which is designed to be used separately from mixing with mother's milk as a feed, can be utilized. Mothers should be instructed to continue pumping until the infants are exclusively breastfed and gaining weight adequately. Pumping three to four times per day to completely empty the breasts at home is critical. Preterm infants usually do not completely empty the breasts at first. They lack the suction strength and sustainable effective organization of sucking until they approach 40 weeks' corrected gestational age, according to Meier.<sup>97</sup> To guarantee adequate production and intake, these preterm infants need scheduling to ensure feeding every 3 hours, although feeding on cue is more effective in the long run.

In Sweden, preterm infants who are less than 32 weeks' gestation are fed their mother's milk or, if that is not available, donor milk. Twenty-seven of 36 NICUs in Sweden that responded to a questionnaire on breast milk handling had their own milk bank.<sup>113</sup> The authors have established national guidelines for the hospital use of human milk. In North America, the Human Milk Banking Association of North America oversees volunteer milk banking (see [Chapter 21](#)). Milk banks are listed in [Appendix H](#).

Follow-up after discharge from the NICU is essential and should be involved as the dyad is prepared for discharge. Independent predictors of human milk receipt at NICU discharge were determined by Brownell et al.<sup>20</sup> from analysis of the Vermont Oxford Network clinical data at a Level IV NICU in the inner city. They concluded that a strong NICU lactation program, in combination with a community-based peer counselor program, may increase rates of human milk consumption among VLBW infants of black/Hispanic mothers, as well as those with more complicated courses.

Community-based peer support programs are very helpful in supporting postdischarge mothers to continue to provide their own milk.

Early discharge with tube feeding of preterm infants under close supervision by pediatric nurse practitioners in the Netherlands was done. The effect was an increase in the duration of breastfeeding.<sup>96</sup> The finding continued for 6 months post-discharge. This approach needs confirmation but is important.

Not all premature infants will need supplementation at home. Before and after weighings ([Chapter 8](#)) can be done while an infant is still in the hospital to measure the infant's intake at each feeding. Digital scales, accurate to 2 g, are available in hospitals, and home models can be rented. When an infant is first discharged, it is helpful to both the physician and the parents to know what intake actually is.<sup>57</sup> Some mothers produce large volumes of milk, but the infants do not gain weight. Pumping first to remove the foremilk (and freeze it) and having the infant suckle the hind milk can help this problem. A pediatrician plays a critical role in the success of feeding after discharge. Monitoring of progress and knowledge of the unique concerns in breastfeeding premature infants are key. The Academy of Breastfeeding Medicine Protocol #12 in [Appendix J](#) details the steps to follow.

## *Improving Milk Production*

1. Begin pumping as soon postpartum as possible.
2. Use hospital-grade double (two-breast) pumps.
3. Pump 10 to 15 minutes every 3 hours until more than a few drops are produced (72 hours).

4. When the amount increases, continue to pump for 2 minutes after the last drop is produced (total 20 to 30 minutes).
5. Keep a record of times pumped and volumes produced.
6. Pump at babies' bedside when possible.
7. Start with kangaroo care.
8. Stroke and massage breast during pumping.
9. As soon as infant is able, place at emptied breast to suckle or during gavage feedings.

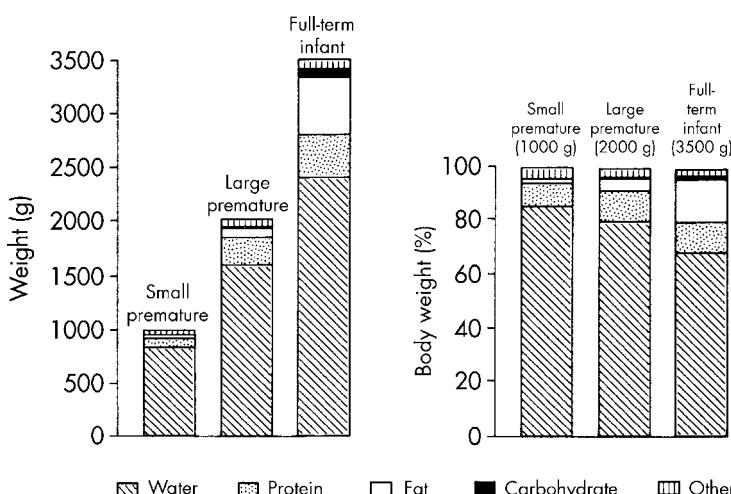

Pump-dependent mothers are at risk for diminishing milk supply. Mothers of preterm infants can attain and sustain high production levels by combining the use of electrical pumps with manual techniques, including hand expression taught by an experienced nurse. This includes mothers of normal term babies. It is essential for mothers of infants in the NICU. Dr. Morton<sup>105</sup> has developed several videotapes demonstrating these techniques that are excellent for mothers and staff alike. [Chapter 8](#) discusses pharmacologic stimulation of milk volume.

## *Concluding Recommendations*

Infants who weigh less than 1800 g at birth and have to be gavage fed and infants of any weight who are acutely ill present complex problems. A mother should be instructed to express her milk initially and contribute any colostrum she produces. This can be given by gastric tube spoon or cup. A hospital-grade electric pump is effective in helping a mother increase the volume produced. When an infant is born at 1000 g, requires ventilator support for days, and is not discharged for 8 weeks ([Figure 15-12](#)), it is difficult to maintain

**Figure 15-12.** 1100-g infant shown at 4 hours of life in a busy NICU. Infants in these situations require early intervention to ensure successful breastfeeding.

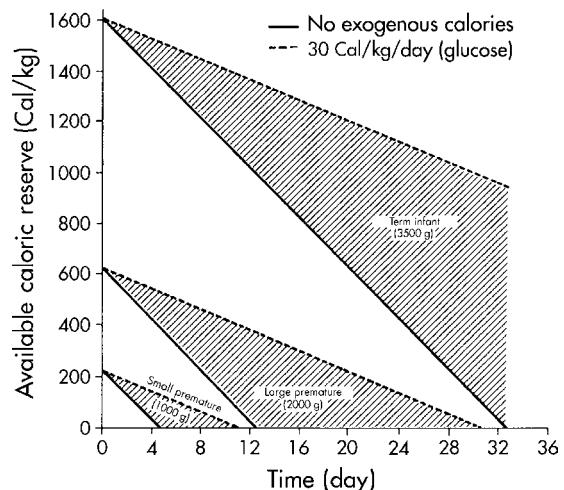

**Figure 15-13.** Absolute and relative body composition of infants weighing 1000, 2000, and 3500 g at birth. (From Heird WC, Anderson TL: Nutritional requirements and methods of feeding low-birth-weight infants. In Gluck L et al., editors: *Current problems in pediatrics*, vol. 7, no. 8, Chicago, 1977, Year Book.)

a large volume of milk by pumping. It can be done, however, with supportive counseling by staff and the initiation of kangaroo care. Milk volumes usually increase when an infant begins to actually breastfeed, not unlike relactation (see Chapter 19) or increasing milk volume in other situations (see Chapter 8).

When nipple feeding is possible, an infant can be put to the breast. It requires less energy to suckle at the breast than to feed from a bottle. The peristaltic motion of the tongue, which is the normal innate suckling mode, initiates the peristaltic motion of the GI tract and triggers the swallow. If no pacifiers or rubber nipples have been given, an infant may be able to suckle at the breast well before he reaches 1500 g. Figure 19-3 illustrates an infant who first nursed at 1100 g. If little or no breastfeeding has been done in the hospital and the mother has been unable to pump enough to sustain the daily needs, then an infant may be frustrated at the breast when sent home from the hospital unless intervention is provided.

One can see that the reserves of premature infants are limited if one studies the absolute and relative body compositions of infants at birth (Figure 15-13). If one considers how little time it takes to starve a premature infant compared with a full-term infant, the risks of starving a premature infant while the infant adapts to nursing at the breast are real<sup>126</sup> (Figure 15-14). The solution to the problem is to provide nourishment while the infant stimulates maternal milk production by sucking at the breast. A piece of equipment called a nursing supplementer provides this setup very effectively (see Figure 19-4). It was developed to provide nourishment for an adopted infant who is being nursed by a mother who has not been pregnant or has never lactated. It sustains the infant while the mother's milk supply develops (see

**Figure 15-14.** Estimated survival of starved and semistarved infants weighing 1000, 2000, and 3500 g at birth. (From Heird WC, Anderson TL: Nutritional requirements and methods of feeding low-birth-weight infants. In Gluck L et al., editors: *Current problems in pediatrics*, vol. 7, no. 8, Chicago, 1977, Year Book.)

Chapter 19). The same effect can be provided for premature or sick infants who have not nursed at the breast since birth and need nourishment while the mothers' supply develops, even though she has been pumping.

The infant can continue to gain weight while stimulating the breast if a supplementer is used. The volume required from the nursing supplementer drops continually in a week or so. Occasional infants require the supplementer for a month. The mother should continue to pump after breastfeedings until her volume increases.

The nursing supplementer provides a simple means of ensuring adequate nourishment while adapting to the breast. It is preferable to using

TABLE 15-17 Postdischarge Nutritional Screening Assessment		Action Values
<b>Growth</b>		
Weight gain		<20 g/day
Length growth		<0.5 cm/wk
Head circumference		<0.5 cm/wk
<b>Biochemical test</b>		
Phosphorus		<4.5 mg/dL
Alkaline phosphatase		>450 IU/L
Urea nitrogen		<5 mg/dL

IU, International units.

supplemental bottles because the infant is not confused by the rubber nipple, which requires a different mechanism of sucking than the human nipple. Furthermore, the suckling of the breast provides the continued stimulus necessary for increasing milk production. Cup feeding is an alternative to the bottle if the infant needs additional nourishment.

The parameters that are to be met before discharge home from the hospital include sustained weight gain, growth in length and head circumference, and stable biochemical parameters<sup>49</sup> (Table 15-17). After discharge from the hospital, these same parameters should be met. If faltering is persistent, fortifying breastfeeding may be indicated. This can be accomplished without interfering with the breastfeeding process again by using a lactation supplementer containing enriched breast milk that had been previously pumped or donor milk, which is preferable to formula.

Posthospitalization breastfeeding patterns of moderately preterm infants (30 to 35 weeks) were studied by Wooldridge and Hall<sup>138</sup> using daily feeding diaries in 55 women for the first month after discharge. Those women who were able to exclusively breastfeed before the end of the first week at home were able to maintain their supply. In general, those women who did not have an adequate supply during the first week were unlikely to achieve it by week 4. The proportion of breastfeeds increased during the 4 weeks of observation, but only 56% achieved exclusive breastfeeds by 4 weeks in this study. Proper preparation prior to discharge and adequate support at home assures success.

# *Medical Complications of Mothers*

---

Suboptimal breastfeeding has been shown to take its toll on women's health. The U.S. maternal health burden from current breastfeeding rates has been calculated in terms of premature death, as well as economic costs, by Bartick et al.<sup>27</sup> Working with a cohort of women between 15 and 70 in 2002, involving 1.88 million, they modeled cases of breast cancer, premenopausal ovarian cancer, hypertension, type 2 diabetes, and myocardial infarction. They considered direct costs, indirect costs, and the cost of premature death (before age 70) expressed in 2011 dollars. They calculated that suboptimal breastfeeding costs 17.4 billion dollars to U.S. society, in premature death and poor health. Breastfeeding and maternal disease is discussed in this chapter.

## *Obstetric Complications*

---

### **ENGORGEMENT ASSOCIATED WITH DRUGS FOR PRETERM LABOR**

Breast engorgement and galactorrhea have been reported to be associated with the use of ritodrine for tocolysis. Evaluations were done in 11 women, with measurements of serum prolactin, progesterone, estradiol, and estriol excretion. No differences were noted in association with the ritodrine. Apparently, the effect is unrelated to hormone changes.<sup>236</sup>

Reports of breast engorgement and galactorrhea have also been reported with other tocolytics. One case was associated with the use of intravenous (IV) magnesium sulfate in a 24-year-old woman at 30 weeks' gestation.<sup>172</sup> Plasma magnesium levels ranged between 4.1 and 6.4 mg/mL. On day 4 of

treatment, engorgement and dripping of milk developed. Prolactin level was 83.6 ng/L; normal range in pregnancy is up to 200 ng/L. Magnesium was replaced with nifedipine, and the symptoms gradually subsided. Another case report describes tocolysis, in which thyrotropin-releasing hormone 400 mcg every 8 hours for four doses was used with corticosteroids to enhance fetal lung maturity. This has been associated with an increase in prolactin. The patient also received magnesium sulfate initially, followed by oral terbutaline. Thirty-six hours after the last dose of thyrotropin-releasing hormone, the patient experienced painful bilateral engorgement, tender masses in both axillae, and lactation. Prolactin level was 55.4 ng/mL. Symptoms subsided in 96 hours.<sup>107</sup>

### **CESAREAN DELIVERY**

When birth takes place by cesarean delivery, a mother becomes a surgical patient with all the inherent risks and problems. If the procedure is anticipated because of a previous cesarean delivery, cephalopelvic disproportion, or some other identifiable reason, a mother can prepare herself psychologically for the event and usually tolerates the process better. When the procedure is unplanned and done during the process of labor, it is psychologically more traumatic, and the mother tends to feel as if she has failed in her role. In addition to this unexpected disappointment, medical emergencies such as a long, difficult labor, abruptio placentae, blood loss, toxemia, or infection may also have an impact on the mother's well-being.

A mother who plans to breastfeed after cesarean delivery should be able to do so if the infant is well enough. The method of delivery makes no

significant difference to the timing of the milk coming in or the changes in the concentration of the major milk constituents in the first 7 days postpartum.<sup>156</sup> Depending on the type of anesthesia and the associated circumstances, the mother may feel alert enough to put the infant to breast within the first hour. The obstetrician, surgeon, and the operating room nurses are key in making it happen.

Bupivacaine is being used as an epidural block for cesarean or vaginal delivery because it does not result in the decrease in muscle tone and strength reported in neonates whose mothers have received lidocaine or mepivacaine.<sup>174,229</sup> Bupivacaine and tetracaine are highly protein bound and appear in milk in low concentrations, in contrast to lidocaine and mepivacaine, which are nonionized and unbound in serum. Because most local or regional anesthetics are used with epinephrine, which causes local vasoconstriction, thus slowing the rate of absorption, the anesthetic effects are prolonged and the amount secreted into the milk is minimal.

Epidural morphine is used for more prolonged analgesia and is used in cesarean delivery because it can then be continued postpartum for the relief of postoperative pain. Bernstein et al.<sup>34</sup> showed that epidurally administered morphine enters the breast milk in low levels compared with the levels in maternal urine, which were several thousand times higher. Most of the morphine in colostrum is in the conjugated form, and thus pharmacologically inactive. Other studies report a milk/plasma ratio of 2:45; the amount received via the milk is calculated to be less than 50 mcg/dL of milk, causing no untoward symptoms in any of the cases reported. At birth, infants may have morphine in their system from transplacental transfer of intrapartum maternal dosing. Transplacental medication has depressed some infants and may interfere with early attempts to suckle.

In a scheduled cesarean delivery under controlled circumstances, the procedure is initiated using local anesthesia to the skin and facial layers. Systemic anesthesia is given as soon as the cord is clamped, sparing the transfer of anesthetics to the newborn.

Regional anesthesia permits the mother to remain awake, and she may be ready to nurse as soon as the IV lines and urinary catheter are stabilized. The mother will need considerable help from nursing staff. She should remain flat if she has had a spinal anesthetic to prevent developing a spinal headache. She can turn to one side and offer the breast by placing the infant on his or her side and stroking the infant's perioral area with the nipple. The normal full-term infant who has not been depressed by maternal medication should do well. If the mother can be turned to the other side, the infant may nurse on both sides. In this first

encounter, the emphasis is on some suckling, not switching. The bedside rails will help the mother turn and provide safety for her.

Maternal fluids and medications in the first 48 hours postoperatively should not affect the infant adversely. Pain medication is usually required for approximately 72 hours. It is best given immediately after breastfeeding to permit the level to peak before the next feeding. The medication used should be limited to short-acting drugs that an adult eliminates quickly (i.e., within 4 hours) and that the newborn is able to excrete. Ibuprofen and acetaminophen are in that category; codeine is also acceptable (see Chapter 11). Low-grade fever may occur and should not interrupt lactation.

Some positive factors are associated with breastfeeding for the mother who has had a cesarean delivery. Lactation is advantageous to the postoperative uterus, in that the oxytocin production stimulated by suckling will assist in its involution. In addition, the traumatized psyche of a mother, whose delivery did not occur naturally as planned, is more quickly healed when she can demonstrate her maternal capabilities by breastfeeding.

Whether breastfeeding can be introduced early, or must await stabilization of medical problems in mother or infant, when the section was done emergently, it is a reasonable goal for the mother to seek in most cases. Supportive nursing care is critical to establishing successful lactation. None of this can take place, however, unless a physician has carefully assessed the condition of the mother and the infant in light of the great advantages and possible disadvantages of breastfeeding to both.

The management should include the following:

1. A postoperative care plan that includes sufficient rest. Most postpartum wards are not scheduled to include adequate rest for postoperative patients.
2. The family must be instructed on the needs for rest at home and assistance with the household chores. With shorter hospital stays, this is even more critical.
3. The impact on the infant should be considered when writing the mother's medication orders.
4. If the infant cannot be put to breast, arrangements should be made to pump the mother's breasts on a regular basis with a quality hospital-grade double electric pump. This should be done at least every 3 hours during waking hours, and at least once at night, even if separation will last only a day or two. Milk should be given to the infant if the infant is able to feed.
5. If the mother is in intensive care, pumping can still be done by a skilled bedside nurse or lactation consultant.

## Hypergalactia or Over-Supply While Breastfeeding

Hypergalactia or overproduction of milk while breastfeeding is the problem of producing excessive amounts of milk, which is then associated with discomfort. It often leads to the mother pumping and storing milk beyond her infant's needs. The real clinical issues early in lactation, however, are rapid let-down, excessive flow, and choking and gasping by the infant. In the long range, it leads to acute mastitis, plugged ducts, chronic breast pain, pumping, and early weaning, especially due to soaked under clothing and wet stains of the outer clothing. During actual breastfeeding, the latch is often shallow, causing nipple pain, milk leakage, and continually engorged and leaking breasts. The infant may also have increased weight gain, fogginess, excessive flatus, and explosive green stools. This is associated with high lactose, low-fat milk. It may also be associated with loose stools resembling mucus.

If simple adjustments to feeding do not help, the mother's thyroid function should be checked as both hyper- and hypothyroidism can be associated with prolactinemia. Prolactin levels can be measured using the standard protocol (see Chapter 8). It requires two levels of prolactin. The mother has a small butterfly needle with a stop cock and attached IV with a heparin lock. After recovery from the needle stick (10 minutes), a sample of blood is drawn and the system turned to the heparin lock. The infant is fed, or the breasts are pumped, for 10 minutes, and a second blood sample is drawn. The baseline level should be 100 or less, and the second level should be about twice the first measurement.

Management that has been effective is called block feeding. This is a process by which the mother nurses from one breast only for a block of 3 to 4 hours, and then from the other breast exclusively for a block of time. Feedings last 30 to 60 minutes. Usually the mother's milk supply drops within 48 hours. If further therapy is necessary, the mother can try pseudoephedrine (available in nose drops), or birth control pills containing estrogen, or herbs such as sage, parsley, or peppermint. Bromocriptine or cabergoline should only be used with the physician's involvement.

The mothers have trouble again when it is time to wean, so efforts should be made to avoid mastitis, plugged ducts, and other complications. An extensive review of hypergalactia is available by Eglash.<sup>76</sup>

## PREGNANCY RELATED HYPERTENSION

The terminology regarding hypertension has been redesigned by the Working Group on High Blood

Pressure in Pregnancy of the National Institutes of Health and is available worldwide. The term toxemia has been replaced with the terms preeclampsia, eclampsia, and HELLP (hemolysis, elevated liver enzymes, and low platelets). In all of these situations, the mother is monitored closely. In preeclampsia, the patient is at risk for cerebral edema, microscopic liver involvement, and glomerular lesion, pathognomonic of preeclampsia. The mother is seriously ill and at risk for serious complications of all these organs, including seizures.

Complications of hypertension usually begin after 32 weeks' gestation, but have also been observed to occur 24 to 48 hours or later postpartum. Close fetal monitoring is essential. Convulsions, renal disease, and cerebral hemorrhage in a mother are complications that can be prevented by careful management. Because serious hypertension in the mother may necessitate delivery of a premature infant, or an infant compromised by a poorly perfused placenta or maternal medications, a number of contraindications to immediate breastfeeding exist in the early postpartum period.

Initial treatment of a patient with preeclampsia includes bed rest, preferably lying on her side in a quiet room that is darkened to prevent photic and auditory stimuli. Blood pressure and proteinuria should be carefully monitored.<sup>59</sup> Magnesium sulfate is superior to phenytoin and diazepam. Treatment also includes salt restriction, and diuretics, such as thiazide or furosemide, may be used. Hydralazine (Apresoline) and methyldopa (Aldomet) or other antihypertensives may be indicated to lower blood pressure. Magnesium sulfate is safest for a breastfeeding infant. Many patients recover quickly after the infant and placenta are delivered, requiring only 24 to 48 hours of postpartum sedation.<sup>59</sup>

Often the infant is small for gestational age, or premature, and may require special or intensive care; therefore, the decision of when to initiate breastfeeding depends on the infant's condition. If the infant is full term and well, breastfeeding is initiated when toxemia precautions are discontinued. Magnesium can be closely monitored if the mother continues to receive it. It may be necessary to wait until the other medications can be discontinued, especially the diuretics, hydralazine, and methyldopa.

After the risk for convulsions is past, some attention can be given to manual expression or pumping, even if an infant cannot be nursed yet. If medications are a problem temporarily, the milk may have to be discarded, but the expression of milk will serve to stimulate the breast and initiate lactation.

Diminution of stress is a critical factor in hypertensive therapy, so maternal anxiety about being able to nurse must be managed with open discussion

of the overall plan and the role of the bedside nurse. On the other hand, the stress of early feedings that do not go well because the infant has been confused by initial bottle-feedings may also present a hazard in the course of maternal management. This can be minimized by cup feedings. The most important element in every case is communication with the patient about her expectations or needs regarding breastfeeding. A physician's therapeutic management design can put this in appropriate perspective. Because of the calming effects of oxytocin and prolactin, it may be therapeutic to breastfeed.

## RETENTION OF PLACENTA AND LACTATION FAILURE

Three cases of failed onset of lactation were reported by Neifert et al.<sup>197</sup> Although the original association of the placenta with delayed lactation was made a century ago, most reports of retained placenta merely discuss persistent hemorrhage as a recognized symptom. In each of the three cases the failure of breast engorgement and leakage of milk was evident from delivery. However, the hemorrhage and emergency curettage occurred at 1 week, 3 weeks, and 4 weeks postpartum, respectively. In each case, spontaneous milk flow began immediately postoperatively, after the removal of placental fragments. The authors suggest that failure of lactogenesis may be an early sign of retained placenta that should not be ignored.<sup>197</sup>

## VENOUS THROMBOSIS AND PULMONARY EMBOLISM

Venous thrombosis and pulmonary embolism are the most common serious vascular complications associated with pregnancy and the postpartum period. Pulmonary embolism has assumed relatively greater importance because of the decline in morbidity and mortality rates from sepsis and eclampsia. Varicose veins also present more problems during pregnancy than at any other time. These vascular complications all represent common features in vein physiology, as associated with the perinatal period.

In addition to the well-being of the mother, major concerns during lactation include procedures that might be necessary to establish a diagnosis and the systemic medications necessary for treatment that could have an impact on the nursing infant via the milk. Accurate diagnosis is urgent and is far more complex than therapy. Besides the health of a mother in this life-threatening state, any program of contraception after childbirth is fundamentally affected by the established diagnosis of thromboembolism. Thus the diagnosis must be precise.

## Diagnosis

Laboratory procedures, such as evaluation of arterial blood gases, liver function studies, and fibrin/fibrinogen derivatives, are not a problem to breastfeeding. The absence of fibrin split products in plasma and serum virtually excludes the diagnosis of embolism, although their presence does not confirm it. The most definitive diagnosis is made with radioactive scanning procedures and angiography.

Contrast venography is the most definitive method available for diagnosing deep vein thrombosis. The perfusion lung scan is the pivotal test for the investigation of patients with suspected pulmonary embolism. The radiopharmaceuticals used are technetium-99m-microaggregated albumin or microspheres (usual dose 3 mCi), which clear the milk promptly, thus requiring pumping and discarding the milk for 8 hours.<sup>93</sup> Pulmonary angiography, the most definitive test for pulmonary embolism, requires fluoroscopy, which is not a risk to a breastfeeding infant. The total dose is approximately 400 mrad, and thus should not interfere with lactation. In deep vein thrombosis of the leg, fibrinogen leg scanning uses iodine-125 (<sup>125</sup>I) fibrinogen, which requires 2 weeks of pumping and discarding the milk. Radioactive materials vary in their half-lives and disappearance time from breast milk. They all appear in breast milk (see Chapter 11).

Another diagnostic technique is duplex ultrasonography. It consistently visualizes the iliac veins. Impedance plethysmography is noninvasive, but not reliable for calf thromboses, and is contraindicated in lactating mothers.<sup>89</sup> At present, computed tomography and ultrasound are effective in diagnosing major arterial aneurysms only.

Magnetic resonance imaging (MRI) is a safe procedure while lactating. Radiocontrast agents, however, may be required. Gadolinium-containing contrast agents are tightly bound to the molecule and are not free in the plasma. They penetrate into milk only slightly and are not absorbed orally. The half-life is short (1.1 to 2.0 hours). They are safe for breastfeeding infants. They should clear a mother's system completely in 5 to 10 hours, depending upon the compound.

## TREATMENT

Anticoagulant therapy is the treatment of choice for established venous thrombosis with or without embolism. Heparin must be given parenterally and is destroyed by gastric juices. Because this large molecule does not cross the placenta or appear in breast milk, it can be used during lactation. This therapy is adequate for a hospitalized patient, where constant monitoring of coagulation is

possible. Warfarin has been considered the best replacement for heparin for home use, but it is secreted in the breast milk (see Chapter 11). The amount transmitted is minuscule, and it is considered safe to breastfeed while taking warfarin. In long-term therapy the prothrombin time should be monitored at least monthly in the infant, and vitamin K can be given if necessary.

The low-molecular-weight heparins are still large molecules. They do not pass into the milk and are orally poorly absorbed.

## Medical Problems

### MASTITIS

Mastitis is an infectious process in the breast that produces localized tenderness, redness, and heat, together with systemic reactions of fever, malaise, and sometimes nausea and vomiting. It no longer occurs in epidemics, as was once seen in hospitals before the common use of antibiotics and when hospital stays were prolonged for normal childbirth. The infection, however, may be hospital acquired if mother or infant is colonized with virulent bacteria before leaving the hospital, especially methicillin-resistant *Staphylococcus aureus* (MRSA).

Prospective studies estimate the incidence to be between 3% and 20%, depending on the definition and the length of follow-up postpartum. The common onset is within the first 6 weeks postpartum, but can occur anytime during lactation. Technically, mastitis is an inflammation of the breast, which may or may not involve an infection. It is not uncommon for the problem to start with engorgement, then become noninfective mastitis, followed by infective mastitis, and then to abscess if treatment is not introduced promptly (Figure 16-1).

The current definition of mastitis includes fever of 38.5°C (101°F) or more, chills, flulike aching, systemic illness, and a pink, tender, hot, swollen, wedge-shaped area of the breast<sup>199</sup> (Figure 16-2).

Table 16-1 lists the significant differential points among mastitis, engorgement, and plugged duct.

The portal of entry of the disease is through the lactiferous ducts to a secreting lobule, through a nipple fissure to periductal lymphatics, or through hematogenous spread. The common organisms involved include *S. aureus*, including MRSA, *Escherichia coli*, and (rarely) *Streptococcus*. Tuberculous mastitis does occur, and the infant often develops tuberculosis of the tonsils. In populations in which tuberculosis is endemic, it occurs in approximately 1% of cases of mastitis.<sup>101</sup>

Factors predisposing a woman to mastitis include poor drainage of a duct and then of an alveolus, presence of an organism, and lowered

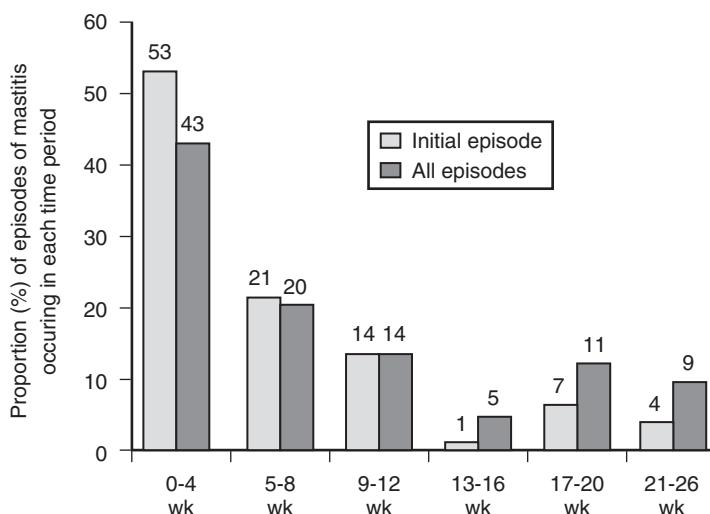

maternal defenses such as those associated with stress and fatigue (Figures 16-2 and 16-3). Insufficient emptying and obstruction of ducts by tight clothing can cause plugged ducts, which can be prevented from becoming mastitis if identified early and treated vigorously with local massage, moist heat, and rest. Missing a feeding or having an infant suddenly sleep through the night may cause engorgement, plugging, and then mastitis. Cracked or painful nipples may herald a problem, more because the mother avoids complete emptying on the painful side than because bacteria suddenly gain access. If a mother has cracked, fissured, sore nipples, then the breast pain and redness is more than likely mastitis.

Devereux<sup>67</sup> described 20 years of experience with 53 lactating patients who experienced 71 acute attacks of mastitis. The highest incidence was in the second and third weeks postpartum. No infant was weaned because of the mastitis. No infants were sick in association with the mastitis. All but five mothers nursed subsequent infants. Six patients had mastitis with other pregnancies. Eight of 71 patients (11.1%) developed abscesses, six of which required incision and drainage. The bacterial cause was not stated. When antibiotic treatment was delayed beyond 24 hours, the abscess rate increased.<sup>67</sup>

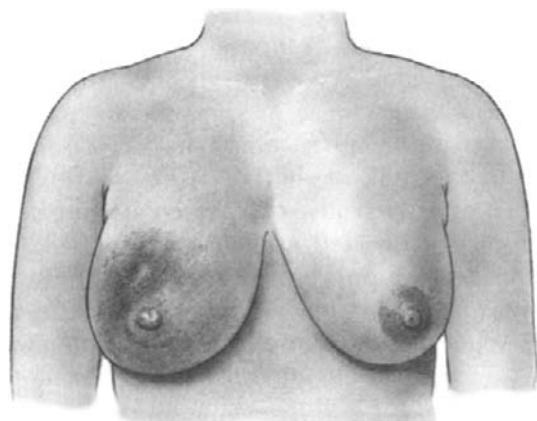

Studies by Fetherston et al.<sup>82</sup> observed increased breast permeability, reduced milk synthesis, and increased concentration of immune components IgA and lactoferrin, with increasing severity and systemic symptoms. They also observed increased sodium and decreased glucose in milk of the involved breast compared with the uninvolved breast and normal breasts (which is suggestive of weaning milk).

Although breastfed infants usually remain well during bouts of acute mastitis in their mothers, there is reported a case of scalded skin syndrome in an infant fed by a mother with mastitis that did not respond to ampicillin for 14 days. The child responded to IV nafcillin.

Using leukocyte counts and microbiologic counts, Thomsen et al.<sup>261</sup> have separated breast inflammations into three clinical states: milk stasis (counts less than 106 leukocytes and less than 103 bacteria per milliliter of milk), noninfectious inflammation (counts greater than 106 leukocytes and less than 103 bacteria), and infectious mastitis (counts greater than 106 leukocytes and greater than 103 bacteria) (Tables 16-2 and 16-3). The authors concluded that no treatment was needed in stasis, but lack of treatment led to recurrence and lactation failure in noninfectious inflammation and abscess in mastitis. Emptying the breast (frequent feedings and pumping or hand-expressing three times per day after a feed) was sufficient in

**Figure 16-1.** Proportion (%) of episodes of mastitis occurring in each time period ( $n=57$ ). (From Scott SA, Robertson M, Fitzpatrick J, et al: Occurrence of lactational mastitis and medical management: a prospective cohort study in Glasgow, *Int Breastfeed J* 3: 21, 2008.)

**Figure 16-2.** Mastitis of right breast, upper outer quadrant.

noninfectious inflammation and ameliorated the course in most cases of mastitis. However, recurrence was inappropriately high. Mastitis requires antibiotics in addition to emptying the breast.<sup>261</sup>

Because cultures require time, when the bacteria count is finally available and the clinical course is clear, the noninfectious variety should already be cleared. Laboratory results are confirmatory; however, a skilled clinician can avoid the relapses and progression to abscess by close monitoring and

selective, aggressive treatment before the cultures are reported (see Tables 16-2 and 16-3).

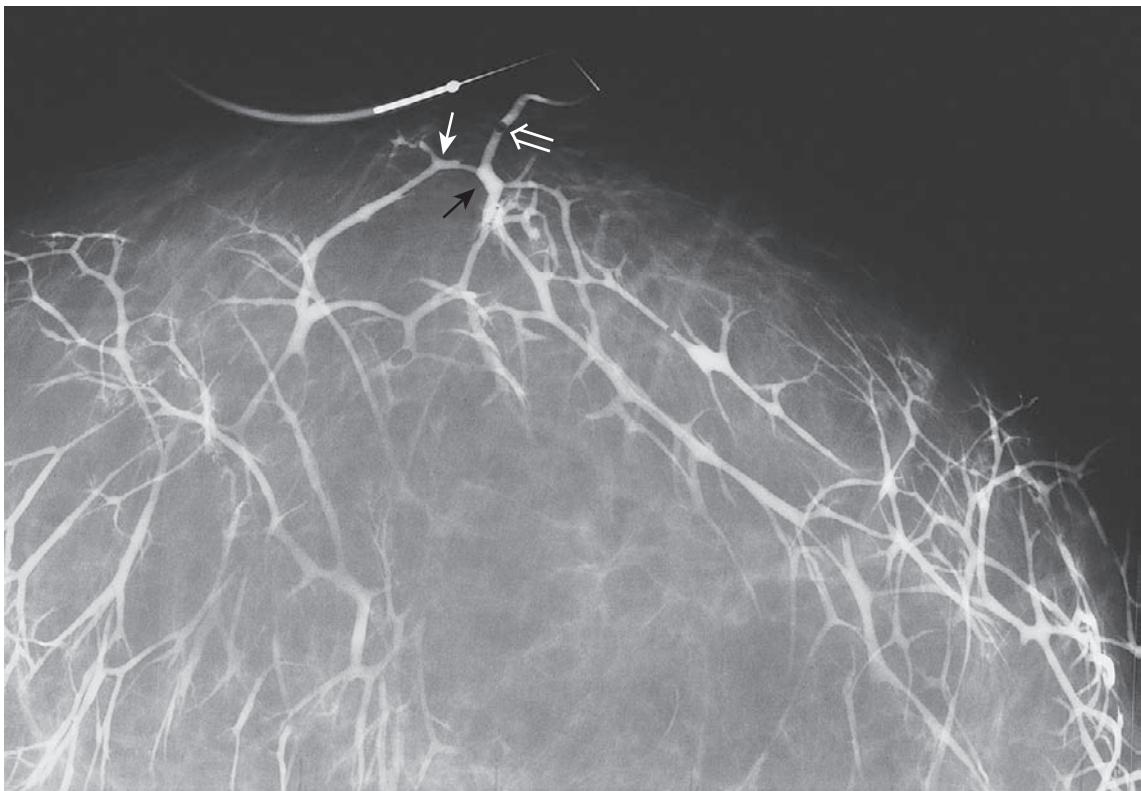

The guidelines of the World Health Organization (WHO) suggest that the breast milk be cultured and sensitivities done only if there is no improvement after 2 days of antibiotics, if the mastitis returns, or if it is hospital-acquired mastitis. Cultures and sensitivities are indicated if a patient is allergic to the usual antibiotics or the illness is exceptionally severe.

Because prevention is the most effective treatment, clinicians must inform patients of the need to contact them if any unusual symptoms occur so that proper management can be initiated early. Inappropriately or inadequately treated cases of mastitis predispose patients to recurrent and ultimately chronic mastitis, which may last for months and require more antibiotics than would have been required initially. A mother should be instructed to contact her physician if she has local pain, heat, redness, or a fever while lactating. Red streaking on the breast may be inflammation of the lymphatics (see Figure 16-4).

A study of 946 breastfeeding women from two sites (Michigan and Nebraska) was conducted by Foxman et al.<sup>88</sup> The women were recruited prenatally and followed prospectively through 3 months

**TABLE 16-1** Comparison of Findings of Engorgement, Plugged Duct, and Mastitis

Characteristics	Engorgement	Plugged Duct	Mastitis
Onset	Gradual, immediately postpartum	Gradual, after feedings	Sudden, after 10 days
Site	Bilateral	Unilateral	Usually unilateral
Swelling and heat	Generalized	May shift; little or no heat	Localized, red, hot, swollen
Pain	Generalized	Mild but localized	Intense but localized
Body temperature	<38.4°C (101°F)	<38.4°C	>38.4°C
Systemic symptoms	Feels well	Feels well	Flulike symptoms

**Figure 16-3.** This 38-year-old patient's craniocaudal view shows segmental duct draining a lobe in medial aspect of right breast (arrow). Ductal patterns differ among women. TABLE 16-2 Categories of Patients With Inflammatory Breast Symptoms		
Symptom	Leukocytes per Milliliter of Milk	Bacteria per Milliliter of Milk
Milk stasis	<10 <sup>6</sup>	<10 <sup>3</sup>
Noninfectious inflammation	>10 <sup>6</sup>	<10 <sup>3</sup>
Infectious mastitis	>10 <sup>6</sup>	>10 <sup>3</sup>

From Thomsen AC, Espersen T, Maigaard S: Course and treatment of milk stasis, noninfectious inflammation of the breast, and infectious mastitis in nursing women, *Am J Obstet Gynecol* 149:492, 1984.

postpartum or until they stopped breastfeeding. Telephone interviews were done at 3, 6, 9, and 12 weeks. The diagnosis of mastitis was made by self-reported symptoms to their health care provider, usually by telephone. The incidence of mastitis was 9.5%.

The strongest risk factor was a history of mastitis with a previous infant. Nipple cracks and sores before onset of mastitis, the use of antifungal cream, and feeding the infant more frequently than usual were key associated phenomena. For women with no history of breast infection, the use of a manual breast pump during the same week was a significant risk factor.<sup>88</sup> As in other studies, the first time the infants

TABLE 16-3 Course of Infectious Mastitis With and Without Treatment				
Treatment	Number of Cases	Duration of Symptoms (Mean Days)	Result (No. of Cases)	
			Normal Lactation	Poor*
None	55	6.7	8	47
Emptying of breast	55	4.2	28	27
Antibiotics and emptying of breast	55	2.1	53	2

\*Breast abscess, 6 cases; symptoms of sepsis, 12 cases; recurrence of symptoms, 21 cases; duration >14 days, 10 cases; impaired lactation only, 27 cases.

From Thomsen AC, Espersen T, Maigaard S: Course and treatment of milk stasis, noninfectious inflammation of the breast, and infectious mastitis in nursing women, *Am J Obstet Gynecol* 149:492, 1984.

**Figure 16-4.** Inflammation of lymphatics of breast demonstrating drainage of breast. Generalized infection of breast, especially Staphylococcal, occasionally presents as lymph duct infection.

slept through the night, or the mothers left the babies for many hours and did not pump, was a prominent feature. Apart from mastitis, one third of mothers reported nipple cracks and sores in the first week postpartum; 64% of cases were diagnosed by telephone (physicians 59%, nurses 23%, and others 18%). The most common symptoms were breast tenderness (98%), fever (82%), malaise (87%), chills (78%), redness (98%), and hot spots (62%).<sup>75</sup> The most frequent treatment was cephalexin (46%), amoxicillin (7%), ampicillin (7%), and amoxicillin clavulanate (Augmentin; 7%).<sup>24</sup>

The use of oral administration of lactobacilli isolated from the milk of healthy mothers for the treatment of infectious mastitis was compared with standard antibiotic therapy.<sup>20</sup> Three groups were formed from 352 women with mastitis. One group ingested colony-forming units of *Lactobacillus fermentum* (CECT 5716) daily, a second group ingested *L. salivarius* (CECT 5713) for 3 weeks, and the third group received antibiotics prescribed by their health care centers. Women who received the probiotics improved more rapidly and had fewer recurrences than the antibiotic group.<sup>20</sup>

Most series of acute mastitis clearly demonstrate that the cases that result in unfavorable outcomes, including abscess and recurrent disease, had significant delay between onset of symptoms and request for medical advice. Recurrence rates run from 14% to 20%.<sup>24</sup> When proper treatment is initiated promptly, the course of the disease is usually brief; if treatment is delayed, prolonged antibiotics become necessary. Treatment with less than 10 days of antibiotics is also associated with recurrence and/or more virulent bacteria. Thus cultures are appropriate in the case of recurrence (Table 16-4).

## Recommended Management Regimen

1. Advise patient to continue to nurse on both breasts, but start the infant on the unaffected side, while the affected side "lets down" to reduce the pain. Be sure to empty the affected side by feeding or pumping.

**TABLE 16-4** Antibiotic Selection for Bacterial Mastitis

Antibiotic	Spectrum	Dose	Safety*	Comment
Dicloxacillin	Nonmethicillin-resistant staphylococci	500 mg PO qid	Yes	Highest activity against MSSA
Clindamycin	Penicillin allergic Many CA-MRSA test susceptibilities	300 mg PO qid	Probably safe	Excreted in milk; active against many strains of CA-MRSA
Erythromycin	Penicillin allergic	500 mg PO qid	Yes	GI intolerance
Azithromycin	Penicillin allergic	500 mg load, then 250 mg/day for 4 days	Probably safe	Limited <i>S. aureus</i> activity; less GI upset than erythromycin
Trimethoprim-sulfamethoxazole	Some CA-MRSA	100 mg PO bid	Yes	Less effective when abscess present
Cephalexin	MSSA	500 mg PO qid	Yes	Relatively poor levels in breast tissue

CA-MRSA, Community-acquired methicillin-resistant *S. aureus*; GI, gastrointestinal; MSSA, methicillin-susceptible *S. aureus*.

\*Data are relatively limited for many antibiotics, but the relative safety is based upon the following review: Nahum GG, UIK, Kennedy DL: Antibiotic use in pregnancy and lactation: what is and is not known about teratogenic and toxic risks, *Obstet Gynecol* 107:1120, 2006.

2. Insist on bed rest (mandatory). The mother can take the infant to bed and obtain assistance for the care of other family members.
3. Choose an antibiotic that can be tolerated by the infant, as well as the mother (avoid sulfa drugs when the infant is younger than 1 month). The decision should be based on local sensitivities and length of time since delivery or exposure to resistant flora.
4. Apply ice packs or warm packs to the breast, whichever provides the most comfort. Experience indicates that heat provides drainage and pain relief.
5. Provide plenty of fluids for the mother.
6. Give an analgesic such as acetaminophen or ibuprofen.
7. The mother should wear a supporting brassiere that does not cause painful pressure.

Empiric therapy without cultures should consider the common organisms causing mastitis: *S. aureus* (50%), *E. coli* or other gram-negative organisms, group A streptococci, *Streptococcus pneumoniae* species, and *Bacteroides* species (especially with abscesses). Less common organisms include *Candida albicans* and *Mycobacterium tuberculosis*. First-line antibiotics that are safe for mothers and infants include first-generation cephalosporins or dicloxacillin/oxacillin. Treatment of suspected gram-negative organisms includes first-generation cephalosporins or amoxicillin clavulanate (Augmentin). Treatment of abscesses should include some anaerobic coverage with Augmentin or clindamycin. Therapy for women with penicillin or cephalosporin allergy can include erythromycin or clindamycin. Suspected MRSA can be treated with vancomycin, clindamycin, or rifampin, considering organism sensitivity.

An unusual case of *S. pneumoniae* mastitis was reported in a 38-year-old woman who was partially breastfeeding her 9-month-old infant. Cultures of breast milk had more than 106 *S. pneumoniae* bacteria per milliliter of milk. Cultures of the infant's nose and throat also grew *S. pneumoniae*, although he was asymptomatic. Treatment was flucloxacillin. C-reactive protein was 177 mg/L at onset and 18.6 mg/L on day 6. The infant was presumed to have infected the mother.<sup>274</sup>

Regardless of the disease course, the antibiotic should be given for at least 10 to 14 days. Shorter courses are associated with a high incidence of relapse. Once relapsed, it can become chronic until the infant is weaned. A Cochrane Review of antibiotics for mastitis failed to identify the best antibiotic, but it did confirm antibiotics were better than supportive care for length of illness and abscess formation.<sup>124</sup>

## COMMUNITY-ACQUIRED METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS

A relative increase in MRSA is being reported, manifesting as cases of postpartum mastitis. Reviewing all cases of postpartum mastitis from 1998 through 2005, Reddy et al.<sup>220</sup> noted MRSA and methicillin-susceptible *S. aureus* (MSSA) increased dramatically from 1 case of MRSA in 1998 to 18 in 2005 and 17 cases of MSSA. Rates were not related to artificial rupture of membranes, epidural anesthesia, vaginal lacerations, episiotomy, cesarean delivery, or intrapartum antibiotics. In another series, 127 women from 136,459 deliveries were admitted for postpartum mastitis. This calculates to 7.8 to 11.1 per 10,000 deliveries with an incidence of abscess of 2.6 per 10,000 deliveries. Community-acquired MRSA was cultured in 18 of the cases (67%). Most did not receive antibiotic therapy to which their bacteria were sensitive.<sup>247</sup> The most common organism cultured in nonpuerperal breast abscesses was MRSA (58%), which was sensitive to clindamycin, trimethoprim-sulfamethoxazole, and linezolid, according to Moazzez et al.<sup>188</sup> Clinicians should be aware of the likelihood of MRSA in the community and the effective therapies. Breast milk culture and sensitivities should be obtained when the patient is unresponsive to the first-line treatment. A full discussion of MRSA appears in Chapter 17.

See also Appendix P, Protocol 4 (Revised 2014) for further information on management of mastitis.

## RECURRENT OR CHRONIC MASTITIS AND CANDIDAL INFECTION

Recurrent mastitis is usually caused by delayed or inadequate treatment of the initial disease. If antibiotics are started, they should be continued for a minimum of 10 to 14 days. Often, because a mother feels better, she discontinues them on her own. At the first recurrence, cultures should be sent of the midstream clean-catch specimen of breast milk and the infant's nasopharynx and oropharynx. The patient should be seen and the circumstances completely reviewed. An aggressive course of rest, nourishment, stress management, and complete drainage of the breast by suckling or pumping should be initiated. The antibiotics should be carefully selected by culture sensitivities and maintained for 2 weeks. Fluids should be increased. Failure of the second treatment is usually caused by failure to complete the entire treatment, which may also mean failure to get adequate rest and build up maternal resistance. The clinical protocol from ABM, MASTITIS, is available in Appendix P, revised in 2014.

When the mastitis continues to recur, several possible reasons exist: chronic bacterial infection, pseudomonas infection, secondary fungal infection, or underlying breast disease, such as a cyst or tumor. If it is chronic bacterial disease, low-dose antibiotics can be instituted for the duration of lactation (erythromycin, 500 mg daily). Fungal infection is usually diagnosed by the nature of the pain, which is described as fiery, throbbing pain along the duct system. Both mother and infant need treatment. If the infection is always in the same breast, examination of the breast for a unilateral unchanging lump or mass may indicate cyst, galactocele, or tumor. (The lactating breast is "lumpy," but the lumps are ever changing.) Needle aspiration or biopsy may be indicated. Ultrasound is a good diagnostic tool and, in some cases, a therapeutic tool in abscess tapping to locate the exact location.

A secondary complication of recurrent mastitis is invasion of the breast by a yeast infection such as *C. albicans* (see Chapter 17), as is frequently seen after antibiotic treatment. Mothers describe incredible pain when the infant nurses as feeling like hot cords burning in their chest wall. Between feedings, the surface of the breast may itch. This is usually fungal infection of the ducts. The best treatment is to massage nystatin cream (Mycostatin) or Mycolog, which also contains cortisone, into the nipple and areola after each feeding. The infant should also be given oral nystatin simultaneously, or the mother will be reinfected, even if the infant has no lesions. If the mother is known to have a recurrent vulvovaginitis, initiation of nystatin prophylactically should be considered when the antibiotics are begun. Although the infant may or may not have oral thrush or a diaper rash, he or she should be treated as well. The nipple may not look unusual, despite exquisite pain. Overuse of nystatin, which is given parenterally, however, has made it ineffective, and fluconazole has been used, even in premature infants.

The incidence of fungal infections has increased dramatically in the past decade due to their overdiagnosis, but also because of the widespread use of antibiotics, which obliterate the normal flora credited with keeping fungal growth under control.<sup>74</sup> Young women often have vaginal yeast infections, which serve as a reservoir of infection. Milk is an excellent culture medium for the fungi, which thrive on carbohydrates. When fungal infections continue to recur the spouse should also be tested and possibly treated. An infant may acquire the fungus during vaginal birth, becoming colonized and inoculating the breast during breastfeeding. The disease state flares up after a course of antibiotics.

When the microbiology of 61 lactating women with burning nipple pain was compared with that of 64 lactating women without pain and 31

nonlactators, growth of *C. albicans* in the nipple and milk was identified in 19% of those with pain and in 3% of those without pain and none among the nonlactators. *S. aureus* was associated with nipple pain and nipple fissures. The authors note the difficulty in actually culturing the fungus.<sup>5</sup>

The milk of women suffering from severe nipple and deep breast pain was cultured by Hale et al.,<sup>104</sup> along with milk of healthy controls. None of the milk samples grew *C. albicans*. The authors suggest *C. albicans* is not associated with all cases of severe nipple and deep breast pain, and, in this series, none of the cases. Fluconazole is effective against cryptococcosis, candida, coccidioidomycosis, and other fungi. On the horizon are other triazoles, as interest and effort in treating fungal infections have increased because of the risk in human immunodeficiency virus (HIV) infections (see Chapter 17). Fluconazole (Diflucan) can be given orally, 200 mg loading dose with 100 mg/day for 14 days. Side effects (e.g., nausea, vomiting, diarrhea) in the mothers are minimal. Although fluconazole does pass into the milk, it is approved for use in infants less than 6 months old and has a safety profile for newborns. It is currently used in neonatal intensive care units (NICUs). The term infant dose for oral thrush is 6 mg/kg stat followed by 3 mg/kg/day.<sup>103</sup> A single dose peaks in the milk at 2 hours, and the milk/plasma ratio is less than 1. Miconazole oral gel can be used for treating both the breast and the infant's mouth for at least 2 weeks. Gentian violet liquid (0.25% to 0.5%) can be used in recurrent resistant cases. It was the only treatment available before antibiotics and antifungals. It is applied to the nipple and areola and to the infant's mouth by swab three times per day; no more than eight applications are recommended (3 days). It colors everything purple and masks the lesions.

Instructions to mothers should also include recommendations to treat any vaginal yeast infection with local therapy, decrease concentrated ingestion of sweets, and add live-culture yogurt or acidophilus to the diet. All clothing in contact with breasts and the infant must be changed daily, washed, and dried in hot temperatures.

Freezing pumped breast milk infected with candida does not kill the fungus. The milk must be pasteurized or discarded.

All burning breast pain is not thrush. History should include a presence or tendency for fungal infections, recent antibiotic therapy, or other supporting evidence to assume it is thrush. Diagnosis should be confirmed by culture. The most common cause of failure of treatment is incorrect diagnosis. Burning pain may be caused by staphylococcal disease and treated with appropriate antibiotics. Therapies that include antifungals, antibiotics, and antiinflammatories in one preparation serve to

sensitize the flora and diminish effectiveness and are not recommended. This type of therapy encourages clinicians to prescribe over the telephone without a clinical observation or a diagnosis. Mastitis usually occurs in only one breast. When both breasts are involved, it is usually due to streptococcus and should be treated aggressively.

## ABSCESS FORMATION

Abscess can also be a complication of mastitis and is usually the result of delayed or inadequate treatment. A true abscess will require surgical drainage, but should be treated with antibiotics, rest, warm soaks, and complete emptying of the breast at least every few hours.

The drainage should be cultured and sensitivities determined so that antibiotics can be adjusted accordingly.<sup>261</sup> The increasing number of oxacillin-resistant *S. aureus* (ORSA) cases occurring in hospitals places women recently delivered or hospitalized within 28 days at risk. An infection with ORSA may require vancomycin therapy, the only antibiotic effective against it. ORSA may start as an inflammation of the lymphatics (Figure 16-4). MRSA has replaced ORSA in the community and in mastitis.<sup>188</sup> With the increased number of water births, there has been an increased incidence of staphylococcus infections in both mother and baby.

The milk will remain clean unless the abscess ruptures into the ductal system. Usually it drains externally. Nursing can be maintained when the breast is surgically drained, as long as the incision and drainage tube are sufficiently far from the areola so that they are not involved in feeding. In any event, the breast should be manually drained of milk frequently to maintain the milk supply until feeding can resume (sufficient healing usually occurs in 4 days). The infant can continue to feed on the unaffected side. The infant should always be monitored for infection, and simultaneous therapy should be initiated, especially with staphylococcal or streptococcal disease.

In isolated cases of abscesses that have been drained surgically, milk also drains during a feeding or pumping. With adequate systemic antibiotics and careful but thorough draining of the breast by suckling or pumping, healing gradually takes place, even while the mother continues to lactate. When the drain is removed, the incision can be closed and breastfeeding resumed on that breast if it was not maintained. The mother should be instructed to press firmly over the incision with sterile gauze to keep milk from flowing from the wound during feedings. The cause of this milk drainage is a severed milk duct, an unavoidable complication of draining a deep abscess. It will heal

completely within 3 to 4 weeks. Rarely is weaning from the involved breast necessary. Continued lactation usually facilitates the healing, whereas abrupt weaning and subsequent engorgement interfere with healing. A diagnostic breast ultrasound will locate the collection of fluid. Utilizing ultrasound guidance, a needle aspiration can be performed.<sup>52</sup> Culture and examination of the aspirate will assist in selecting the appropriate antibiotic. Serial needle aspirations may be necessary. Needle aspiration is less destructive to surrounding tissue, which heals more quickly. In a large loculated abscess or multiple abscesses, surgery may be the best choice.

Recurrent bilateral breast abscess was reported in a woman to be due to nontuberculous mycobacterial infection. This suggests that cultures should include a search for mycobacteria. When they are not found on culture, they should be searched for on biopsy. Specific treatment with clarithromycin (1000 mg/day) in combination with ciprofloxacin (1000 mg/day) was given for a year with successful response and clearing of radiologic findings.<sup>276</sup>

## LABORATORY FINDINGS

Cultures of the breast milk, when indicated, should be done after the breast has been cleaned with water and the mother's hands have been thoroughly washed. The milk stream should be initiated by manual expression and the first approximately 3 mL discarded to obtain a midstream clean-catch specimen. One should check for antibody coating in the bacteria found in the milk to confirm its relationship to the disease.<sup>260</sup> It is important to remember that the normal cell count of uninfected human milk is 1000 to 4000/mm<sup>3</sup>. The presence of cells should not be automatically construed as infection.

A leukocyte count greater than 106/mL of milk is considered diagnostic, plus a bacterial count greater than 10<sup>3</sup> bacteria/mL of milk (see Table 16-1).

The levels of sodium and chloride in milk from breasts with mastitis have been reported in the literature to be extremely elevated (Na 100 mEq/L or greater, Cl 80 mEq/L or greater, potassium 8 mEq/dL or less).<sup>45</sup> Usually, electrolyte abnormalities are associated with recurrent mastitis or chronic subclinical mastitis. The quickest screen for the problem is for the mother to compare the tastes of milk from each side. Elevated sodium will be salty.

## BILATERAL MASTITIS

Bilateral non-Hodgkin lymphoma of the breast presented as mastitis in a 37-year-old woman, with fever, chills, and pain, swelling, and redness of both breasts.<sup>44</sup> She was treated with antibiotics. She had a history of non-Hodgkin lymphoma 7 years

earlier. Biopsy of the red indurated skin revealed recurrent lymphoblastic lymphoma, which responded to chemotherapy. Although rare, breasts can be involved as a primary site or a site of recurrence of non-Hodgkin lymphoma.

Streptococcal mastitis also presents as a bilateral infection, and bilateral mastitis should always be treated as streptococcus unless cultures disprove it. The infant needs to be treated as well.

Idiopathic granulomatous mastitis (IGM) is a rare benign chronic inflammatory breast disease of unknown etiology.<sup>68</sup> It is further defined as chronic and benign, mimicking malignant hyperplasia of the mammary glands. It is unpredictable, frequently presents similarly to a carcinoma, and no consensus about treatment exists.<sup>7</sup> It occurs in premenopausal women shortly after childbirth and has been correlated with breastfeeding and the use of oral contraceptives. An autoimmune component has been suggested. The etiology of IGM was extensively reviewed by Altintoprak et al.,<sup>9</sup> who described the most common presentation as a unilateral discrete breast mass, nipple retraction, and even sinus formation with inflammation of the overlying skin. They searched for the cause beyond autoimmune reaction, oral contraceptives, and even lactation. Other associated factors are hormonal imbalance, unknown microbiologic agents, smoking, and alpha1 antitrypsin deficiency. Almost all patients have a history of at least one live birth and breastfeeding. Geographic distribution shows a high incidence in Turkey, China, South Korea, and the United States as well as the Mediterranean region and developing countries in Asia. When ethnicity was reported in the United States, Mexican and Hispanic origin predominated. Reports come predominantly from Turkey and Iran. It presents with galactorrhea, inflammation, breast mass, tumorous indurations, and ulcerations of the skin in parous women within 5 years of childbirth. On mammography and sonography, nodular opacities are seen. The diagnosis is made histologically with signs of chronic granulomatous inflammation. It can be confused with periductal mastitis. In a 25-year experiment, Al-Khaffaf<sup>7</sup> reports 133 cases of periductal mastitis and 18 cases of IGM. Median age was 36 years (range 18 to 67). Periductal mastitis occurred on average at 52 years old (range 20 to 77 years). Smokers were seen in 60% of periductal mastitis and only 17% of IGM. Patients with periductal mastitis used oral contraceptives and were less likely to be white. Parity was similar in both groups, although IGM occurred at the time of or within 5 years of childbirth. The course of IGM varied from 11 to 105 weeks, regardless of treatment. Antibiotics and steroids had been tried in various combinations. It takes 6 to 12 months to "burn out" and requires understanding, supportive care.<sup>7</sup>

Physical examination suggests breast carcinoma, but the appearance of paraenchymal heterogeneity and abscess formation on ultrasound, especially when enlarged axillary lymph nodes are also seen, supports the diagnosis of an inflammatory process.<sup>145</sup> A biopsy steroid therapy has been widely used (16 mg prednisone twice a day) and is often successful. A survey of the literature found 112 cases where 5 to 85 mg of steroid was used for 5 days to 22 months.<sup>4</sup> Recurrence was seen in 22 patients, steroid-induced diabetes in 5 patients, and no response was seen in 4 patients. Methotrexate has been used more recently, with over a hundred reported cases, in an effort to produce immunosuppression.<sup>4</sup> It has been recommended that:

- Histopathologic evaluation is essential.
- Steroid therapy has high rate of recovery.
- Recurrence rate with steroids is high.
- Steroids are recommended first, and then methotrexate therapy or surgery should be considered.<sup>206</sup>

## PITUITARY AND PROLACTINEMIC DISORDERS

### Galactorrhea

After an infant discontinues breastfeeding, it is not unusual for a mother to be able to express milk from the breasts for many weeks, although spontaneous flow ceases in 14 to 21 days. Postlactation milk is partially a function of the length of established lactation. When spontaneous lactation persists for more than 3 months after the infant has stopped nursing, the cause should be sought. A physician should evaluate the mother to make a specific diagnosis.

Galactorrhea is characterized by spontaneous milky, multiductal, bilateral nipple discharge. It is thought to result from increased prolactin production, either by the pituitary or by removal of hypothalamic inhibition. Pituitary adenomas may be the cause. Galactorrhea can occur with normal ovulatory function for 1 or more years postpartum if everything else appears normal. Galactorrhea has been reported to occur in thyrotoxicosis with such frequency (80%) that it should be part of the differential diagnosis for galactorrhea. Amenorrhea and galactorrhea are also associated with hypothyroidism, which is not surprising because thyrotropin-releasing hormone is known to be a prolactin-stimulating hormone. More complex disorders are rare and are usually named for the physician who first described them.

During pregnancy a risk for pituitary tumor expansion exists, especially with large tumors. In a series of cases of microprolactinomas, no symptoms

of tumor enlargement in pregnancy were noted. The serum prolactin levels were at or below pregnancy levels postpartum. The authors thought these breast-feeding patients, diagnosed as having Chiari-Frommel syndrome, could actually have occult microadenomas that might become radiologically evident later.

Prolactin levels are elevated in about half the patients with galactorrhea, and the prolactin levels show little correlation with the copiousness of milk flow in the patients. Prolactin levels in milk and plasma in women with inappropriate lactation were compared with those of normally lactating women by Adamopoulos and Kapolla.<sup>2</sup> Women with galactorrhea had milk prolactin concentrations similar to nursing mothers. Plasma levels, however, were significantly lower than in lactating women, except for pituitary adenoma-related galactorrhées. Levels in milk remain relatively constant, whereas plasma levels vary by time of day and various stimuli.

Some drugs, including phenothiazines, tricyclic antidepressants, rauwolfa alkaloids, theophylline, amphetamines, methyldopa, and even some contraceptives, can cause galactorrhea. A copper intrauterine device was associated with normoprolactinemic galactorrhea in a fertile woman. When the intrauterine device was removed, the secretion stopped, and when it was reinserted, the flow began again.<sup>91</sup>

The major causes of galactorrhea associated with amenorrhea are (1) medications (e.g., tranquilizers, antidepressants, reserpine, methyldopa, narcotics, oral contraceptives), (2) local stimulation of the nipples and breast, (3) hypothalamic dysfunction, (4) Forbes-Albright syndrome, (5) hypothyroidism, (6) chest lesion, (7) renal disease, and (8) a nonpituitary prolactin-producing tumor (lungs or kidney). A patient has idiopathic galactorrhea if prolactin levels, menses, and fertility are normal. Idiopathic galactorrhea has five possible explanations<sup>31</sup>:

1. The abnormality may be in the breast itself, which is unusually sensitive to circulating prolactin.
2. The breast may have an increased number of prolactin receptors.
3. Prolactin levels may be intermittently high.
4. Excessive sleep-induced increases may occur in prolactin, which normally rises during sleep.
5. Biologically active prolactin may be elevated and is not immunoreactive (i.e., is not detected by immunoassay).

Prolactin exists in three sizes: small (molecular weight 25,000 daltons), large (50,000 daltons), and very large (100,000 daltons). Most of the biologic activity occurs in the small form. The large forms are immunoreactive but weakly biologically active. Thus in patients with persistent galactorrhea

with normal prolactin levels by immunoassay, MRI is necessary to rule out a tumor producing the large prolactin molecules.<sup>31</sup>

## HYPERPROLACTINEMIA

Hyperprolactinemia with and without galactorrhea has been identified in patients with multiple sclerosis,<sup>144</sup> especially in relapse, suggesting hypothalamic dysfunction and not a pituitary prolactinoma.<sup>109</sup> Hyperprolactinemia is also seen in some connective tissue disorders<sup>137</sup> (see later discussion).

Since 1971, when human prolactin was identified as a distinct lactogenic hormone and was isolated and made measurable by a specific radioimmunoassay, previously unrecognized clinical entities associated with hyperprolactinemia have been identified. Physiologic hyperprolactinemia occurs with excessive breast manipulation and is the reason induced lactation and relactation are physiologically possible. In susceptible women, a visit to the doctor, stress, a pelvic examination, venipuncture, or surgical procedures can produce elevated serum prolactin. The half-life of prolactin in these circumstances is 50 to 60 minutes. Placing a heparin lock and drawing a second sample an hour later that is lower may explain this.

**Box 16-1** lists causes of hyperprolactinemia. Pathologic conditions associated with hyperprolactinemia include hypothyroid and hyperthyroid disease, chronic renal failure, and chest wall lesions, such as thoracotomy scars and herpes zoster. Galactorrhea, or the secretion of a lactose/fat-containing fluid independent of pregnancy, can occur in any of these hyperprolactinemic states. In general, pharmacologic hyperprolactinemia does not exceed 100 ng/mL. If a woman has achieved pregnancy with hyperprolactinemia, postpartum lactation is possible.

## CHIARI-FROMMEL SYNDROME

Patients with persistent postpartum or postlactation lactation extending months or years should be evaluated for Chiari-Frommel syndrome, especially if abnormal menses exist.<sup>77</sup> Often, irregular menses will have occurred before the pregnancy as well. The galactorrhea will occur whether the mother breastfeeds or does not breastfeed. The clinical manifestations of Chiari-Frommel syndrome are not only persistent lactation with possible breast engorgement, but also oligomenorrhea or amenorrhea, obesity, uterine and ovarian failure, and, in some cases, hypothyroidism (Table 16-5). Spontaneous remission within 5 years occurs in 40% of patients.

Other possible causes of the galactorrhea include other hypothalamoadenohypophyseal

**BOX 16-1. Causes of Chronic Hyperprolactinemia in Women**

Physiologic
Excessive breast manipulation
Stress, surgery, venipuncture, etc.
Pharmacologic
Depletion of tuberoinfundibular dopamine stores (by extrusion from intracellular granule to cytosol)
Reserpine
Blockade of dopamine receptor binding
Phenothiazines (chlorpromazine, thioridazine, prochlorperazine, perphenazine, trifluoperazine)
Thioxanthenes (chlorprothixene)
Butyrophенones (haloperidol)
Benzamines (metoclopramide, sulpiride)
Dibenzoxapine antidepressants (amoxapine)
Inhibition of dopamine release
Chronic opiate use (methadone, morphine)
Blockade of histamine ( $H_2$ ) receptor binding
Cimetidine
Estrogen-containing oral contraceptives
Interference with dopamine synthesis
$\alpha$ -Methyldopa
Calcium channel blockers
Verapamil
Mechanism unknown
Tricyclic antidepressants (imipramine, amitriptyline)
Papaverine derivatives
Pathologic
Primary hypothyroidism
Hypothalamic disorders
Neoplastic, infectious, vascular, degenerative, or granulomatous hypothalamic lesions
Pituitary stalk section
Pituitary disorders
Prolactin-secreting adenoma
Acromegaly, Cushing disease, Nelson syndrome
Ectopic production of prolactin
Bronchogenic carcinoma, hypernephroma
Chronic renal failure
Chest wall lesions
Surgical scars, herpes zoster
Functional
Idiopathic (no demonstrable tumor)

Modified from Katz E, Adashi EY: Hyperprolactinemic disorders, *Clin Obstet Gynecol* 33:623, 1990.

disorders, including infection and trauma, ectopic production, or lactogenic hormone as in hypernephroma, or end-organ hypersensitivity to prolactin.

Women with hyperprolactinemia do not respond to breast stimulation with a rise in

prolactin as breastfeeding women do, which can be demonstrated with two levels drawn before and after pumping. The patient with hyperprolactinemia has no acute response to suckling in her growth hormone levels either. This indicates that the central dopaminergic tonus was not altered but shows regulatory dysfunction.

**DEL CASTILLO SYNDROME**

Del Castillo syndrome was first described in 1932.<sup>96</sup> All patients had galactorrhea and amenorrhea without evidence of pituitary tumor and with negative urinary gonadotropins. They had small uteri but normal secondary sex characteristics and normal breasts, nipples, and areolae. Remission is rare, as is pregnancy. Clomiphene citrate (Clomid) has been reported to be useful in decreasing the galactorrhea and achieving pregnancy (see Table 16-5).

**FORBES-ALBRIGHT SYNDROME**

Forbes-Albright syndrome was first described in 1954 by Forbes. She reported 15 cases of women without acromegaly who had persistent lactation and amenorrhea or irregular menses, low urinary follicle-stimulating hormone, and pituitary tumor on x-ray films.<sup>85</sup> Both medical and surgical treatments have been used. Pregnancy may cause a recurrence of the galactorrhea (see Table 16-5).

**SHEEHAN SYNDROME AND HYPOPITUITARISM**

Sheehan syndrome is caused by postpartum hemorrhage of such severe degree that it leads to pituitary thrombotic infarction and necrosis or other vascular injury to the pituitary gland, including hypoperfusion. It is the only commonly recognized endocrine disorder associated with lactation failure.<sup>2</sup> It occurs in 0.01% to 0.02% of postpartum women. A highly vascular organ, the pituitary gland is particularly vulnerable to decreased blood flow at the end of gestation because of its increased size. It is thus more sensitive to hypoperfusion and necrosis. The degree of hypopituitarism is variable; hypoprolactinemia generally results following necrosis of the pituitary stalk, causing mammary involution and failure of lactation.

**TABLE 16-5** Comparison of Characteristics of Various Hyperprolactinemic Disorders

Syndrome	Amenorrhea	Galactorrhea	Postpartum	Pituitary Tumor
Del Castillo	+	+	0	0
Chiari-Frommel	+	+	+	0
Forbes-Albright	+	+	±	+

From Gould BK, Randall RV, Kempers RD, et al: *Galactorrhea*, Springfield, Ill., 1974, Thomas.

Other signs of pituitary failure are diabetes insipidus, amenorrhea, hypothyroidism, or loss of axillary hair, postpartum. Spontaneous recovery can occur, depending on the degree of infarction and regeneration. When the pituitary was briefly shocked by hemorrhagic crisis that responded to transfusion, the pituitary returned to normal in a few weeks.

Secretion of pituitary hormones, including prolactin, is usually deficient, and thus patients may fail to lactate postpartum in full-blown Sheehan syndrome. This is considered a key clinical sign of the syndrome. Studies have reported women with Sheehan syndrome who do lactate; the diagnosis had to be established by other means. This is believed to result from the pituitary lactotropes, which have compensatory activity of hypothalamoadenohypophyseal function.<sup>264</sup> Patients usually manifest hyposecretion of all pituitary hormones, with decreased thyroid and adrenal function. They may experience oligomenorrhea or amenorrhea and uteroovarian atrophy. Often the obstetric crisis that caused the hemorrhage has also required hysterectomy, however, and these findings are obscured. Sert et al. reported 28 patients diagnosed with Sheehan syndrome who were followed for 20 years.<sup>235</sup> Some degree of hypopituitarism has been reported in 32% of women with severe postpartum hemorrhage. The extent of damage predicted the rapidity of onset as well as the magnitude of the pituitary hypofunction. The gland has a large reserve so that more than 75% is destroyed to produce clinical symptoms. The diagnosis depends on failure of lactation and failure of resumption of menses. The other symptoms are subtle and progressive, and it may take years to diagnose hypopituitarism. On the other hand, the disease may present with coma and hyponatremia, which is an endocrine emergency postpartum.

Prolactin-stimulating drugs used to augment milk yields, such as sulpiride, require investigation. They have been successful in women who delivered prematurely and were unable to breastfeed immediately.<sup>16</sup> In a case of presumed Sheehan syndrome in our service, use of nasal oxytocin spray and a lactation supplementer (see Chapter 8) with each feeding for approximately 2 weeks resulted in a gradual increase in milk production. The mother weaned herself from the drug and the infant from the lactation supplementer during the next 2 weeks, achieving full lactation for 6 months.

### Treatment

In a review of normal lactation and galactorrhea, Benjamin<sup>31</sup> outlines four treatments for pituitary adenomas: (1) identify nonpituitary causes and

eliminate (e.g., medications), (2) do nothing, (3) perform surgery, or (4) administer bromocriptine. Also, a significant cause of galactorrhea or hyperprolactinemia can be breast stimulation. Stimulation of breast and nipple can cause prolactin to rise 60 to 120 ng/mL (normal levels 15 to 25 ng/mL).

### ACUTE LACTATION FAILURE

Acute lactation failure (when women abruptly lose their milk) has been noted historically in times of great crises, fright, or accident. Two such cases have been reported in the literature by Ruvalcaba,<sup>224</sup> after the Mexico City earthquake in 1985. Stress-induced lactation failure is described in a gravida 3 woman, 24 years old, who had been exclusively breastfeeding for 3 months and had fed two previous children for 14 and 18 months. On the day of the quake, the building she was in collapsed. She ran home to her children, past demolished buildings, and could not produce a drop of milk when her infant suckled then or subsequently. Multiple attempts over the next weeks failed to produce a drop. The second woman was 39 weeks pregnant and had been dripping colostrum for several weeks, as she had with her previous three pregnancies. On the day of the quake, her house collapsed, her husband and two children were missing for several hours, and her sister was killed. She never leaked another drop of colostrum and was never able to breastfeed.<sup>224</sup>

### ALACTOGENESIS

Familial puerperal alactogenesis is described as probably a genetically transmitted, isolated prolactin deficiency. It is a rare disorder with only a few cases reported. Zargar et al.<sup>277</sup> describe a mother and her daughter with eight pregnancies between them with no evidence of lactation at any time. Their only abnormal laboratory value was their prolactin levels, which were undetectable.

### HYPERGALACTIA

Hypergalactia is excessive milk production. It is often heralded by the initiation of milk production beginning in pregnancy, often as early as 25 weeks' gestation, and is characterized by persistent leaking that soaks the clothing and is independent of breast stimulation. Some women will note a drop or two on stimulation or while showering during pregnancy. This is considered to be within normal limits. Hypergalactia then persists after delivery with constant leaking between feedings. Mothers can pump or express several ounces after each feeding with no effort. This does not appear to minimize the leaking. Early in lactation, many women

find that they have a strong let-down reflex with an initially soaking spray of milk. This is not hypergalactia and usually diminishes in 1 or 2 weeks.

If this phenomenon persists for more than 1 or 2 weeks, an evaluation for prolactinoma is in order. A baseline level and a stimulus-associated level of prolactin, after 10 minutes of suckling or pumping with a breast pump, should be obtained. If the patient has associated symptoms of headache or visual disturbances, further work up for pituitary adenoma would be appropriate. The phenomenon, however, may not be associated with any identifiable pathology. Idiopathic hypergalactia may diminish throughout months of breastfeeding. It occurs more often with first pregnancies and may not recur with subsequent pregnancies.

Treatment is palliative, including a tight, well-fitting brassiere that is well padded between feedings. A trial of low-dose estrogen, as available in oral contraceptives, may be effective. A careful history to identify any medications or herbs that are galactagogues or any form of stimulus other than breastfeeding is essential to management. Although bromocriptine would theoretically be effective, it would only be indicated in patients with hyperprolactinemia associated with pituitary adenoma. In such patients the diagnosis should be established first. Bromocriptine has potentially serious side effects and should not be used casually. Cabergoline is preferred as a treatment for pituitary adenoma and may be used cautiously during lactation to control the tumor. Excessive milk production has also been associated with hyperthyroidism and postpartum thyroiditis.

### **HYPERACTIVE LET-DOWN REFLEX**

Hyperactive let-down reflex may occur, especially among primiparas. It is characterized by a spray of milk on initiation of a feeding. If the other breast is checked, it also is flowing. The infant is often overwhelmed by the rate of flow and begins to choke or is gulping frantically to keep up. Milk runs out the corners of the mouth. When the milk is high volume but low fat, it may be accompanied by increased gas formation and colic.<sup>272</sup>

Treatment involves controlling the flow. Initially, expressing a little milk (and saving it in the freezer) until the flow slows and then putting the infant to the breast usually solves the problem. If the fat of hindmilk is slow to come, additional milk can be expressed until the fat begins to be secreted. The high-fat milk, or hindmilk, will decrease the relative volume of lactose and the relative amount of gas produced, reducing the colic, thrashing about during feedings, and green stools.

Mothers may reduce the flow from the opposite breast during feedings by folding the nipple down

and wearing a firm brassiere. Pressing her arm across the breast can also diminish flow.

### **DIABETES MELLITUS**

Interest in lactation among women with diabetes is high, and clinical research on the topic is gradually increasing.<sup>22,47</sup> The laboratory has been the site of considerable study of the disease in the animal model and of the role of insulin.<sup>22</sup> The breast is known to be a target organ for insulin, and insulin receptors are in the mammary gland acini. The mammary gland is an insulin-sensitive tissue, where acute changes in insulin concentration result in a rapid alteration in the rate of lipogenesis and the utilization of glucose. Cultures of mammalian breast tissue serve as ideal laboratory models for the exploration of insulin activity.

It is significant to note that the longer the duration of breastfeeding, the greater the reduction in the incidence of type 2 diabetes. The study was from two large cohorts of women. The authors suggest that lactation may reduce risk of type 2 diabetes in young and middle-aged women by improving glucose homeostasis.<sup>252</sup>

Pregnancy has become a more common event in women with well-controlled diabetes, and fertility rates compare with those of women without diabetes. Much has been said about labor and delivery in mothers with diabetes and almost nothing about lactation in these mothers. Mothers with diabetes should be offered the same opportunity to breastfeed that is offered to all patients, unless the disease is so incapacitating that any metabolic stress is contraindicated. When the progress of the infant of a mother with diabetes is uneventful and the infant can be treated normally, no contraindication exists to breastfeeding. The timely onset of stage II lactogenesis is important for the ultimate success of breastfeeding. Gestational diabetes and/or obesity were reported to be associated with delayed lactogenesis.<sup>178</sup> Therefore, early breastfeeding support is essential for mothers with diabetes. Lactation may be more difficult in mothers with diabetes, perhaps as a result of cesarean delivery or the need to keep an infant in a special care unit for the first few days of life. Congenital malformations in infants of mothers with diabetes are more common (two to six times the normal rate), occurring in 8% to 10% of births of mothers with insulin-dependent diabetes mellitus (IDDM). They cover all organ systems. Congenital cardiac disease continues to be most common. At birth, the major problems are macrosomia, complicating delivery, hypoglycemia, respiratory distress syndrome, hypocalcemia, and hypomagnesemia, polycythemia, and hyperbilirubinemia. Thus close monitoring is mandatory while providing as "normal" an experience as possible.

Cordero et al.<sup>54</sup> reported 530 infants born to 332 women with diabetes and 177 women with IDDM, 36% were large for gestational age, 76 (14%) were born at less than 34 weeks' gestation, 115 (22%) were born at 34 to 37 weeks' gestation, and 339 (64%) were born at term. Almost half (47%) were admitted to the NICU due to respiratory distress syndrome, prematurity, hypoglycemia, or congenital malformation. Hypoglycemia occurred in 137 (27%) and more commonly among mothers with severe types of diabetes; 182 (34%) had respiratory distress syndrome. Although 244 infants were admitted to normal newborn care, 43 had to be transferred for hypoglycemia. Routine care failures were less frequent among breastfed infants. The authors recognize the improvements in care of the mother; however, they caution about hypoglycemia and respiratory distress syndrome in infants who are overstressed. They recommend observation of the infant in a special care nursery, especially when the mother's disease is advanced. They further say breastfeeding should be encouraged in these mothers. Rates of breastfeeding in women with diabetes are lower than in non-diabetics, despite the greater advantages to both mother and infant.<sup>83</sup>

In a retrospective study of 25 mothers who were insulin dependent before pregnancy, breastfeeding was both successful (13) and unsuccessful (12).<sup>81</sup> The successful ones were slightly older and better educated and had diabetes longer (13.7 years vs. 8.2 years). The infants were half a week more mature and spent less time in the intensive care nursery (1.8 days vs. 7.2 days). Delay to first breastfeeding and introduction of a bottle in the intensive care nursery were no different, and both groups of mothers experienced an adjustment period. Observations about diet, insulin, and control of diabetes were similar in the two groups and paralleled the observations made in the study by Ferris et al.<sup>81</sup>

During the last stages of pregnancy in normal women, a more or less constant excretion of lactose occurs in the urine, with the peak reached on the day of delivery. After delivery the lactose excretion immediately drops to a low level, where it remains for 2 to 5 days, followed by a sudden large excretion of lactose.<sup>237</sup> Lactosuria in a mother with diabetes may lead to diagnostic confusion. It normally occurs late in pregnancy and in the postpartum period before the infant takes much milk, if the mother does not nurse, or if the supply of milk exceeds the infant's requirement. Lactose reabsorbed from the breasts is excreted in the urine. Urine sugar tests are not reliable during lactation.

The sparing effect of lactation on the insulin requirement has been observed by many, beginning with Joselin et al.<sup>129</sup> The depression of the level of the blood sugar in normal nursing women with

diabetes may lead to hypoglycemic symptoms. The simultaneous lactosuria may be misdiagnosed as glucosuria and excessive insulin taken. The improved tolerance has been explained by the transference of sugar from the blood to the breast for conversion to galactose and lactose. Joselin et al.<sup>129</sup> reported that the majority of patients at the Joselin Clinic, as well as those at Johns Hopkins Hospital, breastfed in whole or in part. They recommended the increased administration of the B vitamins for the mother with diabetes during lactation.

Milk composition in diabetes has been studied by Butte et al.<sup>46</sup> in a group of moderately well controlled insulin-dependent women (type 1) at 3 months postpartum. Women with diabetes in pregnancy and postpartum have been observed to have low levels of prolactin, placental lactogen, and parathyroid hormone. Whether the observed decreased placental blood flow is associated with diminished mammary blood flow in lactation has not been established.

In this small sample size, no significant difference was seen in the values for total nitrogen, lactose, fat, and calories, given the normally wide variations found among control subjects as well. Mineral content was not different except for sodium, which averaged 140 mg/g compared with reference milk's 100 mg/g. The glucose concentrations were significantly higher in the milk of women with diabetes, and this varied greatly without any pattern throughout the 24-hour collections, although lactose fluctuated little. The mean glucose value was  $0.70 \pm 0.11$  mg/g in women with diabetes and  $0.32 \pm 0.08$  mg/g in the reference women. During the collections the women with diabetes were noted to have periods of hyperglycemia. Total milk volumes were not measured in the study by Butte et al., but the infants were noted to gain weight appropriately.<sup>38</sup> Measurements of glycosylated hemoglobin within a month of the milk collections were noted to be  $8.1 \pm 0.6\%$ , which is above the normal range of 4.0% to 7.6%. It is appropriate for clinicians to be aware of the slightly elevated sodium levels, especially if mastitis develops. The glucose elevations probably have little clinical significance to the infants because glucose makes up only about 0.4% of the total energy content of the milk.

When milk volume and composition were measured serially, on days 3 to 7 postpartum, in a woman with diabetes by Bitman et al.,<sup>35</sup> sodium, potassium, chloride, lactose, protein, calcium, magnesium, and citrate were within the limits of a reference population without diabetes. Unlike Butte et al.,<sup>46</sup> Bitman et al.<sup>35</sup> found that fat content was lower, with free fatty acids 2% of total lipid on day 3 but 23% on days 4 through 7. Lipoprotein

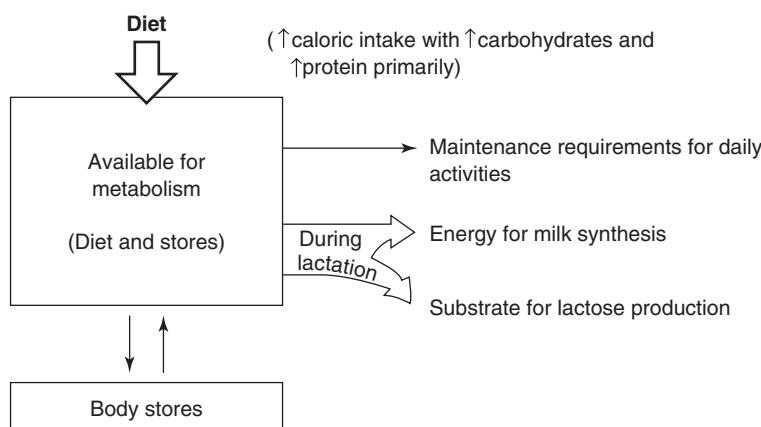

lipase was increased on days 4 and 5. Other changes suggested impaired fatty acid synthesis and high concentrations of polyunsaturated fatty acids. Jensen et al.<sup>127</sup> studied serum levels at 3, 14, and 42 days postpartum from a large group of women. Serum cholesterol levels decreased significantly from days 3 and 14 to day 42 in both women with diabetes and control subjects. Because lipids are a major source of calories, the lipid content of milk of women with diabetes will require further study.

### Diet for Lactating Mothers With Diabetes

Although it is clearly demonstrated that all lactating mothers have an increased energy requirement, it is critical to women with diabetes to identify this need and provide for it in dietary adjustments (Figure 16-5). The 300 kcal required by infants initially means at least 500 to 800 additional kilocalories in the mothers' diets. Because milk is synthesized from maternal stores and substrates, the plasma glucose levels in lactating mothers with diabetes will be lower. The daily maternal insulin requirement is usually much less. The balance is significant between the needs of infants and the energy and nutrition production in mothers. Most postpartum women, including mothers with diabetes, have fat stores that are developed during pregnancy in preparation by the body for lactation. Women with diabetes, when balancing diet and insulin, need to consider that the course of lactation mobilizes these fat stores as substrate for the mammary gland. It has been recommended that the diet include no less than 100 g of carbohydrate and 20 g of protein. This balance will permit the continued mobilization of fat stores to produce the glucose needed for mothers and milk. When mothers with diabetes increase fat metabolism, there is always the risk for ketonemia and ketonuria. Ketonemia and ketonuria indicate a need for increased kilocalories

in both mothers with diabetes and mothers without diabetes. With some careful observations of blood sugar levels and anticipatory guidance, lactation can be managed without hypoglycemia or hyperglycemia. With the availability of newer glucometers, this measurement is more easily accomplished.

A critical analysis of dietary intake and outcome of lactation in a group of women with IDDM was undertaken by Ferris et al.<sup>81</sup> in three major obstetric services in Connecticut. Sixteen of 30 women with IDDM chose to breastfeed (53%) and 14 to bottle-feed compared with 57% of the general maternity population at that time. The authors found that the women with IDDM who sustained lactation received average diet prescriptions of 31 kcal/kg/day (based on maternal weight at 3 days postpartum) or 35 kcal/kg/day (based on preconceptual weight). The mothers who stopped nursing had received only 25 kcal/kg/day (based on maternal weight at 3 days postpartum) or 31 kcal/kg/day (based on preconceptual weight). The latter was the same as that for women with diabetes who were bottle-feeding. When compared with general recommendations, the recommended dietary allowance for lactation is 2000 kcal plus 500 kcal extra. Only one mother who continued to nurse and none who had stopped nursing met this requirement. When it was calculated, mothers who lactated successfully actually consumed more than they thought, and those who "failed" consumed less than they thought. This supports the recommendation that breastfeeding mothers with IDDM need a knowledgeable dietary counselor, as well as other support systems. The weight loss patterns of these women reinforced this observation. Those women who stopped lactating lost considerably more weight than the successful breastfeeders, the bottle-feeders, or the normal control subjects. Fasting blood sugar levels were lower (60 mg/dL) in the successful lactators without an increased insulin dosage.

**Figure 16-5.** Glucose utilization in lactation. From Asselin BL, Lawrence RA: Maternal disease as a consideration in lactation management, *Clin Perinatol* 14:17, 1987.

## ADJUSTMENTS TO LACTATION FOR MOTHERS WITH DIABETES

The woman with mild diabetes whose condition can be controlled by diet alone must modify her diet to include the increased caloric needs, especially ensuring adequate protein intake. Women with diabetes who have been taught to control the problem in pregnancy by diet often continue this dietary awareness after delivery. Thus appropriate counseling for lactation should continue. The mother with IDDM is usually able to increase her diet and maintain her insulin level, although some may find insulin requirements are also reduced. Monitoring blood sugar levels and acetone is necessary at first to achieve the correct balance.

Although hypoglycemia does not cause a reduction in lactose in the milk, the phenomenon of hypoglycemia itself causes increased secretion of epinephrine in insulin shock. The epinephrine inhibits milk production and the ejection reflex. Acetone signals a need for increased calories and carbohydrate. In addition, elevated acetone can cause increased acetone in the milk itself, which is a stress to a newborn's liver. If one merely increases insulin to clear the acetone, it may predispose the patient to hypoglycemia. Each mother will identify the point below which she cannot reduce her insulin dosage without producing acetonuria. While an infant is nursing exclusively at the breast, adjustment is usually smooth. Weaning may present some need for day-to-day adjustment because the amount of milk taken by the infant varies. Many infants take more one day and less the next, and the amount is less predictable. If blood sugar levels cannot be controlled by diet during this time, insulin must be decreased. If the weaning is gradual and continuous, the adjustment is similar.

Social support, including help and encouragement with baby care and family responsibilities, has been a significant difference between successful and unsuccessful breastfeeding among women with diabetes. The management problems, on the other hand, are not related to breastfeeding, per se, but to management of the diabetes. Physicians managing maternal diabetes and infants must understand the issues of diet and insulin and work in concert to help mothers adjust diabetes management to lactation.

## Problems Among Mothers With IDDM in First Days After Delivery

Fewer infants of mothers with diabetes are put to the breast in the first few days, as noted by Ferris et al.<sup>81</sup> Most infants of mothers with diabetes are admitted to the NICU for 8 hours or more of

observation. Not only does this delay breastfeeding, but it also increases the amount of formula and number of bottle-feedings. Breastfeeding women with IDDM fed for the first time at  $35 \pm 5$  hours, whereas bottle-feeding mothers did so for the first time in  $43 \pm 24$  hours! In this study, only two mothers with diabetes and no control mothers were offered a pump. All the mothers who stopped breastfeeding had infants who received a total of 9 oz or more of formula while in the NICU.

Weaning was precipitated in these mothers by problems they saw with the baby, such as crying, fussing, and problems suckling, not because of insufficient milk. No woman with IDDM was told by her physician to stop. Control mothers cited insufficient milk as the cause of weaning. Severity of the disease correlated with the decision to bottle-feed and to wean early.

Supportive hospital management is critical to successful lactation in mothers with diabetes, as well.<sup>22</sup> When 42 mothers with IDDM who breastfed were followed by Whichelow and Doddrige,<sup>270</sup> they found the most important factor in success was the lapsed time to the first breastfeeding. This is usually a function of the infant's medical stability. They were able to initiate a change in hospital policy that minimized separation of infant and mother. Duration of lactation was inversely related to the delay in the first suckling.<sup>22</sup>

The insulin requirement at 3 months in the study by Whichelow and Doddrige<sup>270</sup> was an average 43 units daily, compared with 50 units prepregnancy in bottle-feeders, and 40 units at 3 months, compared with 45 units prepregnancy in the breastfeeders. Ferris et al.<sup>81</sup> reported that insulin dosages were no different among breastfeeders and bottle-feeders, but the numbers were not provided. The subjects in the study by Butte et al.<sup>46</sup> received less insulin while lactating ( $35 \pm 10$  units/day compared with  $63 \pm 14$  units/day during pregnancy).

## Special Features of Lactation for Mothers With Diabetes

Some mothers with diabetes enjoy a postpartum remission of their diabetes that may be minimal or complete. The remission may last through lactation or for several years. This remission has been attributed to the hormone interactions that affect the hypothalamus and pituitary gland during pregnancy, labor, delivery, and lactation. Many women with diabetes report a feeling of well-being during lactation.

Women with diabetes are prone to infection, and therefore mastitis presents a particular problem. With careful anticipatory care, avoidance of

fatigue, and antibiotics for at least 10 days when indicated, mastitis should not pose a threat. Candidal infections are more common because of the glucose-rich vaginal secretions, and most women with diabetes are alert to the early signs of a fungal vaginitis. When the infant is born by cesarean delivery, no exposure occurs in the birth canal. Infection of the nipples can also occur from *C. albicans*, even though the infant does not have obvious thrush. Early specific treatment with nystatin ointment or gentian violet to the breast and mouth of the infant whenever sore nipples do not respond to the usual nonspecific treatment is recommended. Treatment of both mother and infant simultaneously is necessary or they will reseed each other (see Chapter 8).

Infants of women with diabetes present a special problem in breastfeeding because they are often premature, frequently have respiratory distress syndrome and hyperbilirubinemia, and may be poor feeders at first. Hypoglycemia is the immediate problem, and its management may initially preclude dependency on breast milk as the sole source of nourishment. Because less than half of the infants develop problems, many need not be separated from their mothers. For those that require special or intensive care, lactation may have to be postponed briefly depending on the infant's status.

Providing an electric breast pump and assistance in pumping is essential if the infant is too ill to be fed. Attention to this detail is important, regardless of the reason for separation of the mother and infant.<sup>22</sup>

The hypoglycemia of the infant of a woman with diabetes occurs early and is proportional to the level of hyperglycemia in the mother at delivery. Cord blood sugar and microsugar levels at 30 minutes and 1 hour of age provide the curve of glucose disappearance and potential for hypoglycemia. If lactation can be established, the glucose can be managed by breastfeeding. It must be closely monitored, however, so that intervention can be initiated when necessary. Incidence of hypocalcemia in infants of mothers with diabetes is high, which is believed to result from functional hypoparathyroidism, because phosphorus and calcitonin levels are normal.<sup>184</sup> The role of magnesium in this balance has not been clearly defined but needs to be monitored.

Hyperbilirubinemia occurs more frequently in infants of mothers with diabetes.  $\beta$ -Glucuronidase and bilirubin measurements were made on 10 breastfed infants of women with diabetes and 10 normal breastfed control infants by Sirota et al.<sup>240</sup> The concentrations of  $\beta$ -glucuronidase were higher in the serum of the milk of mothers with diabetes, and the bilirubin levels were higher in their infants. None of the control infants

required phototherapy, whereas 50% of the infants of the women with IDDM did. Other investigators compared  $\beta$ -glucuronidase and bilirubin levels in a group of normal breastfed infants on the third and fifth days of life and found no correlation between the values. Although infants of women with diabetes are clearly more prone to hyperbilirubinemia, the central cause remains elusive.

Antenatal breast milk expression by women with diabetes for improving infant outcomes is a controversial procedure.<sup>244</sup> Small studies all express alarm regarding outcomes,<sup>86</sup> but the Cochrane Review expressed concern about lack of evidence and controlled studies.<sup>73</sup> It is being done in many countries per the Internet without benefit of study.

Women with diabetes in pregnancy are being encouraged to express colostrum before birth and store it for use immediately after birth to avoid their infant receiving artificial formula or intravenous dextrose for hypoglycemia in the neonate. The concerns include reports of stimulation of premature labor in multiple cases. Breast stimulus has been used to initiate labor in select cases; in other situations, an increase in the number of infants requiring care in intensive care units or special care nurseries is also observed. There are still no published, randomized, controlled trials, according to the Cochrane report.<sup>73</sup> No benefits have been reported to date either. To avoid use of bovine protein formula at birth, donor milk should be readily available or special non-bovine formula. Of additional concern is the evaluation of the amount of colostrum still available after delivery. This has not been studied. The total amount available to the infant may be diminished.

## Breastfeeding and Onset of Diabetes

Breastfeeding has been associated with the prevention of type 2 diabetes mellitus in women who experience gestational diabetes during pregnancy. Gestational diabetes occurs in 4% of pregnancies and represents 90% of diabetes seen in pregnancy. Breastfeeding is associated with reduced blood glucose levels, postpartum weight loss, reduced long-term obesity, and a lower prevalence of metabolic syndrome, according to Bentley-Lewis et al.<sup>32</sup> Improvement in glucose and insulin homeostasis was seen in lactation in a study of type 2 diabetes mellitus in the Nurses' Health Study I and II reported by Stuebe et al.<sup>252</sup> The longer the duration of breastfeeding was, the lower the incidence of type 2 diabetes documented in this large cohort of more than 2 million person-years. For each additional year of lactation, normal women, without gestational diabetes but with a birth in the previous 15 years, had a 15% decrease in the risk for diabetes (Tables 16-6A and 16-6B).

**TABLE 16-6A**

Duration of Breastfeeding and Diabetes: Comparison of Nurses' Health Study and Nurses' Health Study II Cohorts

	Nurses' Health Study	Nurses' Health Study II
Total number of participants	121,700	116,671
Year of birth	1921-1945	1946-1965
Timing of questionnaires	Every 2 years, beginning in 1976	Every 2 years, beginning in 1989
Assessment of lactation	1986: "How many months in total (all births combined) did you breastfeed?" Response options: did not breastfeed, <1, 1-3, 4-6, 7-11, 12-17, 18-23, 24-35, 36-47, ≥48, cannot remember	1993: "How many months in total (all births combined) did you breastfeed?" Response options: did not breastfeed, <1, 1-3, 4-6, 7-11, 12-17, 18-23, 24-35, 36-47, ≥48, cannot remember 1997: For each of first 4 pregnancies, detailed questions regarding return of menses, use of medication to suppress lactation, timing of introduction of infant formula/solid food, pumping, more than 6 h at night without breastfeeding Response options: 0-2, 3, 4-5, 6-7, 8-11, or ≥12 mo. Cessation of breastfeeding Response options: 1-2, 3-5, 6-8, 9-11, 12-18, or ≥19 months 2003: Supplemental questionnaire sent to women reporting births since 1997; same information gathered as on 1997 lactation questionnaire
Pregnancies	Baseline parity in 1976, additional pregnancies reported in 1978, 1980, 1982, 1984	Baseline parity in 1989, additional pregnancies reported every 2 yr thereafter
Weight	Baseline weight in 1976, update on weight every 2 yr thereafter	Baseline weight in 1989, update on weight every 2 yr thereafter
Weight at age 18 yr	1980	1989
Diabetes	Assessed on questionnaires every 2 yr, confirmed by supplemental questionnaire	Assessed on questionnaires every 2 yr, confirmed by supplemental questionnaire
Gestational diabetes	Not assessed	Assessed on questionnaires every 2 yr

JAMA, November 23/30, 2005-Vol. 294, No. 20 (Reprinted) ©2005 American Medical Association. All rights reserved, Stuebe AM, Rich-Edwards JW, Willett WC, et al: Duration of lactation and incidence of type 2 diabetes, *JAMA* 294:2601, 2005.

Epidemiologic reports<sup>37,87</sup> continue to accumulate, suggesting that being breastfed has a protective effect on the onset of diabetes in childhood. Children in Western Australia who were studied to the age of 14 years revealed an incidence of 0.59 children with diabetes per 1000.<sup>94</sup> No significant trends or associations with illness were made, except that breastfeeding beyond 1 week of age was less frequent in diabetic than nondiabetic cohorts. In a study of 95 children of women with diabetes and their siblings and peers without diabetes, the incidence of breastfeeding was only 18% but was comparable in all three groups. Twice as many children with diabetes had received soy formula as the other children. In a study of IDDM in Scandinavian populations, fewer children with childhood-onset diabetes were breastfed, and those who were breastfed were breastfed for shorter periods.<sup>37</sup> The authors suggest that insufficient breastfeeding of genetically susceptible newborn infants may lead to B-cell infection and IDDM in later

life. The prevalence of diabetes in black populations throughout Africa, where breastfeeding is common, is usually considerably lower than in Western countries among those of African descent.<sup>153</sup>

The Colorado IDDM Registry was studied retrospectively to determine the possible relationship between breastfeeding and development of childhood diabetes, in comparison with randomly selected control subjects.<sup>179</sup> Incidence of IDDM was less frequent among breastfed infants, and the longer the breastfeeding, the greater the effect. The population percentage with attributable risk ranged from 2% to 26%. Because of the increasing incidence of childhood diabetes throughout Scandinavia, a prospective study followed children for 7 years. Results demonstrate a clear relationship between lack of breastfeeding and IDDM in the first 7 years of life, or, conversely, a protective effect of breastfeeding. This effect is strongest with at least 4 months of exclusive breastfeeding.<sup>37</sup>

Other investigators are exploring the possible relationship of early exposure to cow milk and the onset of diabetes. It is suggested that the etiology of the disease has both a genetic and an environmental component. Karjalainen et al.<sup>135</sup> report the identification of a bovine albumin peptide as a possible trigger of IDDM. The antibodies to this peptide are said to react with P69, a B-cell surface protein that may represent the target antigen for milk-induced B-cell-specific immunity. The antibodies decline in 1 to 2 years to normal values. Much lower values were found in all the control children.

Utilizing the Colorado IDDM Registry, Kostraba et al.<sup>152</sup> compared children with high and low genetic risk for IDDM with a group of matched normal control subjects. They used a HLA-DQB1 molecular marker. Early exposure to cow milk and solid foods was strongly associated with IDDM in genetically high-risk individuals. The authors suggest that the inclusion of the HLA-encoded risk in the analyses demonstrates the combined effect of genetic and environmental factors.

The association of serum immunoglobulin A (IgA) antibodies with milk antigens in patients with severe arteriosclerosis is under review. The presence of antibodies against dietary antigens is well documented. Its relevance is under study by Muscari et al.<sup>193</sup> and others.

Rennie<sup>221</sup> showed a relationship between the consumption of cow milk and the incidence of diabetes, between the ages of 0 to 14 years, in countries around the world (Figure 16-6). The association between IDDM and early exposure to cow milk may be explained by the generation of a specific immune response to  $\beta$ -casein. A cellular and humoral anti- $\beta$ -casein immune response is triggered by exposure to cow milk and may cross-react with B-cell antigen. Sequential homologies exist

**Figure 16-6.** Annual consumption of cow milk and incidence of diabetes (ages 0 to 14). (Modified from Rennie J: Formula for diabetes? *Sci Am* 267:24, 1992.)

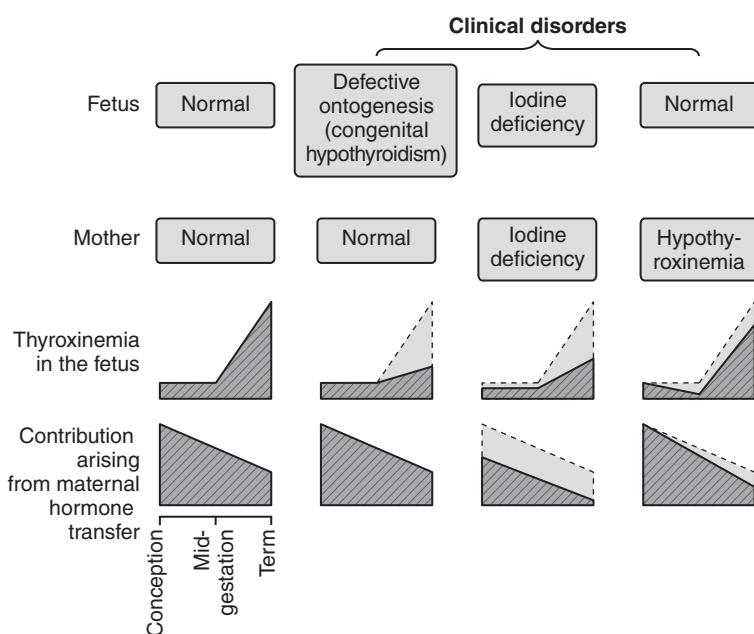

between  $\beta$ -casein and several B-cell molecules.<sup>49</sup> The systemic review of published studies indicated that breastfeeding did influence risk for type 2 diabetes in later life. Maternal type 1 diabetes is not an independent risk factor for being overweight in childhood in these children. However, lack of being breastfed is a risk factor, as well as their higher birth weight.<sup>62,120</sup> The introduction of cereal younger than 6 months of age was shown to increase the incidence of diabetes in at-risk children. Much work remains to be done. In the meantime, this may be one more reason for mothers to consider breastfeeding, especially in families at high risk for diabetes, and delaying the introduction of solid food until 6 months of age, as recommended by WHO/UNICEF for all children.<sup>64,70</sup>

## THYROID DISEASE

The thyroid gland is intimately involved with hormone activity of pregnancy. The metabolic and hormonal demands of pregnancy alter the thyroid gland. Conversely, the outcome of pregnancy may be altered by changes in the thyroid gland. Thyroxine-binding globulin increases secondary to the increased estrogens. The normal pregnant woman may be euthyroid, but changes occur in the basal metabolic rate, radioactive iodine uptake, and thyroid size.

Thyroid disease is four times more common in women than men, and thyroid abnormality is common in pregnancy. The diagnosis is more difficult to make during pregnancy because of problems with the interpretation of thyroid function tests. Treatment must take into account the presence of the fetus once the management decision is made. During the postpartum period, autoimmune thyroid disease is exacerbated. New-onset autoimmune thyroid disease occurs in 10% of postpartum women but is often overlooked when mothers are dismissed as depressed. More than 60% of patients with Graves disease trace the onset to their postpartum period. Most of the immune changes of pregnancy gradually return to normal by 12 months. An explanation for the postpartum autoimmune exacerbation is that a reduction of fetal cells is associated with a reduction in maternal tolerance of the remaining microchimeric cells and a loss of major placental peptide complexes associated with T-cell energy during pregnancy (Figure 16-7).

Thyroid disease is increasingly common postpartum and often presents as depression. No postpartum woman should be started on antidepressive drugs without a thyroid screen, especially if she has not been symptomatic before pregnancy. Unfortunately, most textbooks that discuss thyroid disease

**Figure 16-7.** Thyroid function disorders. Schematic representation of the three sets of clinical conditions that can affect thyroid function in the mother alone, in the fetus alone, or in the fetomaternal unit shows the relative contributions of impaired maternal or fetal thyroid function that may eventually lead to alterations in fetal thyroxinemia. (Reprinted by permission from Glinoer D, Delange F: The potential repercussions of maternal, fetal, neonatal hypothyroxinemia on the progeny, *Thyroid* 10: 871, 2000.)

in pregnancy and postpartum do not discuss breastfeeding or lactation, except Creasy et al.<sup>59</sup>

## POSTPARTUM THYROIDITIS

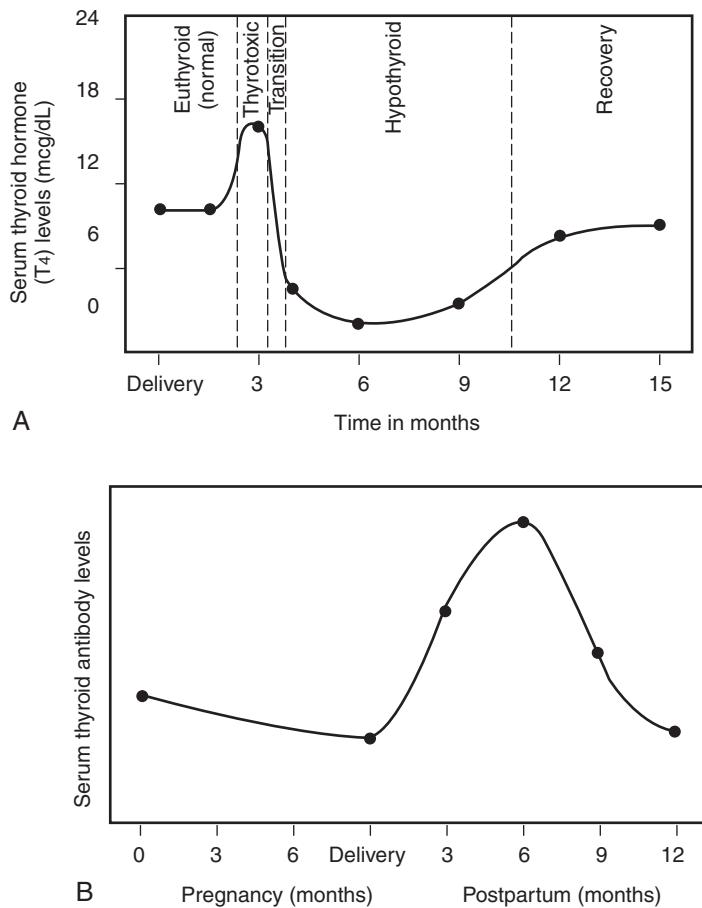

Postpartum thyroiditis is diagnosed when abnormal levels of thyroid-stimulating hormone (TSH) are documented, either elevated or suppressed during the first year postpartum, and Graves disease has been excluded by positive thyroid-stimulating immunoglobulins, or a toxic nodule is present. Usually a transient hyperthyroid phase lasts 6 weeks to 6 months after delivery. This is followed by a hypothyroid phase that lasts up to a year after delivery (Figure 16-8). The incidence of this autoimmune disease is as high as 6% to 9%, and is higher in individuals with type 1 diabetes. The hyperthyroid phase is characterized by fatigue, palpitations, heat intolerance, and nervousness. It is of limited duration, a few weeks to a few months. Antithyroid drugs should be used, although beta blockers may help with symptoms. The hypothyroid phase follows with marked fatigue, hair loss, depression, poor concentration, and dry skin. Treatment with thyroxine ( $T_4$ ) (Synthroid) is appropriate. Postpartum thyroiditis, which is a destructive process, is characterized by positive antithyroid antibodies (antithyroglobulin and antithyroid peroxidase). The TSH levels are suppressed, and  $T_4$  levels are high in the hyperthyroid phase. This is in addition to extremely suppressed radioactive iodine uptake, which should not be done during lactation. The diagnosis can be confirmed by the absence of thyroid-stimulating immunoglobulins, which rules

out Graves disease. Distinguishing postpartum thyroiditis and postpartum depression can be done by measuring thyroid antibodies, which will be negative in most cases of clinical postpartum depression. The two postpartum diseases can coexist. These patients deserve endocrinologist and psychiatrist consultation. Lactation will and can continue if already established. Any faltering in supply can be managed with the usual protocol of increased stimulus and galactagogues.

## MATERNAL HYPOTHYROIDISM

It has long been held that hypothyroidism is associated with infertility. The incidence of hypothyroidism during pregnancy is low. Because of the difficulty in maintaining pregnancy in individuals with hypothyroidism, the number of women who are truly hypothyroid at delivery is also low. Some women who are maintained on thyroid treatment for one reason or another do bear children. If hypothyroidism is diagnosed, it should be treated with full replacement therapy, 75 to 125 mcg of desiccated thyroid daily. The medication should be continued after delivery. The mother should be permitted to breastfeed without question. There is measurable thyroid hormone in the milk of normal women. Breastfeeding is not contraindicated because proper treatment makes her euthyroid.

If a mother is truly hypothyroid, particular care should be used to rule out hypothyroidism in the infant, using neonatal screening with  $T_4$  and TSH if necessary. Diagnosis can be performed by evaluating maternal blood values and is not a hazard to

**Figure 16-8.** Postpartum thyroiditis and changes in thyroid antibody concentrations. **A**, Postpartum thyroiditis manifests with a transient hyperthyroid phase, during which serum levels of thyroxine ( $T_4$ ) are elevated. A hyperthyroid phase follows. **B**, Serum thyroid antibody levels fluctuate during and after pregnancy. (From Smallridge RC, Fein HC, Hayship CC: Postpartum thyroiditis, *Bridge Newslett* (Thyroid Foundation America) 3:3, 1988.)

the nursing. Thyroiditis may well be the cause and should be considered. Because of the small amount of thyroid hormone in breast milk, a breastfed child with hypothyroidism may be undiagnosed unless laboratory values are carefully reviewed.

An increase in hypothyroidism is being identified postpartum, especially when normal women have prolonged "baby blues" and fatigue or appear to have new-onset depression. Screening for thyroid disease is appropriate before prescribing antidepressants. Self-medication has led women to initiate treatment with St. John's wort, thus masking the thyroid disease. Obtaining a thorough history is always important, including self-medication with other drugs and herbs. Herbal treatments are being recommended by paraprofessionals during lactation. Therefore, a physician should be especially vigilant when taking a history, and include specific questions about herbal use.

## MATERNAL HYPERTHYROIDISM

The diagnostic procedures and therapeutic management of the mother with possible hyperthyroidism present some hazards to the breastfed infant.

The diagnosis can be made without radioactive material. The combination of an elevated serum  $T_4$  level and a normal resin triiodothyronine ( $T_3$ ) uptake is helpful. These two determinations can be combined to obtain a free- $T_4$  index, which reflects these determinations in a single value. The possibility of thyroiditis should be considered. Whether the patient eventually has a thyroidectomy or not, her thyrotoxicosis must first be medically stabilized. Surgery is usually not indicated in postpartum thyrotoxicosis.

Postpartum thyroiditis has also increased in frequency to 1 in 20 women. It is characterized by symptoms of hyperthyroidism with pounding tachycardia, rapid weight loss, insatiable appetite, and excessive milk production.<sup>134</sup> One case reported to the lactation center was notable for a stimulating reaction to prenatal vitamins (possible iodine effect), caffeine, and high-protein beverages.

A distinction between postpartum thyroiditis and Graves disease should be made (Table 16-7). Those with postpartum thyroiditis initially appear to suffer from hyperthyroidism but develop hypothyroidism at approximately 6 weeks and usually require thyroid replacement indefinitely.

**TABLE 16-7** Characteristics of Postpartum Thyroiditis and Graves Disease

	Postpartum Thyroiditis	Graves Disease
Blood levels	Modest elevations	Significant elevation
Microsomal antibody	+	++
Thyroid-stimulating immunoglobulin	Normal	High
Gland size	Slight enlargement	Significant enlargement
Diagnostic tests	Irradiating tests not indicated	Diagnostic tests with $^{131}\text{I}$ should be avoided while lactating
Symptoms	Moderate sx	Marked sx
Thyroid levels over time	Return to normal 4-6 weeks	Unchanged
Treatment	Symptomatic: Propranolol, watch and wait (propylthiouracil no effect) May need thyroid therapy when becomes hypothyroid	Start with propranolol, add propylthiouracil
Safety while lactating	No contraindications	Medications—all safe, but $^{131}\text{I}$ treatment contraindicated—may need surgery

The treatment for hyperthyroidism includes anti-thyroid medication with thiourea compounds, which inhibit the synthesis of thyroid hormone by blocking iodination of the tyrosine molecule. Propylthiouracil (PTU) and methimazole (Tapazole) are the drugs of choice for the mothers. The major difficulty in their use in pregnancy is that PTU may cause fetal goiter and possibly hypothyroidism. The goiter is thought to be the result of inhibition of fetal thyroid hormone production by PTU with resulting increase in fetal TSH and thyroid gland enlargement. In 41 pregnancies in 30 patients receiving anti-thyroid medication, five infants developed goiters. Goiter development was not dose related. It has been recommended that the maternal therapy also include desiccated thyroid, on the basis that the various components of thyroid metabolism cross the placenta at different rates. An infant may show withdrawal symptoms at birth and present as hyperthyroid and hypermetabolic.

The lactating mother presents a somewhat similar problem. Thiouracil appears in the milk in significant levels and is contraindicated. Methimazole appears in the milk with a milk/plasma ratio of 1. A 40-mg dose of methimazole would yield 70 mg for the infant. Lamberg et al.<sup>159</sup> treated 12 lactating women with a methimazole derivative, carbimazole, in doses ranging from 5 to 15 mg daily, which is comparable with 3.3 to 10 mg methimazole. All the infants maintained normal thyroid function studies at 4, 14, and 21 days. Two infants were followed to 3 and 4 months and remained normal.

Levels of PTU in milk were reported by Kampmann et al.,<sup>132</sup> who calculated that minimal amounts reach the milk because the drug is ionized and protein bound. They found no evidence of effect in the infants with careful follow-up with  $\text{T}_4$  and TSH

measurements. It has been suggested that infants can be breastfed and monitored biochemically. Microtechniques are available for determining  $\text{T}_3$ ,  $\text{T}_4$ , and TSH levels, and monitoring should not be a technical problem. Physical examination would reveal bradycardia, or other signs of hypothyroidism, and goiter. It has also been suggested that the infants may be given 0.125 and 0.25 grain of thyroid daily.

This situation requires close medical surveillance and continual monitoring by microanalysis. The clinical judgment rests with the physician to ascertain whether sufficient medication is reaching the infant. An older infant (older than 6 months of age), who is receiving other dietary intake (such as solids), would be at less risk than a newborn, who depends solely on breast milk. Lamberg et al.<sup>159</sup> recommend PTU doses of up to 150 mg/day.

When PTU is not an effective drug for a mother, Cooper<sup>53</sup> suggests methimazole or carbimazole in doses up to 10 mg with close monitoring of the breastfeeding infant and thyroid function tests biweekly. Lamberg et al.<sup>159</sup> recommend methimazole doses up to 15 mg/day.

Because iodine appears in milk and the milk/plasma ratio is greater than 1.0, a lactating mother with thyroid disease should not be given iodine for any reason.

## POLYCYSTIC OVARIAN SYNDROME

Polycystic ovarian syndrome (PCOS) is one of the disorders of androgen excess that begins at puberty and progresses slowly. Mild androgen expression in women is characterized by body hair growth, acne, and seborrhea. Prepubertal acne is not part of normal puberty and should be evaluated for androgen

excess. A synonym for PCOS is *hyperandrogenic anovulation*. Excess androgens result in abnormal release of the pituitary hormones that normally control menstruation and ovulation. Thus women with PCOS have irregular menses and erratic or no ovulation and often a history of premature adrenarche. Other symptoms, besides infertility and hirsutism, are amenorrhea, obesity, functional bleeding, dysmenorrhea, virilization, and biphasic body temperature. Obesity may be associated with abnormal fat distribution (upper body android). This fat distribution is associated with risk for diabetes, hypertension, arteriosclerosis, and gallbladder disease. It is strongly associated with insulin resistance, which appears to be due to receptor abnormalities with too few receptor cells and corresponding circulating hyperinsulinemia. Drug therapy for hyperandrogenism does not change the insulin resistance. In contrast, lowering the insulin with drug therapy does improve the hyperandrogenism.

Acanthosis nigricans is also seen with the insulin resistance (especially in axilla, neck folds, and antecubital creases). The disease has been renamed by some to *hyperandrogenic chronic anovulation*.

Pregnancy can be accomplished with clomiphene citrate or naturally if some ovulation occurs. Maternal excessive androgens do not appear to affect the fetus, because the placenta converts androgens to estrogens. The initiation of lactation may be a challenge.

Insufficient milk supply has been observed in women with PCOS who classically do everything right: breast changes in pregnancy, early frequent feeds, good latch, and pumping. Metoclopramide does minimally increase supply while the drug is taken. Supplementation is usually required.

The cause of the lack of milk production may be that estrogen and prolactin receptors have been "down regulated" by the androgen. Perhaps high estrogen postpartum suppresses prolactin. Is insulin resistance at the core of the problem? In some cases, the mammary tissue is inadequate. It is possible that gestational dehydroepiandrosterone-sulfate might negatively influence breastfeeding rate in women with the syndrome, according to investigations by Vankay et al.<sup>262</sup>

With this constellation of symptoms, a clinician would be wise to refer a mother to her obstetrician for evaluation, or to an endocrinologist.

The traditional efforts to increase milk supply should be tried: pumping, domperidone, and other galactagogues. Because insulin plays an important role in lactogenesis and in the insulin-resistant components of PCOS, metformin (glucophage) has been tried with minimal success. Women also pumped and used various galactagogues. Metformin did produce engorgement and increase in milk production. Because it was not initiated until

lactation failure was apparent, the authors suggested it should be initiated when lactation begins<sup>90</sup> in women with a history compatible with PCOS.

Coupled with diet, metformin ameliorates the endocrinopathies of polycystic ovary syndrome and facilitates regular ovulation and conception. Metformin during lactation continues the resolution of the endocrinopathy.<sup>262</sup> It is excreted into breast milk, but in insignificant amounts. It is poorly absorbed orally from the milk. Follow up of infants born to 92 mothers receiving metformin was done, comparing those who were breastfed to those who were bottle fed. No adverse effects were noted on growth,<sup>95</sup> motor-social development, or recurrent illness.<sup>103</sup> Metformin is considered safe during lactation.

Women with metabolic syndrome had a lower incidence and duration of breastfeeding in a study from the Study of Women's Health Across the Nation (SWAN). Parous women who had ever breastfed had a lower incidence of metabolic syndrome according to Ram et al.<sup>219</sup> Metformin is most effective when started during pregnancy. When breastfeeding is not going well, it is important to address attention to the standard management issues, as well as the problems of the syndrome.

## CYSTIC FIBROSIS

Patients with cystic fibrosis (CF) are living longer and enjoying more stable lives as diagnostic and therapeutic advances in the disease continue. Reports have appeared indicating that a number of women with CF have become pregnant and have delivered normal infants. A case was reported of such a mother who had high sodium levels (132 and 280 mEq/L) in her milk. This mother had not been breastfeeding and expressed her milk for the studies only. As pointed out by Alpert and Cormier,<sup>8</sup> milk from involuting breasts is different, and sodium may be closer to serum levels. Sodium levels are always elevated when measured in non-lactators. Since that time, Welch et al.<sup>269</sup> reported one case, and Alpert and Cormier<sup>8</sup> reported two cases of successful breastfeeding with maternal CF. The women were fully lactating, and sodium and chloride levels in the milks were normal.

Hamosh et al.<sup>105</sup> have investigated the fat content of the milk of mothers with CF and report lowered levels of fatty acids.

Another case of successful breastfeeding by a woman with CF is reported by Smith et al.<sup>242</sup> The infant grew along the 50th percentile for height, weight, and head circumference. Milk samples (fore and hind) at 11 weeks postpartum had sodium levels of 11 mmol/L (normal 2 to 19 mmol/L).

Michael and Mueller<sup>186</sup> reviewed five women with CF and their infants. Evaluations indicating their need for enzyme therapy and their pulmonary disease status classified these women as mild cases. The infants averaged  $37.4 \pm 1.5$  weeks' gestation with birth weights of  $3.0 \pm 0.5$  kg. Sweat tests were negative for all the infants. Duration of breastfeeding ranged from 3 to 30 weeks. Four of the five infants maintained good growth during breastfeeding. Four of the five mothers were at or above their standard body weight throughout lactation. The authors conclude that women with mild CF can not only sustain a pregnancy, but also support the growth of a healthy infant through breastfeeding while maintaining their own weight.<sup>186</sup>

Current recommendations for breastfeeding by mothers with CF were published by Luder et al.,<sup>171</sup> after a survey of CF centers (Tables 16-8 and 16-9).

**TABLE 16-8**

Recommendations About Breastfeeding by Cystic Fibrosis Center Directors for Mothers with Cystic Fibrosis\*

Recommendation	Response, No. (%)
Recommend breastfeeding	14 (11.2)
Do not recommend breastfeeding	10 (8.0)
Recommendation made according to each patient's health status	52 (41.6)
Recommendation made according to each patient's personal wishes	40 (32.0)
Not applicable and/or other category	9 (7.2)
Total	125 (100)

\*Many centers chose more than one answer; therefore the response rate for each answer is calculated as a percentage of total responses.

Modified from Luder E, Kaltan M, Tanzer-Torres G, et al: Current recommendations for breastfeeding in cystic fibrosis centers, *Am J Dis Child* 144:1153, 1990.

**TABLE 16-9**

Duration of Breastfeeding as Reported by Cystic Fibrosis Center Directors for Mothers With Cystic Fibrosis

Duration (mo)	Centers, No. (%)
<3	35 (41)
3-6	9 (10)
>6	1 (1.2)
Not applicable and/or other category	41 (48)
Total	86 (100)

Modified from Luder E, Kaltan M, Tanzer-Torres G, et al: Current recommendations for breastfeeding in cystic fibrosis centers, *Am J Dis Child* 144:1153, 1990.

For mothers with CF, 11% of centers recommend breastfeeding, 8% do not recommend it, 42% tailor their recommendations to the mother's health, and 32% make recommendations on the basis of the mother's wishes. Of the centers, 41% report breastfeeding duration of less than 3 months. Table 16-9 lists factors that preclude breastfeeding and factors contributing to discontinuation, as reported by directors of CF centers. 81 centers (94%) have support services available throughout the course of lactation.

As the survival of patients with CF continues to improve and more women reach the childbearing years, an increasing number will choose to breastfeed.<sup>171</sup> Additional research is necessary to help mothers with CF maintain their health while lactating and to monitor growth in infants with CF, and their general health status, while breastfeeding. Breastfeeding usually enhances the health of an infant with CF, because it helps to protect against infection and provide active enzymes (see Chapter 15).

Studies demonstrate that mothers with pulmonary and pancreatic disease of CF can breastfeed and that their infants do well. It is appropriate, however, to test milk samples occasionally for sodium, chloride, and total fat, and to follow the infant's growth pattern critically.

## CELIAC DISEASE

All the clinical and epidemiologic evidence suggests breastfeeding is protective against celiac disease, delaying the onset and reducing the severity. The milk of mothers with celiac disease is characterized by a reduced abundance of immunoprotective compounds (TGF- $\beta$ 1 and sIgA) and bifido bacteria. It is possible this could somewhat reduce the protective effects of breastfeeding.<sup>205</sup> However, these constituents are still present in significant amounts. Trace amounts of gluten ( $\alpha$ -gliadin) can be found in breast milk. No evidence shows that gluten in breast milk triggers celiac disease in susceptible babies. Mothers of at-risk infants or infants who have been diagnosed can go on a gluten-free diet while breastfeeding.<sup>18</sup> In a case, a 6-month-old breastfeeding infant, whose older brother had been diagnosed with celiac disease at 18 months of age after months of crying, colic, abdominal pain, and gas, began developing similar symptoms. The mother began a gluten-free diet and within 48 hours the infant was dramatically better and continued to breastfeed.<sup>18</sup> See the discussion of when to initiate change in diet of an infant in Chapter 14.

## HYPERLIPOPROTEINEMIA

The effect of pregnancy and lactation on lipoprotein and cholesterol metabolism was studied in the rat model by Smith et al.<sup>241</sup> It is well established that cholesterol levels are elevated in normal

women during pregnancy and lactation. These new findings further defined the process. The origins of this hyperlipidemia and cholestasis were traced through plasma and hepatic cholesterol metabolism during pregnancy, lactation, and postlactation. The activities of hepatic enzymes were significantly lower for SR-B<sub>1</sub>, which was elevated. Once lactation began the enzymes increased, except for SR-B, which was decreased compared with nonpregnant nonlactating normal women. In later stages of lactation, most hepatic elements returned to near-normal levels. Plasma cholesterol levels were higher at birth and during lactation with an increase in low-density lipoprotein (LDL)-sized particles. Twenty-four hours after lactation ceased (i.e., suckling ceased), plasma triglycerides were 3.7-fold higher, but cholesterol was unchanged. Very large lipoproteins were present, but LDL-sized particles were absent. Hepatic cholesterol acyltransferase was only 27% of control levels, while diacylglycerol acyltransferase increased three times and LDL lipoprotein receptors doubled. Three weeks after weaning, most values were normal except for lipoprotein receptors, which were still elevated.<sup>241</sup>

The study of a mother with type I hyperlipoproteinemia nursing her second child is reported by Steiner et al.<sup>248</sup> The milk and plasma were carefully analyzed, and it appeared that the deficit of lipoprotein lipase extended to the mammary gland. The milk had low total lipids and a bizarre composition of fatty acids. Her milk differed greatly from her plasma triglycerides in comparison to normal mothers, whose fatty acid profile in the milk matched the plasma. Low concentrations of essential linoleic ( $C_{18:2,20:4}$ ) and arachidonic ( $C_{20:4}$ ) acids in her milk made it inadequate for her infant. Other women in the literature with hyperlipoproteinemia have been reported to develop pancreatitis during pregnancy. Lactation is not advisable when the milk has major deficiencies.

## GALACTOSEMIA

The case of a 25-year-old woman, who had been diagnosed with galactosemia, herself, at the age of 3 weeks, was reported by Forbes et al.<sup>85</sup> at the time of her first baby, whom she breastfed. The woman had blood transferase activity that hovered from zero to 1.9 U (normal 18 to 25 U/g hemoglobin). Despite irregular menses, she conceived and delivered a normal girl who thrived on breastfeeding exclusively. Solid foods were added at 5 months. The analysis of her milk at 4½ weeks postpartum revealed protein 1.42 g/dL, lactose 7.5 g/dL, fat 4.25 g/dL, and calculated energy content 74 kcal/dL. The fatty acid profile was normal, except for 18:3, which was low. Macrominerals were all within normal range. Glucose was 26 mg/dL and galactose

less than 15 mg/dL. The authors point out that, because lactose can be found from uridine diphosphogalactose (by means of epimerase) and glucose (a reaction stimulated by lactalbumin) in the absence of transferase enzyme, one could have predicted that lactose would be present in her milk.<sup>85</sup>

## PHENYLKETONURIA

The success of newborn screening and early treatment has resulted in a population of adolescents with phenylketonuria (PKU) moving into the childbearing years with normal intelligence. Matalon et al.<sup>176</sup> reported a pregnancy and lactation experience in a woman who had stopped her diet and did not seek medical care until 16 weeks' gestation. They also reported their experience with 32 young adults who had discontinued their diets. The authors make the following recommendations:

1. Diet restrictions for PKU should not be discontinued at any age, especially in women.
2. Strict control should begin before conception to bring blood phenylalanine levels to 4 mg/dL or lower.
3. Breastfeeding is permitted.

Matalon et al.<sup>176</sup> report that the milk of mothers with PKU controlled by diet is normal (Table 16-10).

## RADIATION EXPOSURE AND INTERVENTIONAL RADIOLOGY

The diagnosis and treatment of a lactating woman with malignancy may well necessitate the use of radioactive compounds or antimetabolites. Because the breast is a minor route of excretion for most of these compounds, it is probably inappropriate to continue nursing during such exposure. Although the dose of the material drug in a single aliquot of milk may be small, the effects are cumulative. No long-range studies indicate the outcome of offspring exposed in utero. In addition, a mother with malignancy should be encouraged to spare all her resources to overcome the disease. Lactation is as draining in such a situation as pregnancy.

**TABLE 16-10** Amino Acid Levels (mmol/dL) in Milk of Mothers With Phenylketonuria (PKU)

Amino Acid	PKU Milk	Reference Values
Phenylalanine	0.5	0.62
Tyrosine	0.5	1-2
Taurine	36.7	41-45

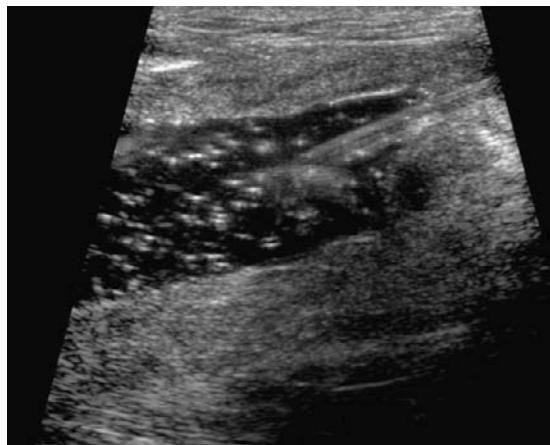

Iron, zinc, copper, magnesium, and selenium were also within normal range.

Diagnostic or therapeutic measures using radioactive materials are contraindicated in pregnancy and lactation because they tend to accumulate in the fetal and neonatal thyroid gland and the maternal breast. If radioactive testing is deemed essential before treatment can be carried out, a test dose of iodine-123 ( $^{123}\text{I}$ ) can be given and breastfeeding discontinued for 66 hours. (The half-life of  $^{123}\text{I}$  is 13.2 hours;  $5 \times 13.2 = 66$  hours.) The validity of the test during lactation has been questioned because the mammary gland may divert a disproportionate amount of  $^{123}\text{I}$  to the milk. The milk should be expressed during the 66-hour period and discarded.<sup>39</sup> The milk should be scanned for radioactivity before breastfeeding is resumed.

Breast interventions beyond the diagnosis of pathology are becoming more common and may be urgent. Acute breast situations are those specifically related to breastfeeding such as abscesses, extreme plugged duct, and breast swelling requiring irrigation. Cannulation of a duct can be done by an interventional radiologist.<sup>121</sup> Trauma to the breast may require an invasive technique. See Figure 16-9, an abscess irrigated with saline, and Figure 16-10, hemorrhage following biopsy.

## BREAST CANCER

In the young patient with cancer, another concern is what risk lactation adds to the mother's long-range prognosis. The automatic response tends to be not to become pregnant and, in any event, not to breastfeed. This question was examined by Hornstein et al.,<sup>118</sup> who indicate that "the current data suggest that pregnant women with early breast carcinoma may be treated in the same way as non-pregnant women without affecting the pregnancy."

**Figure 16-9.** The abscess is irrigated with saline. (From Ingram AD, Mahoney MC: An overview of breast emergencies and guide to management by interventional radiologists, *Tech Vasc Interv Radiol* 17:55, 2014 (Figure 12).)

**Figure 16-10.** Postbiopsy hemorrhage has led to significant asymmetric enlargement of the left breast and bruising extending over the left breast and down the side and flank. (From Ingram AD, Mahoney MC: An overview of breast emergencies and guide to management by interventional radiologists, *Tech Vasc Interv Radiol* 17:55, 2014 (Figure 13).)

Disease that is detected toward the end of pregnancy may be treated with surgery immediately, and then the patient may receive adjuvant therapy if indicated after delivery. Advanced disease should be treated aggressively, and the infant delivered and not breastfed. During lactation, the diagnosis of breast carcinoma requires the immediate suppression of lactation by medications other than estrogens. The carcinoma is then treated by standard methods. When a woman has already had a radical mastectomy for breast cancer, she can have subsequent pregnancies, but they should be delayed until the period of greatest risk is over (i.e., at least 3 to 5 years). She may also breastfeed.

Kalache et al.<sup>130</sup> report that 7% of fertile women have one or more pregnancies after mastectomy; 70% of these pregnancies have occurred within 5 years after treatment. Women who have pregnancies after potentially curative mastectomy have survival rates of 5 to 10 years—as good or better than those who do not become pregnant. The patients with the best prognosis, however, may be a function of selection, because they are healthier and thus able to become pregnant. Uneventful pregnancy does not guarantee cure, although the highest rate of recurrence is in the first 3 years, and gradually declines. It is never zero. Metastases to the axilla increase the risk. Recurrence in the chest

wall during pregnancy can be treated with local shielded radiation, but anything more extensive requires aggressive intervention.

The importance of careful monitoring during pregnancy is obvious. One of the major contributors to a more grave prognosis of the original disease that appears during pregnancy and lactation is not the underlying disease. Rather, it is the difficulty of detecting the lesion during pregnancy and lactation, and the reluctance of patient and physician to make a diagnosis and initiate treatment. The greatest risk for neoplastic growth occurs in the first 20 weeks of pregnancy, when the immune system is suppressed, and growth of the mammary tissues is at its peak under the stimulus from estrogen, progesterone, and prolactin levels.<sup>167,223</sup> No data were provided on the influence of postmastectomy lactation on long-range survival. Some women have wanted to nurse with the remaining breast. The decision would necessitate consideration of the individual situation. It represents a different risk/benefit ratio than pregnancy itself. Extensive epidemiologic studies of large populations of women do not indicate that breastfeeding has any relationship to the overall risk for breast cancer. Epidemiologic data about breastfeeding on the remaining breast are not available.<sup>167</sup>

The incidence of cancer in the remaining breast has fueled the question of prophylactic contralateral mastectomy. The women who are at the greatest risk for cancer in the second breast are those who have a family history of breast cancer in their mother or sister, who have had onset in childbearing years, or whose original cancer involved multiple lesions in the primary breast. In their discussion of the other breast, Leis and Urban<sup>167</sup> state that if a postmastectomy patient were to become pregnant and deliver, "it would be rare indeed that the patient would allow or the attending physician would condone the use of the remaining breast for nursing." Although some women cherish the remaining breast, most, in the experience of Leis and Urban,<sup>167</sup> are ashamed of it and keep it hidden.

Lactation after primary radiation therapy for carcinoma of the breast was reported in a major literature search by Burns<sup>45</sup> to have occurred successfully in one patient, whose primary lesion was in the tail of Spence. One year after radiation, she became pregnant and successfully breastfed. She had less milk on the treated side. Her malignancy had not recurred. Another patient received radiotherapy after biopsy for an invasive duct carcinoma known to be present for a year. She had a week of boost therapy 8 weeks later. She became pregnant a year later, delivering a full-term infant 22 months after the original radiation. She successfully established lactation on the unininvolved side but was unable to obtain any response from the

irradiated breast. No comment was made about the radiated breast's response to pregnancy. She weaned her infant at 6 weeks.<sup>63</sup> Two years after treatment the patient had no evidence of recurrence.

The incidence of breast cancer diagnosed during pregnancy in a large series was 3 per 10,000 pregnancies, or 1% to 2% of breast cancer cases. Delay in diagnosis is the primary reason for the seemingly worse overall prognosis for breast cancer diagnosed during pregnancy and lactation, with the duration of symptoms averaging 5 to 15 months. The incidence of spread to the axilla is 70% to 80% in the perinatal period, compared with a 40% to 50% node-positive rate in nonpregnant women.<sup>116</sup>

Breast cancers continue to be reported in the literature during lactation. The case of a 33-year-old lactating woman presented with a 10-cm breast abscess.<sup>6</sup> Biopsy of the abscess wall was done following IV antibiotics and drainage of 300 mL of pus.<sup>6</sup> The woman had been treated with multiple rounds of antibiotics for mastitis, and then the abscess was diagnosed by ultrasound. After several months of antibiotics, she was referred for evaluation and treatment. Biopsy is standard treatment for abscesses in this surgical clinic. The biopsy revealed an adenosquamous carcinoma requiring surgery, chemo, and radiation. The authors recommend biopsy for all breast abscesses that require surgical drainage.<sup>6</sup> In another case, a 29-year-old women was lactating when a mass was noted in the right breast.<sup>218</sup> She was diagnosed with a granular cell tumor, which was difficult to diagnose and finally to surgically remove and treat. Breastfeeding had to be discontinued.

Any dominant mass during pregnancy or lactation should be evaluated promptly. Ultrasound is effective and safe during pregnancy and lactation. A fine-needle biopsy will distinguish cystic from solid lesions. A solid mass can be biopsied during pregnancy or lactation.<sup>226</sup> The risk for milk fistulas is very low. Suppression of lactation is not necessary. After the diagnosis of cancer is made, staging is essential before treatment is begun. Staging during pregnancy is more difficult because of the need for ionizing radiation.

Further surgery, including mastectomy, can be done during pregnancy and lactation. Because radiation and chemotherapy will also be necessary, breastfeeding is not recommended. When breast cancer is diagnosed during lactation, treatment should be initiated promptly and the infant weaned when chemotherapy is begun. Newer chemotherapy drugs have short half-lives so that it may only be necessary to pump and discard for 10 to 12 hours ( $5 \times$  half-life = clearance time). The half-life of the specific drug can be obtained on Lact-Med (see Chapter 12).

When young patients are treated with breast-conserving therapy and radiation for early-stage breast cancer, they may experience full-term pregnancies subsequently. Successful breastfeeding on the untreated breast as well as the treated breast is possible after conservative lumpectomy and radiation in some patients. The volume and the duration of lactation are less on the treated side. When the incision is circumareolar, successful lactation is less likely. Usually the function of the untreated breast is unaffected.<sup>113</sup>

Treatment with chemotherapy is changing as new protocols are developed. Mothers determined to breastfeed can indeed pump and discard for the required time and then resume breastfeeding. It takes a flexible infant for this schedule as well. Each chemotherapeutic agent is being evaluated for half-life and clearance time.

African-American women have a disproportionately high incidence of estrogen receptor-negative breast cancer, a subtype of unexplained etiology. A study by Palmer et al.<sup>208</sup> looked at parity and breastfeeding, in relationship to cancer. African-American women had more pregnancies and little or no breastfeeding. They stated that lactation might be an effective tool for reducing the occurrence of the subtypes of cancer that contribute disproportionately to breast cancer mortality.

## AUTOIMMUNE THROMBOCYTOPENIC PURPURA

Reports are conflicting regarding the passage of antibodies to platelets via the breast milk in mothers with autoimmune thrombocytopenic purpura.<sup>106,183</sup> Laboratory efforts to demonstrate absorption of these antibodies from the breast milk failed. One case report detailed the successful breastfeeding of a severely affected premature infant who had required exchange transfusion and multiple platelet transfusions at birth.<sup>175</sup> No relapses occurred with introduction of maternal milk at 5 days of age. Steroids were discontinued at 2 weeks, and the infant thrived at the breast.

## RHEUMATOID ARTHRITIS AND OTHER CONNECTIVE TISSUE DISORDERS

The influence of lactation on the development and progression of rheumatoid arthritis (RA) has been the subject of several epidemiologic studies. Previous observations noted an increased risk for RA developing postpartum, particularly after the first pregnancy. The contribution of hormonal factors occurring before onset of RA, such as age of menarche, parity, age at first birth, breastfeeding, use of oral contraceptives, irregular menstrual cycles, and postmenopausal hormone use, to the development

of RA was examined by Karlson et al.<sup>136</sup> in the 121,700 women enrolled in the Nurses' Health Study. RA was diagnosed in 674 women between 1976 and 2002, confirmed by connective disease screening questionnaire and blinded medical record review using the American College of Rheumatology criteria. Rheumatoid factor was positive in 60% of the patients. Using Cox proportional hazard risk models, a strong trend was found for a decreasing risk for RA with increasing duration of breastfeeding ( $p = 0.001$ ). Only irregular menses and onset of menses at less than 10 years were weakly associated with RA risk. Other parameters were not associated. The authors concluded that there was a dose-dependent protective effect of breastfeeding duration against RA.<sup>222</sup> Several additional series have shown similar results where rheumatoid arthritis onset was reduced or delayed with breastfeeding, and the effect was dose dependent. Long-term breastfeeding is associated with significant reduction in the risk of RA. This was shown in a population involving 121,700 women from the Nurses' Health Study, 7349 Chinese women in the Guangzhou Biobank Cohort Study, and 18,326 women linked to regional registers.<sup>1</sup> RA is two to four times more common in women, suggesting the protection of androgens. Protection from oral contraceptives has been suggested in some studies<sup>128</sup> and refuted in others.

A national cohort of 187 women who developed RA within 12 months of pregnancy was studied. Of the 88 women who developed the disease after their first pregnancy, 71 breastfed (81%), compared with only half of control mothers. A smaller risk was noted after the second pregnancy. No added risk with the third pregnancy was associated with breastfeeding. The increase in risk was highest in those women whose disease was erosive and rheumatoid factor positive. Other investigators, who reviewed a cohort of 176 women with RA who had at least one child and a mean age of 46 years at diagnosis, concluded that parity and, to a lesser degree, breastfeeding before RA onset worsened the prognosis for severe disease. Oral contraceptive use had a protective effect.<sup>128</sup>

The evidence regarding reproductive events as risk factors for RA is conflicting. A population-based study of 63,090 women, followed from 1961 to 1989, examined reproductive factors and mortality rates. The role of parity, age at first and last birth, or age at menarche and menopause showed no relationship to RA. A protective effect of lactation was noted, however, with total time of lactation associated with decreased mortality rate from RA with a dose-response relationship.<sup>42</sup>

Rheumatic disease may necessitate treatment of pregnant and lactating patients with disease-modifying active rheumatic disease drugs or

immunosuppressive drugs. Nonsteroidal antiinflammatory drugs (NSAIDs), in general, are passed into the milk in low doses. Shorter acting drugs are safer. The immediate postpartum period is usually associated with a flare up. Medications need to be selected carefully. The benefits of breastfeeding are significant for these infants. Safe drugs are short-acting NSAIDs, prednisone and prednisolone, antimalarials, and sulfasalazine. AZA and anti-TNF- $\alpha$  inhibitors are also safe. The newer small molecule UAK-inhibitors methotrexate and leflunomide are not recommended. Cyclosporine is not recommended as a therapy during breastfeeding.

Prolactin levels are greatly elevated during pregnancy in women with systemic lupus erythematosus.<sup>125</sup> Most patients with systemic lupus erythematosus have elevated prolactin levels, as do patients with RA, osteoarthritis, fibromyalgia, and polymyalgia. A dysregulation of pituitary response has been suggested as the etiology in RA. The role of prolactin in other autoimmune disorders is not understood, but supports the concept that a close relationship exists between neuroendocrine and immune systems.

If symptoms can be controlled with NSAIDs, such as acetaminophen, ibuprofen, hydroxychloroquine (Plaquenil), ketorolac, and piroxicam, which are all acceptable according to the American Academy of Pediatrics (AAP) list, treatment is not a problem during lactation. The use of corticosteroids (prednisone 120 mg/day) is considered safe. Injections of steroids into the joint, even the more potent triamcinolone, provide only low doses in the serum and can be tolerated for brief courses. The disease-modifying active rheumatic disease drugs, which include methotrexate, gold salts, and azathioprine, are critical to management. They cannot be delayed in a patient with a confirmed diagnosis and joint pain with an elevated sedimentation rate. They are toxic and breastfeeding is contraindicated. Gold salts, which differ from gold, have been found in milk and in a nursing infant.<sup>268</sup>

Postpartum flare of inflammatory polyarthritis may be induced by breastfeeding, according to a prospective study of over 100 women with RA.<sup>13</sup> The first-time breastfeeders had increased disease activity 6 months postpartum based on symptoms, joint counts, and C-reactive protein levels. Not all women had flares, and long-term implications were not investigated. It was less frequent and less severe in those who had breastfed previously. The authors relate it to prolonged, elevated levels of prolactin.<sup>25</sup>

Karlson et al. reported that women who breastfeed more than a total of 24 months reduce their risk for rheumatoid arthritis by 50%. This finding was part of a study of more than 120,000 women.<sup>136</sup>

Primary Sjögren syndrome, which involves the glands of secretion (sweat, salivary), is known to be associated with hyperprolactinemia. However, because of the characteristic abnormalities of secreting glands, lactation may not be successful.<sup>14</sup> Sjögren syndrome has also been seen in association with Raynaud phenomenon<sup>123</sup> (see later discussion). Breastfeeding is not contraindicated.

## HYPERTENSION AND CARDIOVASCULAR DISEASE

Hypertension is a major public health problem. Successful management of hypertension, however, is pharmacologic. Before one considers the drugs involved, it is appropriate to consider that lactation may present some therapeutic advantages. The high levels of prolactin may be physiologically soothing to the mother, and it has been shown in animals that females given high levels of prolactin respond with nesting and mothering behavior. The breast is also an organ of secretion, and a liter or so of fluid is produced per day. In dehydrated women, lactation continues while urine production diminishes. The appropriate use of low-dose diuretics may control hypertension, whereas high-dose thiazides can cause suppression of lactation. Chlorothiazide, hydrochlorothiazides, and chlorthalidone are minimally excreted in milk (see Chapter 11), as are spironolactone and its metabolite canrenone, according to single-dose kinetics.

Propranolol has been widely studied and is probably the safest of the beta blockers during lactation. This is due to its low level in milk compared with other beta blockers, which are weak bases with an average pKa of 9.2 to 9.5, predisposing them to appear in slightly acidic human milk. Methyldopa appears in low amounts in milk, but its direct action on the pituitary to suppress prolactin release presents a theoretic risk for suppressing milk production. An obstetrician should be aware of this potential if lactation is going poorly. Reserpine poses a recognized risk to infants during delivery and postpartum. Other drugs appropriate to hypertension management are discussed in Chapter 11.

Maternal risk for cardiovascular disease is reduced by breastfeeding during the reproductive years. Data from 139,681 postmenopausal women in the Women's Health Initiative were reviewed by Schwarz et al.<sup>233</sup> to determine the dose-response relationships between the cumulative number of months of lactation and disease. More than 12 months of breastfeeding provided a reduced risk for hypertension, diabetes, hyperlipidemia, and cardiovascular disease, which is now the leading cause of death for women in developed countries.

Never breastfeeding or limited breastfeeding has been correlated with increased incidence of

chronic disease, including hypertension. An observational cohort study of 55,636 parous women in the US Nurses' Health Study II was conducted by Steube et al.<sup>249</sup> Never breastfeeding, or curtailed breastfeeding, was associated with an increased risk of incident hypertension. Women who never breastfed were more likely to develop hypertension than those women who breastfed their first child at least 12 months.

Primary prevention of hypertension is a major public health priority.

Breastfeeding has been reported to affect the cardiovascular function of a woman, but some of the studies have been conflicting. Two separate studies examined the effects of breastfeeding on cardiovascular function. The first study<sup>185</sup> compared the pre-ejection period (PEP), heart rate, cardiac output (CO), and total peripheral resistance (TPR) in groups of breastfeeding women and bottle-feeding women. Breastfeeding women had higher cardiac output throughout the session. When the mothers fed their infants, both groups increased blood pressure and decreased heart rate. Blood pressure was increased more in the breastfeeding women. The authors reported that both arms of the study supported the theory that breastfeeding alters maternal cardiovascular function, possibly due to the action of oxytocin.<sup>252</sup>

Orthostatic reflex tachycardia is tachycardia, extreme weakness, and hypertension and is often associated with pregnancy and delivery. It tends to dissipate, but if it lasts more than 6 months it is referred to as postural orthostatic tachycardia syndrome. Provided the medications are compatible, breastfeeding is not contraindicated. Any condition that leads to worsening the tachycardia should be avoided, such as dehydration and other symptoms of fever, anxiety, or bleeding. Postural orthostatic tachycardia syndrome is difficult to diagnose accurately and difficult to treat. Treatment is symptomatic, chiefly with antihypertensives. Breastfeeding in a semireclined position (i.e., not totally flat or sitting at 90°) is helpful. Elastic stockings are essential.

## CARDIAC, LIVER, AND RENAL TRANSPLANTATION

The number and survival times of patients receiving heart transplants are increasing, as is their quality of life. In young recipients, childbearing becomes important. Teratogenicity has not been reported with traditional immunosuppressive agents, such as prednisone and azathioprine, or with cyclosporine. Osteoporosis prophylaxis is important in

pregnancy and lactation associated with chronic use of prednisone. A successful pregnancy after cardiac transplantation is reported with the birth of a normal infant who had normal growth and development for the 3 years of follow-up. The infant was not breastfed.<sup>141</sup>

Successful pregnancy after liver transplant has been reported in at least six patients.<sup>239</sup> Immunosuppression was maintained throughout pregnancy, and the infants were normal. Breastfeeding was not recommended because of the cyclosporine therapy.

Of infants born to mothers with renal transplants, 60% to 70% have uncomplicated neonatal courses. Thymic atrophy, leukopenia, anemia, thrombocytopenia, chromosome aberrations in lymphocytes, and certain abnormalities of the immune system have been seen.<sup>141</sup>

Breastfed infants of mothers with renal transplants have normal blood counts and show no increase in infection and above-average growth rates.<sup>151</sup> The immunosuppressants azathioprine, 6-mercaptopurine, and 6-methylprednisolone have been found in milk in very low levels. Cyclosporine, however, has been detected in breast milk at levels approximating maternal concentrations. The advice when cyclosporine is the drug has been not to breastfeed, with varying decisions about 6-mercaptopurine and azathioprine.

Pregnancy after renal transplant is relatively safe when renal function is adequate before conception and when maintenance immunosuppressive therapy is instituted. Most patients receive azathioprine and prednisone or methylprednisolone. When the actual levels of these compounds were studied in two patients, one of whom breastfed her infant,<sup>51</sup> measurements of IgA were also done because of the concept that immunosuppressed women might produce immunoincompetent milk.

The levels of 6-mercaptopurine in the milk averaged 3.4 ng/mL in one patient and 18 ng/mL in the other. The therapeutic level is 50 ng/mL, with the use of the normal daily dose. The levels of methylprednisolone in the milk (daily dose 6 mg) were at or below the levels measured in normal drug-free control subjects. The IgA determination in the milk was similar in both transplant and control mothers. The breastfed infant whose mother had a transplant had normal blood cell counts, no increase in infections, and an above-average growth rate.<sup>55</sup> Improved outcome of allogeneic bone marrow transplantation, due to breastfeeding-induced tolerance to maternal antigens, has been demonstrated by Aoyama et al.<sup>17</sup> Exposure of offspring to noninherited maternal antigens through breast milk reduced the graft-versus-host disease in the experimental model.

## BREASTFEEDING AND MATERNAL DONOR RENAL ALLOGRAFTS

With the advent of renal transplants, a new mode of investigation with the role of human milk in the host-graft relationship has developed.<sup>22</sup> Large numbers of living maternal lymphocytes are present in human milk. Campbell et al.<sup>48</sup> investigated the question of whether exposure of an infant to maternal lymphocytes during breastfeeding would affect the subsequent reactivity of a patient to a maternal donor-related renal transplant. They studied the posttransplant course of 55 patients with a primary maternal donor transplant, 27 of whom were breastfed and 28 of whom were not. The 1-year graft-function rate was 82% for those breastfed and 57% for the bottle-fed ( $p \leq 0.05$ ) infants. Five-year follow-up did not sustain the statistically significant difference. Paternal donor relationship in a small group of patients did not reveal significant difference.

The same group of investigators<sup>150</sup> reported that a history of breastfeeding was associated with improved results in a different patient population (HLA-semiidentical sibling donors). Breastfed patients in whom both donor and recipient were breastfed by the same mother showed dramatic improvements in graft-function rates, compared with nonbreastfed counterparts, at all intervals studied up to 9 years ( $p \leq 0.001$ ). The authors<sup>150</sup> concluded that the breastfeeding effect is not entirely specific for maternal antigens because transplantation was improved for both sibling donor and maternal donor. They consider a history of being breastfed an important variable in clinically related renal transplantation.

Because these studies used retrospective questionnaires, they did not take into account the length of time breastfeeding took place, which included all cases "ever breastfed." Although this is potentially important, studies of graft recipients' donors are another means of understanding more about the role of breast milk for humans.

In a study of renal transplants, 45 breastfed subjects with maternal donor transplants were compared with 43 bottle-fed subjects with maternal donor transplants and 62 subjects with paternal donor transplants.<sup>84</sup> No statistically significant differences were seen in graft survival between the groups. Length of breastfeeding was not stated.

Since women who have had transplants have been experiencing pregnancy in greater numbers, the number who have been breastfed has also increased from a rate of  $\pm 5\%$  of infants in 1994 to over 35% in 2012. Breastfeeding is recommended,

except in the rare situation that the immunosuppressive medications are contraindicated. Prednisone, AZA, CSA, and tacrolimus are acceptable. Infant blood levels can always be checked. On the other hand, sirolimus, everolimus, and belatacept (MPA product) are a concern, and there are no data to prove their safety.

## GLOMERULAR DISEASE AND LACTATION

A high percentage of pregnant patients show their first evidence of renal disease, probably not because pregnancy precipitates the disease, but because it is the first time these young women have had urinalysis and blood pressure studies. The series of glomerular disease in pregnancy published by Surian et al.<sup>253</sup> reported that, in most cases, the disease is not made worse by pregnancy. A disease with a poor prognosis such as membranoproliferative glomerulonephritis is neither worsened nor bettered by pregnancy. When the nonpregnant serum creatine and urea nitrogen levels exceed 3 mg/dL and 300 mg/dL, respectively, normal pregnancy is uncommon. Lupus nephropathy, however, has a poor prognosis in pregnancy, with considerable fetal loss and morbidity.<sup>55</sup> Eclampsia, however, increases the future risk of cardiovascular and renal disease.

Hypertension, as a complication, influences the obstetric complication rate and the fetal outcome. The infant may be premature, small for gestational age, or both. The option to breastfeed is a matter of the risk/benefit ratio.<sup>22</sup> It involves not only the medical status of the mother, but also that of the infant and the drugs that must be used to keep the mother stable. The obstetrician, nephrologist, and neonatologist must determine the appropriateness of breastfeeding on a case-by-case basis.

## OSTEOPOROSIS

Tremendous attention has been focused on osteoporosis in women, particularly following childbirth and lactation. Clearly the demands for calcium and phosphorus during the perinatal period are great, but they can be met by diet with any degree of attention. In addition to dairy products and other supplemented foods, such as orange juice, other sources of calcium exist (Box 16-2). Modern advertising in the wave of the calcium hysteria has suggested women take various medicinal forms of calcium. The incidence of calcium-containing renal calculi has increased as a result.

**BOX 16-2. Calcium Content of Foods (mg per serving)**

<b>100±</b>	<b>150±</b>	<b>200±</b>	<b>250±</b>
10 Brazil nuts	1 cup ice cream	1 cup beet greens	1 cup almonds
1 medium stalk broccoli	1 cup oysters	1 oz cheddar or Muenster cheese	1 oz Swiss or Parmesan cheese
1 cup instant Farina	1 cup cooked rhubarb		1 cup cooked collard greens
3 oz canned herring	3 oz canned salmon with bones		1 cup cooked dandelion greens
1 cup cooked kale	1 cup cooked spinach		4 oz self-rising flour
1 Tbsp blackstrap molasses	1 oz feta or mozzarella cheese		1 cup milk
3 Tbsp light (regular) molasses	½ cup cooked chopped collard greens		3 oz sardines
1 cup cooked navy beans			½ cup cooked ricotta cheese
3.5 oz soybean curd (tofu)			
3.5 oz sunflower seeds			
5 Tbsp maple syrup			
1 cup cottage cheese, regular or low fat			

Modified from Kleinman RE, editor: *Pediatric nutrition handbook*, ed 6, Elk Grove, Ill., 2009, American Academy of Pediatrics.

A syndrome of severe osteoporosis is associated with pregnancy and lactation. Three cases are reported by Gruber et al.<sup>99</sup> These young women had vertebral fractures and skeletal complications, but most of their studies were normal except for their bony structure. They had no osteomalacia, however. They apparently recovered after lactation ceased and had no residual high-turnover osteoporosis. This suggests an association with low calcium in the diet. A rare cause of postpartum low back pain was found to be due to pregnancy and lactation-associated osteoporosis after exclusion of other causes.<sup>259</sup>

Bone density changes during pregnancy and lactation in active women were followed in a longitudinal study by Drinkwater and Chesnut.<sup>71</sup> The variations at the femoral neck, radial shaft, tibia, and lumbar spine were attributed to mechanical stress of weight gain and changes in posture in pregnancy and lactation. Further studies have confirmed that lactation-associated bone-mineral mobilization does not require parathyroid hormone or parathyroid tissue.<sup>114</sup>

Extended lactation (70% or more of infant energy intake provided for 6 months or more) is associated with bone loss; however, evidence exists of return to baseline by 12 months.<sup>246</sup> Those who breastfed a month or less lost no bone mass. Age, diet, body size, and physical activity were not correlated in these healthy white women. A return to normal bone densities was observed 6 months after weaning. A systematic review of maternal bone health to determine the influence of pregnancy and lactation was undertaken. Osteoporosis is considered an important public health problem in postmenopausal women. There was no

consensus, despite controversial results regarding the protective effect that pregnancy has been considered to have on bone, especially if followed by lactation.<sup>227</sup>

### HYPOMAGNESEMIA CAUSED BY LACTATIONAL LOSSES

As magnesium sulfate is used more frequently in obstetrics, it is important to understand its action. Magnesium acts by competition with calcium either at the motor end plate or at the cell membrane. Myometrial contractility is inhibited when maternal serum levels of magnesium are 5 to 8 mg/dL. Deep tendon reflexes may be lost when levels rise to 9 to 13 mg/dL. At 14 mg/dL, respirations are depressed. Magnesium sulfate is excreted by the kidneys, and almost 90% is gone in the first 24 hours. Increases in magnesium result in hypocalcemia. Magnesium ions cross the placenta, rapidly increasing parallel to maternal levels. The half-life in the fetus or neonate may be as long as 40 hours, however.<sup>59</sup> An infant born to a woman on a magnesium drip may be hypotonic, requiring calcium therapy immediately.

When 10 preeclamptic patients received magnesium sulfate, 1 g/hour IV in the first 24 hours after delivery, magnesium levels in the breast milk were 64 mcg/mL, as compared to only 48 mcg/mL in untreated controls. Twenty-four hours after stopping the magnesium levels were 38 mcg/mL in the cases, and 32 mcg/mL in the controls. By 48 hours the levels were equal.<sup>40</sup> There is a normal concentrating mechanism for magnesium in the milk. Oral magnesium absorption is very poor, so

little would be absorbed from the milk. Studies of women taking over-the-counter laxatives containing magnesium showed no change in the stools of their breastfed infants.<sup>103</sup>

A case of hypomagnesemic tetany caused by excessive lactation was reported by Greenwald et al.<sup>98</sup> The 20-year-old patient had been fully nursing her own 3-month-old infant and contributing 50 oz per day to the local milk bank. She was hospitalized with painful muscle spasms of her hands and feet that improved slightly but did not clear with calcium (serum level 9.6 mg/dL). Serum magnesium levels were low (0.4 mEq/L).

Kamble and Ookalka<sup>131</sup> reported on a 24-year-old woman who was breastfeeding a 15-day-old full-term infant. She presented with the sudden onset of rapidly progressive weakness of all her limbs. She had successfully breastfed two previous children. Electrocardiogram showed "hypokalemia" and multiple ventricular premature beats. Serum magnesium was 0.5 mmol/L (normal 0.8 to 1.7 mmol/L); milk magnesium was 4.9 mmol/L (normal 1.6 mmol/L). Serum calcium was 2.8 mmol/L, phosphate 1.1 mmol/L, and parathyroid hormone normal. Urinary potassium was 36 mmol/L. After treatment with potassium and magnesium, the electrocardiogram and muscle tone returned to normal. This woman continued to breastfeed. She had three times the normal level of magnesium in her milk.

Lactational hypomagnesemia is well described in the bovine model.

## CROHN DISEASE AND ULCERATIVE COLITIS

Inflammatory bowel disease (IBD) includes both ulcerative colitis and Crohn disease. They are similar, involving inflammatory conditions of the luminal gastrointestinal tract. They differ in terms of the layer of the intestinal wall involved and the part of the intestinal tract involved (colitis only involves the colon). There is a genetic component. There is increased inflammatory response against the tissues of the gastrointestinal tract. A meta-analysis, systematically reviewing breastfeeding and the risk of IBD, showed that breastfeeding was protective against the diseases.<sup>146</sup>

The preferred treatments during pregnancy and lactation are sulfasalazine, 5-amino salicylates, and corticosteroids, which are considered safe during lactation as well as pregnancy. It is important to note that there is a case reported of early vitamin K deficiency bleeding in a neonate, associated with maternal Crohn disease. Possible repeat dosing of vitamin K is recommended if the infant is breastfed. Close monitoring in such cases is essential.<sup>204</sup>

Ulcerative colitis and Crohn disease (and recently rheumatoid arthritis) are treated with salazosulfapyridine (SASP). Because of the concern about exposing the fetus to sulfisoxazole at the end of pregnancy or during lactation (owing to the suggestion that sulfa drugs, even at low levels, predispose to kernicterus), this therapy has been discontinued in the third trimester. Recently, it was noted that sulfapyridine (SP), the main split product of SASP, has a low affinity for albumin-binding sites.

Esbjorner et al.<sup>78</sup> studied the binding capacities in both mothers and babies and found them low. They measured cord blood levels in the mothers of 11.5 mmol/L and in the infants of 20 mmol/L. Follow-up infant blood levels showed a clearance in 70 to 90 hours. Infants who were being breastfed did not increase their levels of SASP or SP. The milk/serum levels for SP were 0.4 to 0.6, and those for SASP were undetectable. Infant serum samples were 10% of maternal SP levels, and only one infant had detectable SASP. No children had complications of hyperbilirubinemia or kernicterus. All the infants were term infants without major complications. The authors<sup>67</sup> concluded that it is safe to continue the SASP throughout pregnancy and lactation in full-term infants. The effect on premature infants is under study. Prednisone therapy is usually safe because levels in milk are low.<sup>4</sup>

## Irritable Bowel Syndrome

Irritable bowel syndrome is recognized more frequently in modern medicine, and more women with the disease are achieving pregnancy. It affects young women more commonly. It is characterized by chronic abdominal pain and altered bowel habits without obvious organic cause. It is the most common gastrointestinal disease. The pain is persistent, crampy, and relieved by defecation. The patient alternates between constipation and diarrhea. Patients also have GERD, dyspepsia, and nausea. All symptoms are made worse with stress. Treatment is nonspecific and symptomatic and is made better when the physician is sympathetic and understanding. Dietary changes can be effective. Medications are needed only by a few patients. Low-dose antispasmodics in the belladonna family, such as hyoscyamine, are sometimes used, causing drying of secretions, constipation, and dilated pupils. They are excreted into milk in only trace amounts. The drug should be safe for the infant if it is taken after breastfeeding and breastfeeding does not begin again until 2 hours after dosing. Chronic use can decrease milk supply, just as it decreases production in the other secreting glands (dry mouth and decreased sweat). The diarrhea and

constipation can be mitigated with drugs that act directly on the gut and are not absorbed.

## EPILEPSY

A history of epilepsy in a mother is of concern for an obstetrician during pregnancy, and much has been written on the topic. Seizures in pregnancy are more dangerous to the fetus than the medication is. Antiepileptic drugs (AEDs) include phenobarbital, primidone, phenytoin, carbamazepine, ethosuximide, valproic acid, diazepam, and topiramate (Topamax). The concern regarding lactation includes the effect of the disease on the fetus in terms of major and minor malformations, the level of drugs in the infant's serum at birth, and the state of the mother postpartum. Breastfeeding may provide a means of gradually withdrawing the infant from maternal medication and avoiding the syndrome of withdrawal (i.e., hyperirritability, tremor, vomiting, poor sucking, hyperventilation, sleep disturbances). A good mother-infant relationship is important for a mother with epilepsy. Brodie<sup>41</sup> recommends alternating the breast with an occasional bottle (once per day or more) if the infant is sedated by maternal medication to reduce the effect and dilute the blood levels.

**Table 16-11** lists the half-lives of various AEDs. These compounds have a sedating effect and may prevent the infant from suckling adequately in the first few days. Attention must be paid to the infant's behavior to avoid not only under nutrition, but also failure to provide sufficient stimulus to the breast. The infant may need some supplementation and the mother some stimulus with an electric pump, carefully coordinated with support.

Whether an infant is breastfed or bottle fed, it is necessary to establish that the mother will remain seizure free and be able to care for the infant. Kaneko et al.<sup>133</sup> studied 42 infants of 32 epileptic mothers for harmful side effects of AEDs while breastfeeding. The duration of poor sucking was correlated with the drug and the levels. The poor

weight gain of the mixed-fed infants (breast/bottle) was associated with vomiting and infant drowsiness during feeding. These authors recommend mixing feedings (breastfeeding and formula) early postpartum to reduce the medication to the infant until levels in infant serum taper a little and the infant's metabolism increases to promote drug clearance. Full breastfeeding can then proceed if care has been taken to establish a good milk supply with supplementary pumping.

Topiramate is used most frequently with much success in the treatment of seizures. It is excreted in breast milk, which is not surprising as it is of low molecular weight, minimal protein binding (15%), and prolonged plasma elimination. In three mother/baby dyads, who were breastfeeding and were tested at 3 months, the weight adjusted doses for the infants were 0.1 to 0.7 mg/kg/day or 3% to 23% of the maternal dose.<sup>40</sup> No adverse effects were detected at 3 months of age. Breastfed infants whose mothers are taking topiramate should be closely monitored for alertness, changes in behavior, or diminished feeds due to sleepiness.

## NEUROPATHIES ASSOCIATED WITH BREASTFEEDING/NUMBNESS AND TINGLING OF THE ARM

A number of neurologic symptoms have been described in association with lactation. During periods of engorgement, pressure on nerves in the axilla, especially from an engorged tail of Spence (see [Chapter 2](#)), has caused numbness and tingling down the arms on the flexor surface to the ulnar distribution of the hands, similar to crutch palsy. The numbness and tingling usually abate as soon as the infant nurses and then gradually return as the breast fills again. Symptoms gradually disappear after several weeks, as engorgement disappears.

**TABLE 16-11** Pharmacokinetic Data on Antiepileptic Drugs (AEDs) in Newborns

AED	Free Fraction (% Unbound)	Volume Distribution (L/kg)	Half-Life (h)	AAP Rating	Hale Rating
Phenobarbital	57-72	0.6-1.5	40-500	5	L3
Primidone	?	?	7-60	5	L3
Phenytoin	15-30	0.7-2.0	15-105	6	L2
Carbamazepine	?	1.1-2.6	8-28	6	L2
Ethosuximide	?	?	40	6	L4
Valproic acid	~15	0.2-0.4	14-88	6	L2
Diazepam	~14	1.8-2.1	40-400	4	L3
Topiramate	85	0.7	18-24	Not rated	L3

## TENNIS ELBOW WITH HAND PUMPING

Symptoms similar to those associated with tennis elbow—pain and tingling with flexion of the forearm—have developed in nursing women who are pumping milk with a Kaneson-style hand pump.<sup>271</sup> Similar symptoms have been experienced by mothers just holding a newborn over time, especially primiparas and especially heavy infants.

Carpal tunnel syndrome has been described in pregnancy, causing paresthesia of the hands. Two cases were reported by Yagnik,<sup>275</sup> in which symptoms developed 1 month postpartum in breastfeeding women. The diagnosis was confirmed by electromyography and nerve conduction studies. The second case was bilateral. Symptoms disappeared after the infants were weaned. Five other cases are described in the literature: all the women were breastfeeding, all showed improvement with temporary suspension of breastfeeding, and all recovered completely within a month of complete weaning.<sup>243</sup>

A retrospective study of 27 women who had developed carpal tunnel syndrome postpartum was carried out by mail.<sup>266,267</sup> The women affected were older (mean age 31.5 years) and were primiparous, and 24 of 27 were breastfeeding. The three women who were bottle-feeding had less severe symptoms that cleared in less than 1 month. Symptoms (predominantly paresthesias, clumsiness, and pain) began at a mean of 3.5 weeks postpartum and lasted 6.5 months. Resolution began after 2 weeks of beginning to wean. Two women required surgical intervention. All were symptom free within a year.<sup>266</sup> The recommended treatment for carpal tunnel syndrome is conservative, with rest, diuretics, hand splint, and local corticosteroid injection, because it is usually reversible. No woman had residual signs or symptoms, so perseverance with lactation and symptomatic treatment is appropriate.

## RAYNAUD PHENOMENON

Raynaud phenomenon was first described by Maurice Raynaud in 1862 as episodic digital ischemia provoked by cold and emotion. The true cause remains obscure, despite elaborate efforts to identify it. It is widely thought to be a cutaneous manifestation of a generalized vascular disorder, often associated, in complex cases, with scleroderma and vasoconstriction of the kidneys, heart, and lungs. Patients with Raynaud phenomenon have significantly more migraine headaches. The basic research on the subject does not mention vasospasm of the nipples. The digital vessels of patients are more sensitive to the cold. Not all vasospasm is Raynaud phenomenon and is limited to individuals with other signs and symptoms compatible with the diagnosis.<sup>273</sup>

Five cases of Raynaud phenomenon of the nipple are described in the literature as severe blanching and debilitating pain.<sup>163</sup> Several women had white, blue, and red color changes, but only of the nipple. All were treated with nifedipine (10 mg three times per day or 30 mg by slow-release tablet). Nifedipine (Adalat, Procardia) is an antihypertensive calcium channel blocker. It does pass into the milk and is estimated to provide about 7.0 mg/kg/day (5%) of the pediatric dose. The AAP rates nifedipine a category 6 and Hale rates it an L2, which are equivalent, suggesting it is safe during lactation (see Table 19-18). All the women responded with a decrease or obliteration of the painful blanching. Oral bioavailability is only 50%, which reduces the risk to the breast-feeding infant.

The clinical parameters used to diagnose this disease are important.<sup>75</sup> Some history or other evidence of Raynaud phenomenon is essential when associating it with nipple blanching.<sup>273</sup> The patient should have some history of sensitivity to cold. Hands and feet are common sites of blanching and pain.<sup>26</sup> It is questionable that it is Raynaud's of the nipples, unless it occurs elsewhere, associated with cold. Before prescribing a medication, the other therapeutic first options should be initiated.<sup>162</sup> Discontinuing smoking or avoiding secondhand smoke is imperative. Steady ambient temperature and warm clothing are important. Adding fish oil to the diet has helped some patients, as has evening primrose oil, which is a rich source of essential polyunsaturated fatty acid, especially  $\gamma$ -linoleic acid.<sup>13</sup> Evening primrose oil has been used effectively in patients with mastalgia of unknown origin.

Peripheral tissue ischemia in neonates has been treated with topical nitroglycerin ointment, which is well absorbed through intact skin. Effects are usually seen within 30 to 60 minutes and last 6 to 8 hours. Because of the risk for hypotension, constant observation is necessary. Although this is theoretically an effective therapy for blanched nipples, no studies report on its safety. No data are available on its secondary effect on the infant, who would receive it through the milk or directly from the nipple. When mothers ingest nitrates, which have a short half-life, little is found in the milk and it is rapidly cleared from serum. Other medications that have been used for Raynaud phenomenon include angiotensin-converting enzyme inhibitors (e.g., captopril, enalapril) and prostaglandins for severe prolonged attacks.

## Restless Leg Syndrome/Willis-Ekbom Disease

Restless leg syndrome (RLS), or Willis-Ekbom disease, is common in pregnancy and lactation. It is estimated to involve one in five pregnant women

in Western countries. Little appears in the medical literature about occurrence in pregnancy and lactation, although it is reported in other individuals. An international study group for RLS was formed to develop guidelines. Twelve consensus questions were developed to explore the world literature and the following recommendations were made. It is known to be associated with iron deficiency and prolonged immobility (in a car, plane, etc.). It is suspected to be related to caffeine, tobacco, alcohol, hypoxia, sleep apnea, sleep deprivation, medications such as antiemetics, antipsychotics, and sedating antihistamines.

Symptoms are the irresistible urge to move legs constantly, brief relief by moving legs, and family history of the disease and peak activity in the third trimester. The first treatment should be non-medicinal. Check hematocrit, RBCs, and iron levels, and eliminate caffeine, alcohol, and medications. Initiate exercise and leg massage. If symptoms continue, reassess and try medication. Low-dose clonazepam or levodopa are safest in both pregnancy and lactation.

## SMOKING

The number of women who breastfeed and smoke varies from 5% to 20% of breastfeeding women. Mothers who smoke choose bottle-feeding more frequently than women who do not smoke. Of those smokers who are breastfeeding on discharge from the hospital, more have discontinued breastfeeding by 6 weeks than those who do not smoke.

Smoking behavior patterns prenatally, during pregnancy, and postpartum, as studied by O'Campo et al.,<sup>202</sup> show that 41% of women quit during pregnancy, with the highest rate of quitters being older, better educated, and white. Among black women, only the intention to breastfeed affected behavior. Early postpartum relapse rates differed by ethnicity, with formula feeding being the strongest predictor. Clinicians may be able to assist women in their resolve to quit, as well as to breastfeed, by providing strong support at the critical time in the early postpartum period.

Tobacco-exposed newborns<sup>161</sup> were more excitable and hypertonic, required more handling, and showed more stress and signs of abstinence, not only neurologically but gastrointestinally and visually, than unexposed infants. In this study, none were breastfed, but often breastfeeding relieves abstinence. Heavy smoking (i.e., a pack or more per day) resulted in similar findings with increased irritability, increased muscle tone, and later behavioral dysregulation in a large community study.<sup>251</sup> How breastfeeding from a mother who smokes affects the infant was evaluated by Mennella

et al.<sup>181</sup> They tested 15 mother/baby dyads in which the mother smoked, but not in the presence of the infant, and then breastfed on demand for the following 3.5 hours. They monitored infant behavior and nicotine in milk. "Smoked" infants took the same amount of milk as controls, in spite of taste, but spent more time awake and less sleeping (both active and quiet sleep). The infants were between 2.3 and 6.7 months and had been having milk with an unpleasant taste. The association between breastfeeding duration and maternal smoking, before, during, and after pregnancy, was measured with data from the Oregon Pregnancy Risk Assessment Monitoring System. At 10 weeks postpartum, 25.7% of mothers who initiated breastfeeding had already stopped. Mothers who had quit smoking or quit and relapsed had the same breastfeeding rates as nonsmokers. Those who smoked more than 10 cigarettes per day were 2.2 to 2.4 times more likely to wean before 10 weeks.

The active components of cigarette smoke, nicotine and carbon monoxide, have been implicated in the birth weight reduction seen in infants of mothers who are heavy smokers. Nicotine has acetylcholine-like actions on the central nervous system, skeletal muscle, and upper sympathetic and parasympathetic ganglia. Nicotine initially stimulates and then depresses. Nicotine has been shown to interfere with the let-down reflex, but it does not appear to disrupt lactation once it has been initiated. Smoking has been associated with a poor milk supply. It has been reported that women who smoke 10 to 20 cigarettes per day have 0.4 to 0.5 mg of nicotine/L in their milk. Calculations indicate this is equivalent to a dose of 6 to 7.5 mg of nicotine in an adult. In an adult, 4 mg of nicotine has produced symptoms, and the lethal dosage is in the range of 40 to 60 mg for adults. On the basis of gradual intake in a day's time, the neonate would metabolize it in the liver and excrete the chemical through the kidney.

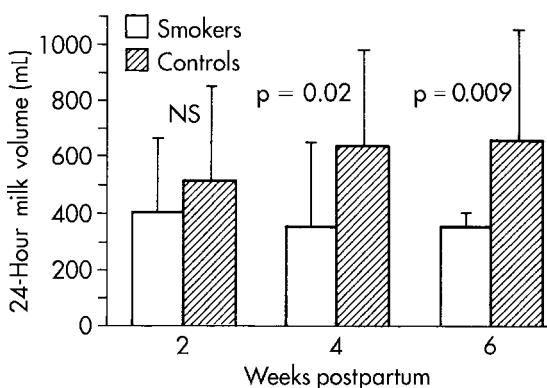

Multiple studies of nicotine and cotinine concentrations in nursing mothers and their infants have confirmed that although bottle-fed infants born to smoking mothers and raised in a smoking environment have significant levels of nicotine and metabolites in their urine, breastfed infants whose mothers smoke have higher levels.<sup>157,170</sup> A direct correlation exists between the mother's plasma level and the amount in the milk, but not with the amount in the infant's urine in a study of smokers.<sup>157,232</sup> When the infant was removed from the environment and secondhand smoke, the correlation between milk and infant urine levels was high. The half-life of nicotine in the milk is 95 minutes. Nicotine levels were higher in milk than in maternal serum because maternal serum is basic and milk is acidic.

Somatostatin levels in plasma in smoking breastfeeding women were significantly higher at onset of lactation on day 4 postpartum and throughout lactation. Somatostatin is a widely distributed peptide with multiple hormonal and neurogenic actions. It inhibits the release of prolactin; it inhibits GI functions; and its presence in milk suggests it may be produced by the mammary gland. That milk yield is significantly decreased in smoking women was demonstrated by deuterium-dilution methods.

Similar results were reported in the mothers of premature infants initiating lactation by pump in a carefully controlled study by Hopkinson et al.<sup>117</sup> Smokers weaned their babies more quickly than nonsmokers. The heavy smokers had the lowest prolactin levels and weaned earliest.

The effect of maternal smoking on the infant includes decreased growth (Figure 16-11). Weight increase of infants of smokers was  $340 \pm 170$  g, compared with  $550 \pm 130$  g in control subjects over 14 days. In a comparison group of breastfeeders, Schulte-Hobein et al.<sup>232</sup> reported no significant weight difference when the infants were 1 year old. Gross motor and mental development were also no different. A group of infants followed from the sixth month of pregnancy through 1 year of age included breastfed infants of 74 smokers, breastfed infants of 195 nonsmokers, and bottle-fed infants of 64 smokers. Every 10 cigarettes smoked while breastfeeding was related to an additional 3% infant body mass at 1 year of age. This group of infants whose mothers smoked paradoxically had significantly higher body mass and were heavier than those of nonsmokers.<sup>169</sup>

Children of smokers had more respiratory illnesses in the first year and had been weaned sooner.<sup>102</sup> In a matched-pair group of 28 smokers and 28 nonsmokers, the smokers weaned at 4.5 months and the nonsmokers at 6.7 months.

**Figure 16-11.** Milk production of smokers. From Hopkinson JM, Schanler RJ, Fraley JK, et al: Milk production by mothers of premature infants: influence of cigarette smoking, *Pediatrics* 90:934, 1992.

The infants of smokers required treatment for respiratory infection with antibiotics 38 times and the infants of nonsmokers 19 times. The relationship to colic in infants breastfed by a smoker is significant.<sup>225</sup> Forty percent of infants breastfed by smokers (five cigarettes/day or more) had infantile colic, defined as 2 to 3 hours per day of excessive crying, compared with 26% of those breastfed by nonsmokers, according to Matheson and Rivrud<sup>177</sup> ( $p < 0.005$ ). This observation has been made for bottle-fed infants with one or more smokers in the home.

Sleep/wake patterning in infants of smoking mothers was altered by smoking. The infants were studied by Mennella and colleagues<sup>181</sup> and observed to spend significantly less time sleeping after mother had smoked. The milk was shown to taste unpleasant, but it did not change their total milk intake. The smoking made the infants wakeful.

Sudden infant death syndrome (SIDS) is more common in infants of smokers. Breastfed infants of smokers have a SIDS rate equal to that of bottle-fed infants of nonsmokers. Infants of smokers have more respiratory disease, as do infants exposed to passive smoke. This effect is improved if the infant is breastfed.

Many women who want to stop smoking have tried nicotine gum.<sup>168</sup> Its safety in lactation has not been determined. Levels of nicotine in mothers and the physiologic effect on their fetuses have been measured by Doppler effect in Sweden. Nicotine gum exposes the child only to nicotine and its metabolites and not to the other effects of smoking, including thiocyanate and carbon monoxide. The Swedish Nicorette chewing gum, containing 4 mg nicotine, was compared with one cigarette (high dose provides 1.6 mg). The gum did not appear to affect the fetus. Maternal plasma levels after a high-dose cigarette are double the levels after the gum or a low-dose cigarette. Nicorette gum in the United States contains 2 mg nicotine, which produces a plasma level of 11.8 ng/mL (Box 16-3).

The nicotine patch provides nicotine transdermally continuously while worn (it is recommended that it be removed while sleeping). The estimated rate of release of nicotine depends on the total dose in the patch, the number of layers, and the size of the patch (skin contact area). Up to 114 mg nicotine may be in a patch with a delivery rate of 21 to 22 mg/hour. Lower doses (7 mg/24 hour) can be prescribed. The serum level will vary accordingly.

In counseling a nursing mother who smokes, consideration should be given to the data, which suggest that mothers should not smoke while nursing or in the infant's presence. If it is not possible to stop, they should cut down and also consider low-nicotine cigarettes. Feedings should be delayed as long as possible after smoking.

**BOX 16-3 Available Nicotine in Tobacco Products and Nicotine Therapies**

Tobacco Products	Nicotine Treatments
<b>Smoking Tobacco</b>	
1-g cigarette contains ~1.5% nicotine, or 13-19 mg per cigarette	
Cigar 15-40 mg	
Cigarette butt 5-7 mg per butt	
<b>Snuff</b>	
1.5% nicotine	
Snuff contains about 30 g, of which 1.5% is nicotine, or total of 45 mg	
Dry snuff inhaled	
Wet snuff more alkaline and absorbed more readily, reaching plasma levels of cigarette smoking in 10 minutes	
<b>Chewing Tobacco</b>	
2.5-8% nicotine	
Sweeter in taste than smoking tobacco	
"Chaw" 7.8 mg nicotine per gram of tobacco	
8-10 "chaws" equivalent to smoking 30-40 cigarettes	
<b>Nicotine Gum</b>	
Nicotine polacrilex, Nicorette	
Contains 2 mg nicotine per piece in United States or 4 mg per piece in Canada and Europe	
Buffered to pH of 8.5 for enhanced absorption	
Nicotine rapidly and completely absorbed through oral mucosa	
30 minutes of chewing releases 90% of nicotine	
1 hour of chewing 2-mg piece produces 11.8 ng/mL and 4-mg piece 23.2 ng/mL nicotine plasma concentrations	
Gum must be chewed to release nicotine	
<b>Nicotine Transdermal Systems</b>	
Usually in three doses	
Provide 21, 14, and 7 mg of nicotine in 16-24 hours	
Provide average plasma nicotine concentrations of 17, 12, and 6 ng/mL, respectively (smoking provides 20-50 ng/mL)	
21 mg per 24 hours, equivalent to smoking for 15 hours	
Elimination half-life of transdermally absorbed nicotine 3-6 hours	

Bupropion (Wellbutrin) has been used in smoking cessation programs. A trade name product, Zyban, is marketed for this purpose. Bupropion is an antidepressant drug, unrelated to the tricyclics. It has a large volume of distribution and is highly protein bound, which may explain why it is not detected in three out of four breastfed infants. Experience has not revealed any problems with breastfeeding and bupropion.

Because some vegetables contain measurable amounts of nicotine (but not cotinine), they should be avoided as well. Highest levels are found in eggplant, green and pureed tomatoes, and cauliflower. Ten grams of eggplant provides 1 mg of nicotine, the same amount obtained in 3 hours in a room with minimal tobacco smoke.<sup>69</sup>

### Clove Cigarettes

Clove cigarettes contain 60% to 70% tobacco and 30% to 40% clove. Exposure to tar, nicotine, and carbon monoxide is twice that from regular cigarettes. Eugenol, the major active ingredient, is used as a topical dental anesthetic. It is more toxic in smoke than by ingestion.

### Marijuana

If the mother smokes marijuana, an entirely different risk is created. Animal studies have shown that structural changes occur in the brain cells of newborn

animals nursed by mothers whose milk contained cannabis. Nahas<sup>194</sup> and Nahas et al.<sup>195</sup> describe impairment of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) formation and of proteins essential for proper growth and development. Results seen in some humans suggest that serious and long-lasting effects can occur. Impairment of judgment and behavioral changes may interfere with an individual's ability to care for the infant or adequately<sup>126</sup> breastfeed. If the mother smokes while nursing, the infant not only ingests the drug in her milk but also inhales the effect of the smoke from the environment. Because brain cell development is still taking place in the first year of life, any remote chance that DNA and RNA metabolism is altered should be viewed with concern. Cannabis use in pregnancy and lactation increases the risk to the fetus/infant of neurodevelopmental and behavioral problems, especially executive function in later life.<sup>126</sup>

## THE MOTHER WHO REQUIRES HOSPITALIZATION

### Emergency Admission

The mother who suddenly develops an emergency condition that requires hospitalization presents a unique problem in management. The emergency condition must be dealt with appropriately, whether medically, surgically, or psychiatrically. It is equally important in all three situations to deal with the patient as a lactating mother. Failure to do

so may have an impact on the successful outcome of the primary condition.

**Medical Admission.** Medical problems such as acute infection or metabolic disturbances should be analyzed in relationship to lactation, to the infant, and to any other children at home. Is it contagious? In the case of lactation, will the drugs pass into the breast milk? If so, are there alternative treatments? What is the prognosis for recovery? Is the recovery phase more or less than 2 weeks, and is maintaining lactation realistic? This decision should not be made without an understanding of the mother's commitment to further breastfeeding. If the prognosis is poor for recovery, or the drugs involved are contraindicated for the infant but necessary for the mother, provision should be made for the mother's adjustment. Abrupt cessation of lactation can cause a fever and a flulike syndrome, which will confuse the management picture. It may be advisable to include the mother's obstetrician or pediatrician in the discussion to provide the mother with the necessary support to accept alternatives (see Chapter 11).

For instance, the management of asthma during pregnancy or lactation must consider the risk for drugs to the infant. Inhaled  $\beta_2$ -agonist medication (metaproterenol, terbutaline, albuterol) by metered dose delivers the least drug to the infant. Steroid therapy may be dramatic in the acute disease. The breast milk levels are minimal and will drop slowly, providing a weaning mechanism from the drug. Theophylline, as with caffeine, can cause irritability and wakefulness in the infant and is no longer considered the primary treatment. The approach is initially focused to decrease the inflammation and not the spasm. Therapy need not interfere with breastfeeding in most cases.

**Surgical Admission.** As with any surgical procedure, communication must occur among the surgeon(s), anesthesiologist, other consultants, and the primary care physician to establish the process for breastfeeding when a lactating woman is the patient. Surgical emergencies such as trauma, appendicitis, or cholecystitis<sup>19</sup> require immediate attention, including anesthesia and surgery.

Breast biopsy during pregnancy and lactation represents special challenges to the surgeon and pathologist. The risk for milk fistula and infection is increased, although no published data are available. The risk is low in peripheral biopsies and high in central biopsies involving the areola. In 105 benign biopsies, 71% of patients had conditions similar to nonpregnant, nonlactating women. Those lesions peculiar to pregnancy and lactation, in decreasing order of frequency, are fibroadenoma, lipoma, papilloma, fibrocystic disease, galactocele, and inflammation. Localized breast infarcts also occur either from overgrowth of preexisting

fibroadenoma or spontaneously. The risk for cancer diagnosis in one series was 22% of breastfeeding women, compared with 19% of nonpregnant, nonlactating women overall. Most lumps were preexisting, but growth rate was accelerated by pregnancy.<sup>212</sup>

Thiopental sodium (thiopentone) as an induction agent was studied in lactating women. One group had had cesarean deliveries, and the other group had been fully lactating for at least 2 weeks and were to have elective surgery.<sup>12</sup> The dosage of thiopentone was 5 mg/kg for the first group and 5.4 mg/kg for the second. The maximum concentrations in colostrum were  $1.3 \pm 0.5$  mmol/L and  $3.4 \pm 0.68$  mmol/L in the mature milk, which were lower levels than those in the maternal serum ( $2.21 \pm 0.31$  and  $7.09 \pm 1.4$ , respectively). The maximum dose of drug in 100 mL mature milk was calculated to be 0.090 mg and in colostrum 0.034 mg. No effect was anticipated or seen in the fully breastfeeding infants.

In the immediate postpartum period, tubal ligation may be performed on a multiparous woman. This type of procedure requires anesthesia and a brief interruption of mother-infant contact. The choice of anesthetic is important. Specific information is slowly accumulating regarding actual milk levels and infant responses. The highest morphine levels were reached 30 minutes after the IV, intramuscular, or epidural doses, and were slightly higher than the maternal plasma levels at all points. Some specimens were pumped from lactating patients having tubal ligations in the immediate postpartum period.<sup>79</sup> The peak dose was estimated at 500 ng/mL in the milk. Because of the low oral bioavailability of morphine in the breastfed infant, the drug is of minimal risk.<sup>34,79</sup>

Alfentanil has been measured in colostrum of nonlactating but postpartum women having tubal ligations postpartum. When the women were in the operating room before medication, both breasts were pumped with an electric pump for 10 minutes.<sup>12</sup> The women received diazepam, d-tubocurarine, succinylcholine, and thiopental sodium. Mothers were maintained on mechanical ventilation for the procedure. Then 50 mg/kg alfentanil was given intravenously with additional 10-mg/kg doses as needed for control. Four hours after the last injection of alfentanil, colostrum was collected from the right breast and at 28 hours from the left breast. The mean level at 4 hours was 0.88 ng/mL and 0.05 ng/mL at 28 hours. The drug cleared the colostrum rapidly.<sup>92</sup>

Interpleural bupivacaine in the seventh right interspace, 10 cm from the spinous process, was given for operative and postoperative pain to a woman for biliary surgery. She was breastfeeding a 10-month-old infant four times per day.<sup>23</sup> The dosage of bupivacaine was 0.13 mL/kg/hour. Peak

maternal serum level was 1.6 mg/mL at 47 hours. The drug was undetectable in the infant's blood; maximum milk levels occurred immediately post-operatively. Despite numbness of the right nipple, breastfeeding continued uninterrupted, except for time in the operating room. The numbness would suggest that the pain fibers are from the thoracic spinal nerves, and the suckling sensory nerve fibers from the median branches of the intercostal nerves.

Major surgical trauma has a rapid, profound, and long-lasting effect on gonadal activity and less effect on adrenal activity. Prolactin levels rise significantly and return to baseline slowly. Initiating lactation postoperatively may be influenced by hormonal changes and the effects of pain.

With self-limited trauma or disease with a short postoperative course, as in appendicitis, the mother can go back to breastfeeding on her return home. If the hospitalization will be more prolonged, as in trauma with immobilizing fractures, different considerations are important. The infant can be brought to the hospital several times per day for nursing. Unless the mother is mobile enough to provide some of the infant's bedside care, rooming-in is too taxing to a recovering patient. It is also stressful to other patients and staff who are not equipped for neonates. The mother would require a single room. If she has provision for her own nursing care, or if the nursing staff is agreeable, an arrangement could be worked out. The only contraindication would be whether it would interfere with recovery.

When bone healing is important, attention should be given to the dietary demands of bone healing and lactation, especially in calcium, phosphorus, and vitamin intakes. Working in concert with the orthopedic surgeon regarding breastfeeding and bone metabolism is key. If the mother is to be cared for but immobilized at home, breastfeeding is easier, but provision for ample assistance is mandatory. The need for assistance does not differ for the breastfed or bottle-fed infant of the same age. Home care services are available in most communities.

Cosmetic breast augmentation (breast implants) is one of the most common surgical procedures worldwide especially in high income countries in recent decades. Potential for breastfeeding had not been explored until Schiff et al.<sup>230</sup> undertook a systematic review of multiple databases. A few small studies met criteria. There was no significant difference in attempted breastfeeding with and without augmentation. Among women who breastfed, there was a reduced likelihood of exclusive breastfeeding among those with implants. In an earlier study<sup>250</sup> those women with periareolar incisions had trouble breastfeeding, especially regarding milk insufficiency, compared to mothers with

more distal incisions. The need for implants when breast tissue is meager may be the real reason for insufficient milk supply.

## **Psychiatric Admission**

The onset of a psychiatric crisis in a lactating mother rarely occurs unless the mother has already been identified as having a psychiatric problem. Childbirth has an established etiologic role in postpartum psychosis. A report in the literature, however, details a case of mania precipitated in a mother each time she weaned her children from the breast, but at no other time. We had treated a patient with a known psychiatric disorder who decompensated during pregnancy, did well during lactation, and had difficulty after weaning. With her fourth child, she weaned abruptly at 3 months and committed suicide 2 weeks later.

Breastfeeding itself does not cause psychosis. Women with a postpartum psychosis have acutely decompensated when they wean abruptly. Thus the management of weaning is an important part of the mother's treatment, and the process should be orchestrated by a psychiatrist and not the pediatrician, obstetrician, or the lactation consultant.

As the number of women who breastfeed increases, understanding of the relationship of these physiologic events to psychiatric disease will increase.<sup>164</sup> The role of the mother in lactation will be a part of her psychiatric care, and the decision to breastfeed or not should be worked out with her psychiatrist. Most psychiatric wards can accommodate young infants whether they are breastfed or bottle fed, so it is less of a novelty than on medical or surgical wards. The management of postpartum psychosis includes the concerns of the mother caring for the infant as part of recovery. The drugs used when the mother is nursing should be appropriate for both mother and nursing infant. See later discussion on psychologic problems while breastfeeding.

## **Elective Admission**

At times a lactating mother may have to plan for hospitalization. The urgency will be determined by the underlying disease. If the admission date can be made for more than a month away, there is time for gradual weaning of the infant, if necessary. If weaning is appropriate or necessary, the impact will largely be determined by the age of the infant. A very young infant who would profit greatly by continued breastfeeding is one type of problem. If the infant is 1 year old, it may be less traumatic for the child to be weaned when the separation is going to be greater than 48 to 72 hours. A child who is also receiving solids and some other

liquids from a cup can be sustained during the separation without much more than sadness. If the caregiver and the surroundings are familiar, the support of this infant is easier. For the mother of the older child, the impact of forced separation during hospitalization is also manageable and less likely to produce "milk fever."

A young infant can be sustained by cup feedings, bottle-feedings, or "cross-nursing" by another lactating mother until the infant can be breastfed by the mother again. The mother, in the first few months of lactation, will have more problems with engorgement, discomfort, and even malaise. Provision should be made to express or pump milk to maintain the supply if the mother will be nursing again or for comfort if lactation is to be discontinued. Milk can be collected in sterile bottles and sent home for the infant. When the admission is elective, plans can be made in advance to have a pump available, renting one if the hospital is not equipped. Methods for collecting, refrigerating, and transporting milk home to the infant can be planned along with her other needs, such as a babysitter.

During an elective admission for a self-limited disease, rooming-in for the infant may be possible if the circumstances of the illness permit. The prime purpose of the hospitalization is to treat an illness. If surgery is involved, rooming-in should not be a stress to the mother when she is in the operating room, in the recovery room, or heavily medicated. Day-of-surgery, same-day surgery, and ambulatory surgery units have minimized hospital stays and the need for alternative nourishment for the infant.

The purpose of this section is to point out that it is possible to maintain lactation when hospitalization is necessary for the mother. It is also possible to have an infant accompany the mother, or vice versa, in a rooming-in arrangement. The theoretic threat of infection in the hospital setting is outweighed by the advantages of human milk in most cases. On the other hand, the decision rests with the physician in charge of the case, who will have the responsibility of looking at the total picture, including the medical problem in question, the necessary treatment, and the short-range prognosis for resuming normal breastfeeding. The expertise of the mother's obstetrician and the infant's pediatrician may be invaluable. They can also assist in coping with family and friends who have confused the mother with their personal experiences or opinions.

## EVALUATION OF NIPPLE DISCHARGE

Reports of nipple discharge usually exclude problems during lactation. In a consecutive series of 8703 breast surgeries, Leis and Urban<sup>167</sup> noted that 7.4% of patients had a discharge. To be significant, they point out, a discharge should be true,

spontaneous, persistent, and nonlactational. Discharges can be milky, multicolored and sticky, purulent, clear (watery), yellow (serous), pink (serosanguineous), and bloody (sanguineous). Except in lactation, the latter four are the surgically significant ones.

Most nipple discharges are caused by benign lesions, and many do not require surgical intervention.<sup>166</sup> They could, however, represent a malignant condition and deserve careful investigation. Nipple discharges associated with lactation have a different etiologic incidence profile, but they are no less significant. In general, discharge is more common in older women. Most texts discussing discharge from the nipple are written by surgeons, and the distinction regarding the relationship to breast-feeding is not made.

A discharge from the nipple is defined as fluid that escapes spontaneously. A secretion, on the other hand, is fluid present in the ducts that must be collected by nipple aspiration or by other means, such as a conventional breast pump or gentle massage and expression from the ducts (nonspontaneous secretion).<sup>144</sup>

Nipple secretion is usually not observed in nonlactating women, because the lactiferous ducts are plugged with dense keratotic material. The secretions are seen on histologic sections. If the keratotic plugs are removed, fluid can be aspirated by use of a simple device in most women.<sup>144</sup> Various solutions have been injected into the duct system, and their absorption into tissue, lymphatics, and blood have been traced. The presence of fluid among nonlactating women depends on age, race, and menstrual, menopausal, and breast disease status.<sup>11</sup> The latter is the most important, but lactation is still the ultimate secretory product.

## Diagnosis

Galactographic findings in digital mammography have been evaluated in patients with nipple discharge. They effectively differentiated between benign and malignant lesions.<sup>142</sup> Radiographic findings can be compared with biopsy findings. Galactography is obtained using full-field digital mammography.

Needle aspiration biopsy and aspiration biopsy cytology have made it possible to achieve a diagnosis without open biopsy and are standard clinical procedures for the evaluation of many palpable breast masses.<sup>147</sup> They are also used for nonpalpable lesions and can be used for multiple nodules, in mastitis, for evaluating vague masses and painful areas, and for assay of hormonal receptors. Biopsy is a prompt, cost-effective, safe procedure and can be done without interrupting lactation, often in the office setting, if imagery has not been diagnostic.

Breast cytologic examination is an important part of an evaluation during pregnancy and lactation, as well as any other time. During pregnancy, the ductal lobular system undergoes marked hyperplasia with rapid proliferation of the epithelial linings as they form new ductules.<sup>207</sup> Lymphocytes, plasma cells, and eosinophils infiltrate during the proliferation process. After 16 weeks, colostrum-like fluid is present in the ducts. Cytologic appearance of the breast during pregnancy is cellular; the cell types are the same as in the resting breast, although the proportions differ.<sup>115</sup> Epithelial cells are numerous and suggest a papillary structure. Neutrophils are abundant as well. The most common cell types are foam cells, leukocytes, histiocytes, and gland epithelial cells consisting of single cells and cell clusters.<sup>115</sup> The foam cells in pregnant patients exhibit nuclear enlargement, binucleation, multinucleation, and increased cytoplasmic vacuolization, compared with those of nonpregnant women. Unexpectedly large numbers of ductal epithelial cells are present in pregnancy and lactation. Groups of cells are papillary in structure and similar to the papillary fronds of an intraductal papilloma. In the immediate postpartum period, a lactating woman's secretions are virtually acellular at the end of the first week; nonlactators exhibited cellularity characteristics of pregnancy, according to work by Holmquist and Papanicolaou.<sup>115</sup>

Biopsies during the third trimester of pregnancy, as described by Kline and Lash,<sup>148</sup> had "tufts of cells forming spurs or invaginations into duct and alveolar lumens and similar structures that were desquamated into lumens and groups of cells found in the breast secretions." The investigators also commented that the "spurs" were closely associated with the formation of new alveoli, suggesting their origin. Delicate capillary networks within these tufts of cells might easily be traumatized and result in the bloody secretion described in pregnancy and early lactation. Kline and Lash<sup>127</sup> reported the persistence of the antepartum cellular findings in 31 of 72 postpartum women. The correlation to lactation or its suppression was not made. Biopsies, however, demonstrated findings similar to those in pregnancy; these changes lasted up to 2 months.

Conclusions drawn from multiple studies by King and Goodson<sup>143</sup> are that breast-fluid cytologic examination during pregnancy and lactation reveals the following:

1. Increased cellularity is seen and is most marked in late pregnancy.
2. Cellularity is variable postpartum.
3. Increased numbers of duct epithelial cells in groups are similar to intraductal papilloma or papillary hyperplasia.

4. Blood may be found in pregnancy and lactation in the absence of clinical lesion.
5. Interpretation of secretions in pregnancy and lactation justifies caution.

Cytologic findings referred to as "hyperplasia" in lactation have no apparent association with increased risk for breast cancer. Lesions usually not associated with increased risk for cancer are apocrine metaplasia, cyst, duct ectasia, fibroadenoma, fibrosis, mastitis, periductal mastitis, squamous metaplasia, and milk hyperplasia.

## Milky Discharge

Persistent bilateral lactation is the presentation following breastfeeding and, as noted, may represent pituitary disease. If no surgical disease (e.g., adenoma) exists, medical treatment to suppress prolactin (e.g., estrogens, bromocriptine) is no longer employed, and involution is left to take place naturally. In a nonlactating woman, this finding is called galactorrhea and is a spontaneous, milky, multiductal, bilateral discharge (see earlier discussion).<sup>214</sup>

## Multicolored and Sticky Discharge

Multicolored, sticky, spontaneous bilateral discharges from multiple ducts usually show only normal skin flora when cultured.<sup>167</sup> This discharge is usually green, but may be yellow, brown, reddish-brown, or gray; it is Hemastix or guaiac negative. The discharge can occur from puberty to the postmenopausal years and is most common in parous women. It is often associated with nipple manipulation, especially when seen in the third trimester or early lactation. Simple cases can be treated with good hygiene and discontinuing nipple manipulation. If it occurs at delivery, lactation can be initiated after cleansing and removal and discarding of early secretion. Normal colostrum usually follows.

Duct ectasia, or comedomastitis, is the most common cause of multicolored sticky discharge.<sup>214</sup> It begins as a dilatation of the terminal ducts and may occur during pregnancy, although it is most common between the ages of 35 and 40. It is rare in virgins and most common in women who have lactated. An irritating lipid forms in the ducts, producing an inflammatory reaction and nipple discharge. Cytologic examination shows debris and epithelial cells. Duct ectasia may be associated with burning pain, itching, and swelling of the nipple and areola. Palpation reveals a wormlike tube, once called a varicocele tumor of the breast. As the disease progresses, a mass may develop that mimics cancer, and chronic inflammation leads to fibrosis.

Surgery is not indicated unless the discharge becomes bloody. The disease is usually treated with thorough cleansing with pHisoHex or povidone-iodine (Betadine) daily and avoidance of nipple manipulation. Lactation would aggravate preexisting diseases but would not be an absolute contraindication. When the nipple becomes inflamed and clogged with a thick, sticky, gray-green discharge with no apparent cause, especially nearing menopause, treatment is warm compresses, antibiotics, and, if necessary, surgical removal of the duct. Pink milk observed while pumping has been detected to be due to *Serratia marcescens* contaminating the pump and breast.<sup>198</sup>

### Purulent Discharge

Purulent discharge is caused by acute puerperal mastitis, chronic lactation mastitis, central breast abscess, or plasma cell mastitis. It is usually unilateral, involving one or two ducts. Once diagnosed, the treatment is antibiotics. When an abscess does not clear after withholding of lactation and adequate treatment, a biopsy should be done to rule out secondary necrosis and infection of an underlying lesion. Ultrasound or other imaging may assist in the diagnosis.

### Watery, Serous, Serosanguineous, and Bloody Discharges

A volunteer survey among members of the Nursing Mothers Association of Australia resulted in a report of 37 cases in 32 women who had bloody or serosanguineous secretion in either pregnancy or lactation. The condition usually occurred in the first pregnancy (27 of 37) or was a recurrence in a second pregnancy (five cases), with one case occurring in the third pregnancy. It was usually bilateral, although onset might be unilateral. The earliest case started in the fourth month of pregnancy, although most began at delivery and in early lactation. More than 50% of the women had practiced prenatal nipple "exercising." Most cases cleared within 3 to 7 days of onset of lactation. These cases were distinct from trauma, cracked nipple, or mastitis.

The Lactation Study Center frequently receives calls regarding pink (guaiac positive) or frankly bloody milk, referred to by some as "rusty-pipe syndrome." It is painless and may go unnoticed unless the mother is pumping her milk or her infant vomits blood that is positive for adult hemoglobin (Apt test). This eliminates cases of bleeding of the newborn GI tract, which is positive for fetal blood by Apt test. If the infant tolerates the milk, breastfeeding can continue and the blood usually disappears in 3 to 7 days.

The explanation for this phenomenon is probably the increased vascularization of the breast coupled with the rapid development of the alveoli.<sup>149</sup> If the blood persists or is recurrent, the breast should be evaluated by mammography.

The cytology of breast secretions obtained during the third trimester from 50 pregnant women aged 16 to 39 years was reported by Kline and Lash.<sup>149</sup> Cellularity was increased with epithelial cell clusters and capillary groupings forming "spurs" or invaginations into duct and alveolar lumina. The authors noted that the spurs were closely associated with the formation of new alveoli; the delicate capillary networks within these tufts could be easily traumatized and result in blood escaping into the breast secretions.

The other cells found in secretions during pregnancy and lactation, when breast secretions were aspirated, were foam cells, leukocytes, histiocytes, and gland epithelial cells. Foam cells are also referred to as colostrum bodies and have large nuclei or are binuclear or multinucleated. When lactation is suppressed postpartum, the secretion is almost acellular by the seventh day.<sup>149</sup>

Nipple discharges are primarily of surgical significance. They are the second most common indication for breast surgery. Watery or colorless, serous or yellow, serosanguineous or pink, and sanguineous discharges are more common in women older than the age of 50 years, but younger women do not escape them.<sup>214</sup> Bloody discharge in pregnancy and lactation is most often caused by vascular engorgement or breast trauma. The next most common causes in pregnancy and lactation are intraductal papilloma (50%) and fibrocystic disease (31%). Because the type of discharge does not identify the malignant or nonmalignant nature of the problem, all patients with unusual discharge should be seen by an appropriate surgeon for diagnosis.

Nipple discharges with blood visible, or detected by cytologic examination, are common during pregnancy and lactation. LaFreniere<sup>158</sup> estimated that 15% of asymptomatic lactating women have blood in their early secretions when they are examined cytologically. An intraductal papilloma is a small, usually noncancerous growth protruding into a duct near the nipple in women 35 to 45 years old.

In intraductal papilloma the discharge is usually spontaneous, unilateral, and from a single duct. It is occasionally associated with a nontender lump in the subareolar area. Symptoms may include bleeding, which is usually painless, during pregnancy. It is possible to excise the involved duct and wedge of tissue, leaving the rest intact to preserve mammary function, when surgery is required for intraductal papilloma. Painless bleeding during pregnancy may be bilateral or unilateral and may cease after

delivery. After serious disease has been ruled out by physical examination and cytologic evaluation, lactation is possible.<sup>158</sup>

To be significant, a discharge should be true, persistent, spontaneous, and nonlactational. Single-duct unilateral discharges are more apt to be surgically significant. A true discharge comes from a duct to the surface of the nipple. Pseudodischarges occur on the surface and may be associated with inverted nipples, eczematoid lesions, trauma, herpes simplex, infections of the Montgomery glands, and mammary duct fistulas. Discharges are more common in women taking oral contraceptives, tranquilizers, or rauwolfia alkaloids and in those who are postmenopausal and menopausal. Cytologic examination should be part of any examination for an abnormal discharge from the breast, although a high percentage of false negative tests occur, as well as some false positive results. Absence of a mass is reassuring, but should not dissuade one from further diagnostic studies.

## PAGET DISEASE

Paget disease of the breast is an uncommon type of cancer that occurs in only 1% to 4% of all women with breast cancer. Signs and symptoms include itching, burning, and redness or scaling of the surface of the nipple and areola. A bloody discharge may be present. The nipple may appear flattened against the breast. It has been mistaken for candidiasis during lactation, greatly delaying proper treatment. A biopsy of the areola is necessary. Mastectomy is usually recommended, although early lumpectomy may be adequate. Chemotherapy and radiation are recommended.

## LUMPS IN THE BREAST

A lactating breast is lumpy to palpation, and the lumps shift day by day. The most common cause of a persistent lump is a plugged duct (see Chapter 8); the second most common cause is a mass associated with mastitis. Lumps that persist beyond a few days and do not respond to palliative treatment deserve investigation.<sup>210,211</sup> In young pregnant or lactating women, ultrasound is the ideal method for evaluation of the breast. It visualizes the breast architecture dynamically, facilitates differentiation between benign cysts and solid lesions, and further suggests if a solid mass is benign or malignant. It could be a benign shape with smooth edges. It also establishes a baseline for subsequent follow-up. The American College of Radiology standard for the performance of a breast ultrasound examination states that breast sonography is the initial imaging technique to evaluate

palpable masses in women younger than 30 years or in pregnant and lactating women.<sup>10</sup>

Ultrasound is also useful to diagnose and guide drainage of breast collections and check for abscess when mastitis presents. A small abscess, identified early, can be treated with percutaneous drainage before surgical drainage is necessary. When a mass is to be evaluated, a mother should nurse immediately before the procedure. If a mass is in a lactating breast that warrants biopsy, percutaneous core biopsy can be done. MRI is also useful because it can identify masses not detected by ultrasound and assist in the effort to do a needle biopsy.

Adenomas of the breast and ectopic breast under lactational influences were reviewed by O'Hara and Page.<sup>203</sup> They reported five ectopic lactating adenomas located in the axilla, chest wall, and vulva. Tubular adenomas have been associated with lactation and show lactational changes in a fibroadenoma, thus making diagnosis difficult by fine-needle aspiration. Fine-needle aspiration of the breast has been recommended as a safe, simple diagnostic tool to use in an ambulatory setting without interrupting lactation.<sup>165</sup>

Once a breast mass is palpated, prompt evaluation is indicated to rule out breast cancer. A palpable lump in pregnancy has been noted by investigators to delay the time to treatment as long as 8 months.<sup>33</sup>

Of women diagnosed with breast cancer, 3% are pregnant or lactating.<sup>212</sup> Data suggest that pregnant or lactating women with breast cancer, stage for stage, have similar survival rates as nonpregnant women. Average delay during the perinatal period is 2.2 months compared with 0.59 month in the total population of patients with breast cancer; thus a higher proportion of pregnant women are in advanced stages when first seen.<sup>234</sup> Lumpectomy can be performed safely during pregnancy and lactation.

## FIBROCYSTIC DISEASE

Fibrocystic disease is a diffuse parenchymal process in the breasts that has many synonyms, none of which is satisfactory. The process involves hormonally produced benign proliferations of the alveolar system of varying degrees that occur in response to the normal menstrual cycle. A patient with full-blown disease has pain, tenderness, palpable thickenings, and nodules of varying sizes that are most symptomatic with menses. Fibrocystic disease is prominent in the childbearing years and regresses during pregnancy. It often disappears during menopause. It is not a contraindication to breastfeeding. Some women have achieved relief by totally eliminating caffeine and related products from their diet.

Diagnostic procedures include mammography and aspiration biopsy. When no fluid is obtained and a smooth, freely movable mass is present, lumpectomy can be performed. Microscopic examination will clarify the diagnosis and the need for further treatment.

A rare cause of hematemesis in the newborn was reported in which the mother had fibrocystic disease.<sup>5</sup> Spontaneous vomiting of blood began on day 3; the newborn had been breastfeeding without difficulty. Apt test demonstrated it was maternal blood. Pumping each breast revealed bloody milk only on the left. Ultrasound showed cystic disease only on the left with the bloody milk, which persisted for several months.

## GALACTOGRAPHY

Galactography is radiography of the mammary ducts after the injection of radiopaque contrast material (see Figure 16-3). It is done to identify the cause of abnormal nipple discharge, especially when no lesion is palpable or radiologically detectable. Cytologic examination of the discharge material should always be done first. Positive cytologic examination is helpful, but false negative results do occur. The procedure involves cannulation of the duct with a blunt needle under sterile precautions with the slow injection of 2 mL of sterile, water-soluble contrast material. Preexisting mastitis or abscess is a contraindication to the procedure (see Figure 16-2). Galactographic findings in digital mammography can be helpful. The nipple discharge may be caused by ductal ectasia, fibrocystic changes, papilloma, papillomatosis, or intraductal carcinoma. Galactography is performed to localize the abnormality and not to make a histologic diagnosis, because the appearances of some benign and malignant lesions overlap significantly. In lactating women, fewer than 10% with abnormal discharge are malignant (Figure 16-12). IGM is a rare, inflammatory, chronic, and benign disease that mimicks malignant hyperplasia of the mammary gland, usually as a unilateral, distinct, painful mass. It is treated surgically by hemi-mastectomy or medically with azithromycin and prednisolone.

## BREAST CYSTS

Benign cysts of the breast are being identified in younger and younger women, probably because of the more careful self-examination of the breast that is now recommended. They should be removed and biopsied but do not interfere with lactation. Fibroadenomas that result from a disturbance in the normal menstrual cycle usually proliferate and regress before age 30 years. Pregnancy and lactation stimulate their growth. They

**Figure 16-12.** Bi-fed nipple or double nipple. Note milk at both orifices and third on face or surface of areola. With gentle pressure all three orifices have major spray.

are firm, smooth, lobulated masses and are freely movable without fixation. They can be diagnosed radiologically. They can be removed while the patient is under local anesthesia, if necessary, without causing cessation of breastfeeding.

## LIPOMAS

Lipomas are common in the breasts, which have considerable fat in their stroma. They are usually solitary, asymptomatic, slowly growing, freely movable, soft, and well delineated. They can be easily identified radiologically or with ultrasound imagery in lactating breasts, which have less fat present.

## FAT NECROSIS

Fat necrosis is usually associated with trauma and is caused by local destruction of fat cells with release of free lipid and variable hemorrhage. Organization with fibrosis may lead to fixation. Fat necrosis can be identified radiologically and appears as a fat density or oil cyst with a capsule.

## HEMATOMAS

Hematomas of lactating breasts may occur from trauma or in women receiving anticoagulant therapy. They generally regress without treatment. When they occur with minimal trauma, the presence of a tumor should be considered.

## GIGANTOMASTIA (BREAST HYPERSTROPHY WITH PREGNANCY)

Massive hypertrophy of the breast with pregnancy is a rare condition of unknown etiology, referred to as gigantomastia of pregnancy.<sup>190</sup> It is reported in

all races during childbearing years. It is less common than juvenile or virginal hypertrophy,<sup>36</sup> which usually has its onset between ages 11 and 19 years old. When associated with pregnancy, hypertrophy usually begins during the first trimester and progresses until delivery and may even lead to necrosis and incapacity. The first report was in 1948, and a total of 55 cases have been reported in the world literature.<sup>190</sup> Since our first mention in 1990, several reviews have reported another 121 cases, most requiring surgery.<sup>15,30,61,254,263</sup>

The typical case involves a previously healthy pregnant woman who observes excessive enlargement bilaterally early in pregnancy. The breasts may double or triple in size, becoming not only grotesque but incapacitating. They are firm, edematous, and tense, with a prominent venous pattern. The rapidity of the changes predisposes to necrosis, infection, and hemorrhage. According to the literature, after delivery, in the immediate postpartum period, in some cases the breasts recede to almost their previous size. With subsequent pregnancies, they almost always enlarge again and even more extensively. The literature reports those requiring surgery so milder cases go unreported (Figure 16-13).

A patient presented to our center with moderate breast hypertrophy during pregnancy and massive enlargement during the immediate postpartum period. She had planned to breastfeed but was completely incapacitated. Her caregivers described her breasts as the size of basketballs. Some pain relief was achieved with a Velcro abdominal binder applied to support the breasts and provide some counter pressure. Pillows for support under the arms were also used. Ice packs did little for relief, and analgesics were mildly palliative. The mother was hospitalized for weeks, unable to get out of

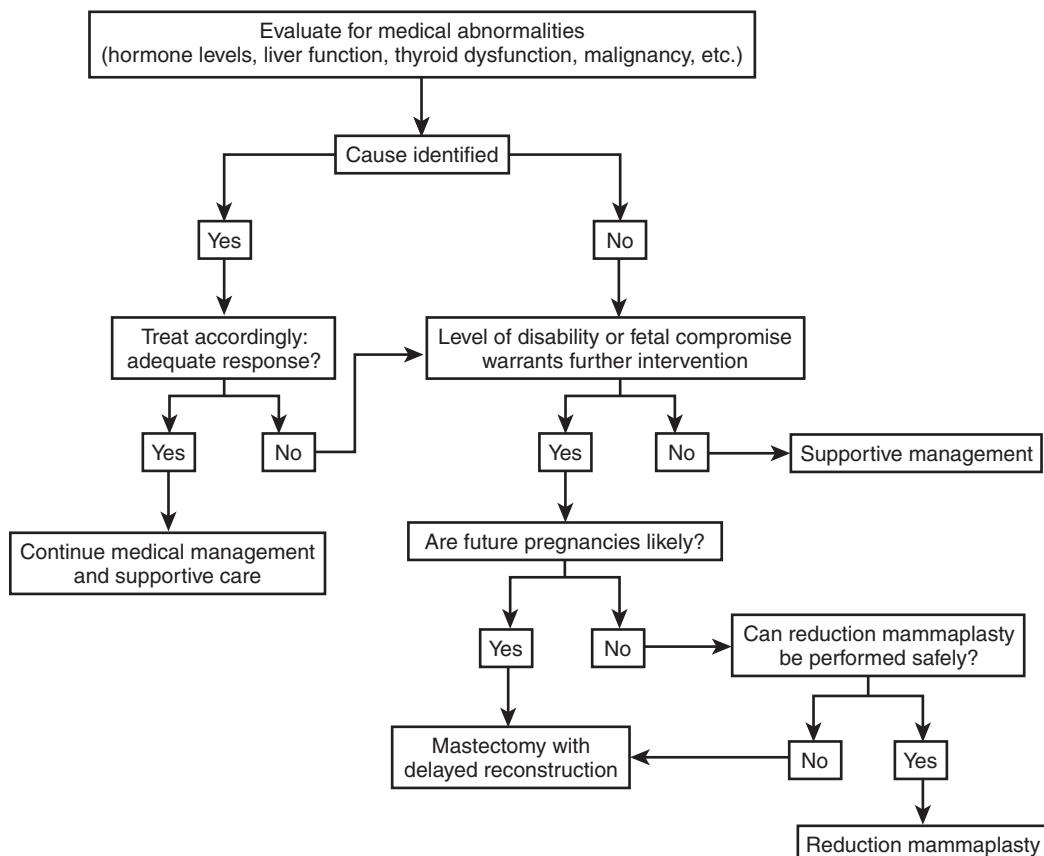

**Figure 16-13.** A 34-year-old woman at 22 weeks' gestation presents with massive breast hypertrophy and ulceration. (From Swelstad MR, Swelstad BB, Rao VK, et al: Management of gestational gigantomastia, *Plast Reconstr Surg* 118:840, 2006.)

bed. Gentle pumping helped establish milk flow, and breastfeeding was initiated. Breast size diminished sufficiently to allow discharge home. At about 3 months postpartum, the excessive enlargement recurred, weaning was unpreventable, and surgical intervention was planned. Another patient with massive enlargement during pregnancy was assisted to breastfeed postpartum; she did well until 6 weeks, when she developed mastitis requiring hospitalization and weaning to cure the overwhelming septicemia. This recurred with the second pregnancy and she had reduction mammoplasty after delivery.

When gigantomastia becomes incapacitating during pregnancy, management is initiated with medical treatments that usually begin with bromocriptine or now, preferably, the less toxic, more effective cabergoline (0.25 every 12 hours for 2 days). Binders can be used to support the breasts, and nutritional support should be provided. Other hormones do not seem to suppress the progress. Several cases report intrauterine growth retardation. Most cases do not have associated disease, although work ups have been thorough for immune disease and eclampsia. When progression intensifies the skin becomes fragile, and ulceration and infection occur. Many cases experience oozing then hemorrhage, requiring multiple transfusions. If the fetus is mature enough, delivery can be induced. Often postpartum growth intensifies, however. Surgery has been performed during pregnancy with bilateral simple mastectomy.<sup>15,30,61,254,263</sup> A management protocol is illustrated in Figure 16-14. A case of gestational gigantomastia is pictured in Figure 16-15.

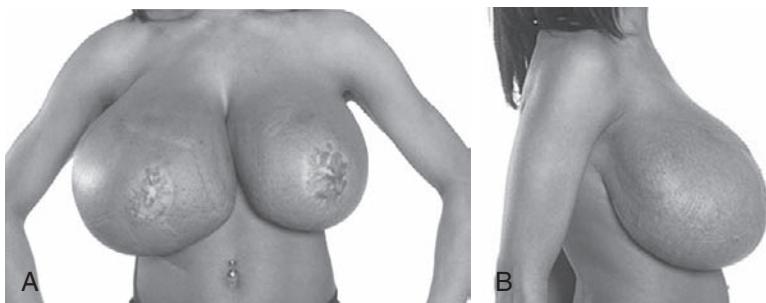

The cause of gigantomastia is unknown, but most authors agree it is hormonal in nature,<sup>190</sup> whether it is an overproduction or an overreaction of the target organ to the stimulus. Various hormonal therapies, including estrogen, testosterone, and hydrocortisone, have not been effective. Diuretics have been mildly helpful for some. Liver dysfunction has been postulated, but essentially discarded when all studies of liver function were normal.

Pseudohyperparathyroidism has been associated with this condition, with improvement after therapy for the underlying disease. A case of gigantic mammary hypertrophy during pregnancy was associated with severe nonparathyroid hypercalcemia. Vigorous diuresis reduced the calcium level to 11.1 mg/dL. No galactorrhea was present, and the prolactin level was 26 ng/mL. No enlargement of parathyroids was detected. An emergency partial bilateral mastectomy was performed because of necrosis and bleeding. Intraoperatively, 16 units of blood were required. The breast tissue removed weighed 12.5 kg (left) and 11.3 kg (right). Pathologic examination showed virginal hypertrophy

**Figure 16-14.** Management algorithm for gestational gigantomastia. (From Swelstad MR, Swelstad BB, Rao VK, et al: Management of gestational gigantomastia, *Plast Reconstr Surg* 118:840, 2006 (Figure 4). Available at <http://www.prjournal.com>.)

with no duct formation. Postoperatively, the serum calcium level returned to normal.<sup>242</sup>

If delivery is not imminent, surgical intervention to relieve severe pain, massive infections, ulceration, hemorrhage, or necrosis may be life saving. After delivery the patient should be counseled about the risk for recurrence and the option of reduction mammoplasty, preserving the nipple and duct system.<sup>234</sup> Lactation after delivery has not been described in these patients.<sup>190</sup> Recurrence in subsequent pregnancy is common. Many of the patients had previous normal pregnancies. In milder

cases, breastfeeding can be attempted on a case-by-case basis with substantial supportive care.

## SURGICAL PROCEDURES

Surgical manipulation of the breasts may result in residual loss of sensation for several months, but only rarely permanently. The nerve involved is the anterior cutaneous branch of the fourth lateral cutaneous nerve, which passes deep into the breast tissue unaccompanied by arteries. Preoperative and postoperative evaluation of breast sensation was

reported by Courtiss and Goldwyn.<sup>57</sup> Preoperatively, they found the areola to be the most sensitive. For 2 weeks after augmentation mammoplasty, sensation was decreased to the areola and nipple. Erectility did return in all patients. The return of significant sensitivity, however, usually took 6 months or longer, even 2 years, with the larger implants being associated with the greatest loss. Hyperesthesia and paresthesia were also reported.

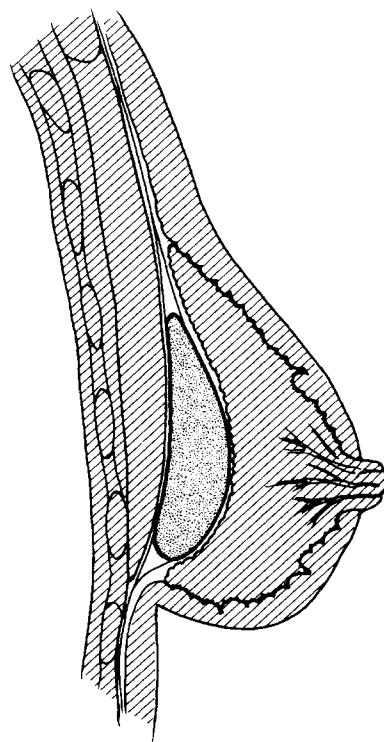

Immediately after reduction mammoplasty (see next section), breasts were insensitive to testing, and it took about 6 months for sensation to return. The greater the resection, the greater was the loss of sensation. Nipple erectility returned before complete sensation in the skin in approximately 2 months, but complete recovery took approximately 1 year. With mastopexy for sagging breasts, normal sensation in the skin returned in approximately 2 months, but complete recovery could take up to a year.<sup>57</sup>

## AUGMENTATION MAMMOPLASTY

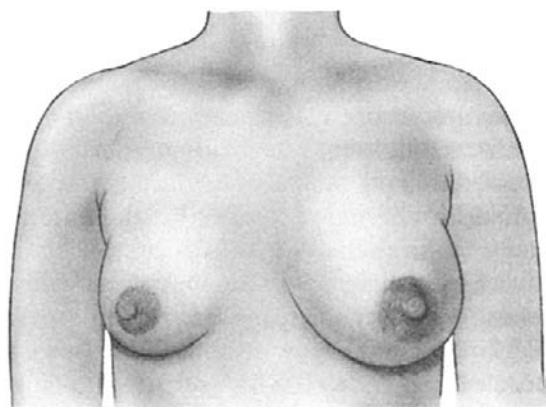

Augmentation mammoplasty has become a more acceptable procedure, and techniques have improved tremendously.<sup>255</sup> The implantation of inert material is the approach. Young women may request it and then choose to lactate. The surgery should cause no destruction of breast tissue or interruption of ducts, nerve supply, or blood supply to the gland or nipple, so that breastfeeding is possible and successful (Figure 16-16). The incision is inferior near the chest wall and not perialveolar. Injections of silicone are no longer used. The silicone caused fibrosis and duct destruction.<sup>255</sup>

Implants for augmentation present different problems and different risk/benefit ratios than implants done after mastectomy as prostheses. An indication that still remains is the unilateral use when one breast is significantly underdeveloped (Figures 16-17 and 16-18). The underdeveloped breast may present a problem of underproduction during lactation. The flood of reports of rupture of the implants and the leakage of silicone into the breast tissue caused considerable alarm. The U.S. Food and Drug Administration (FDA) concluded, after extensive study, that it is not necessary to remove intact implants or to check milk for silicone when the prosthesis is intact and the woman chooses to breastfeed. Measurements of levels of silicone and degradation products in urine and milk are not readily available. Silicone and simethicone are present in many medications and toiletries, and silicon is the second most common element on the earth's surface. Nonaugmented cadavers have measurable amounts of silicone in tissues.

The FDA's position is that breast implants filled with silicone gel will be available only through

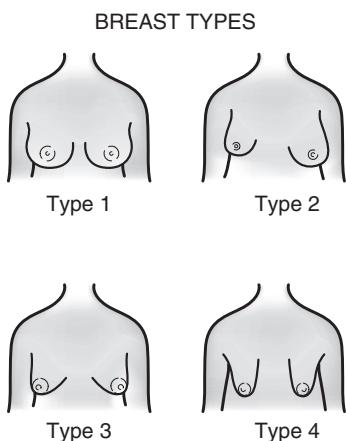

**Figure 16-16.** Placement of implant in augmentation mammoplasty, with no interruption of vital ducts, nerve supply, or blood supply.

**Figure 16-17.** Asymmetric breasts, with right breast significantly smaller.

controlled clinical trials.<sup>140</sup> Women needing reconstruction will be assured of access. This is based on the lack of knowledge about the safety of silicone implants 35 years after their introduction. It has not been recommended that these implants be removed, except on a case-by-case basis for medical reasons.<sup>129</sup> Saline implants have replaced the silicone. Silicon analysis of breast and periprosthetic capsular tissue from patients with saline or silicone gel breast implants demonstrated that silicon levels of breast tissue specimens from saline prostheses

**Figure 16-18.** Breasts are asymmetric and often variably shaped. Tubular breasts (type 4) usually have minimal functioning tissue.

were in the same range as those of control subjects. The levels in the periprosthetic tissue with intact saline implants were significantly higher than those of control subjects, but not as high as those of ruptured silicone gel implants.<sup>231</sup>

Polyurethane implants are no longer available. They had been associated with long-lasting complications, the most common being contractions. Polyurethane is a polymer formed by reaction of diisocyanates and polyols. The polymer sponge breaks down into its reactive monomers, toluene-2,4- and 2,6-diisocyanate. Diamine metabolites have been identified in the urine of patients implanted with the material.<sup>50</sup> The disfigurement of the breast from fibrosis and contractions has led to their removal from the market.

More than 700 articles are found in the literature relating to illness and silicone gel implants, many of them single-case reports. After a thorough study of the literature the Practice Committee of the American Academy of Neurology reports that studies to date (1) show no clear relationship between silicone breast implants and connective tissue disease and (2) do not support a causal relationship between silicone breast implants and neurologic disorders at present.<sup>80</sup> Renewed efforts to make silicone implants available should include data on infants born and those breastfed while implants are in place. No such data are currently available.

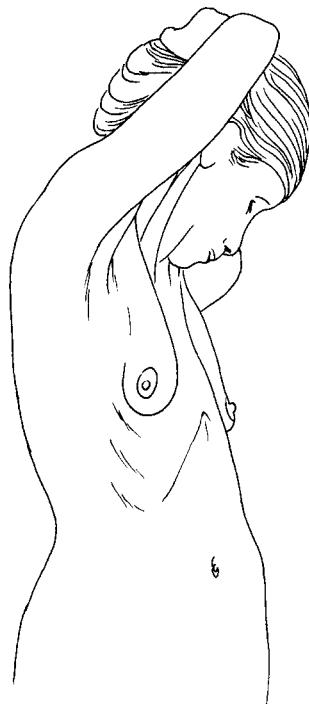

Cosmetic breast augmentation (breast implants) is one of the most common surgical procedures worldwide, especially in high income countries in recent decades. Potential for breastfeeding had not been explored until Schiff et al.<sup>230</sup> undertook a systematic review of multiple data bases. A few small studies met criteria. There was no significant difference in attempted breastfeeding with and without augmentation. Among women who breastfed, there

was a reduced likelihood of exclusive breastfeeding among those with implants. In an earlier study, those women with periareolar incisions had trouble breastfeeding, especially regarding milk insufficiency, compared to mothers with more distal incisions. The need for implants when breast tissue is meager may be the real reason for insufficient milk supply.

Breasts requiring augmentation mammoplasty may lack adequate functional breast tissue. A woman may want to have this evaluated by real-time ultrasound before the insertion of an implant if she plans to breastfeed later.

## POSTLACTATION INVOLUTION

Postlactation involution of a severe degree occasionally occurs. After multiple pregnancies and lactation, some women note considerable regression and seeming atrophy after weaning, which alarms them. The fat deposition has not recurred when the ducts regress. In most of these women the breasts return to their normal contour in approximately 3 years if no further pregnancy or lactation has occurred. Loss of tissue turgor and fat padding occurs without pregnancy or lactation as well (Figure 16-19). Augmentation is possible, if desired, once childbearing is completed. If subsequent pregnancy occurs, the breast regenerates and lactates well.

**Figure 16-19.** Extreme postlactation involution.

## REDUCTION MAMMOPLASTY

Some women have breasts so large that they cause shoulder and back pain, deep grooves in the shoulders from brassiere straps, and negative self-image. These women sometimes want surgical correction. Reduction mammoplasty is more destructive than augmentation because of the necessity of replacing the nipple symmetrically, which requires interrupting the ducts.<sup>255,256</sup> Although reconstructive surgeons report that these women do not want to breastfeed, it is our experience that many of them do choose to breastfeed later, when they bear a child and are suddenly aware of their maternal role. At surgery, they are consumed with their perceived affliction. The surgeon should clearly discuss the options with the patient or provide a procedure that leaves the ducts intact. If the ducts are intact, breastfeeding can be successful postoperatively. The nerve must also be intact for tactile sensations to trigger let-down.

In general, surgery of the breasts for nonmalignant lesions does not preclude breastfeeding unless the ductal structure has been interrupted. Surgeons need to consider mammary function in counseling young women about breast surgery.

A follow-up study of 73 patients, all in the childbearing years, was done by mailed questionnaire. In the series of 68 patients with reduction mammoplasty procedures who responded, 20 patients became pregnant. All 20 lactated; 7 (35%) breastfed successfully and 13 (65%) decided not to breastfeed or discontinued breastfeeding for a variety of personal reasons. These patients had all undergone an inferiorly based pedicle reduction mammoplasty, which retains the ability to lactate because the nipple and areola are maintained on a ductal pedicle. A prospective study of 319 normal, healthy women by Neifert et al.<sup>196</sup> identified 22 women with previous breast surgery, including 11 excisional biopsies, five augmentations, four reductions, and two chest surgeries involving breast tissue. Ten of the 22 had periareolar incisions (four reductions, one augmentation, five excisional biopsies). In this series, previous breast surgery was significantly correlated with the final outcome of lactation, that is, a threefold risk for insufficiency compared with women without surgery. Those women with a periareolar incision had a fivefold risk for lactation insufficiency. Breast reduction was the condition most highly correlated with insufficiency. Poor sensation after breast reduction is widely reported. Even when there is no sensation due to spinal cord injury, they can train themselves to let-down with visualization only (Saenze, August 2013).

It has been reported that large breasts are a major image issue for some young women who take extreme efforts to lose weight and decrease their

breast size. In the management of several patients with bulimia, in spite of the fact that surgery to change the body is not recommended, these patients had reduction mammoplasty by a skilled plastic surgeon. Postoperatively, they recovered from their underlying disease.<sup>154</sup> Breastfeeding after inferior pedicle reduction mammoplasty was reviewed by Brzozowski et al.,<sup>43</sup> who evaluated 544 patients. They contacted patients by telephone and found 78 who had had at least one child. Of these, 27 were discouraged from breastfeeding, but eight attempted breastfeeding anyway; 26 were encouraged to breastfeed. Only one patient had nipple numbness, and 19 were successful (73.1%). Of the 41 who did not attempt breastfeeding, 31 experienced engorgement and milk production. The authors recommend the use of a relatively thick inferior pedicle that is left attached and that the nipple and areola be preserved. They also encourage breastfeeding and lament that clinicians discourage breastfeeding after reduction mammoplasty. Obese women, however, have been shown to lactate poorly.<sup>155</sup>

## GASTRIC BY-PASS SURGERY

Gastric by-pass surgery has become an increasing issue for pregnancy and lactation. In 1 year alone more than 100,000 procedures are performed in the United States. Most patients are women in the childbearing years. Pregnancy has been a challenge for the obese, and lactation has been shown to be less successful when BMI exceeds 30. A study of 20 women with 23 pregnancies and 24 infants was reported by Crill et al.<sup>60</sup> The participants were interviewed by telephone in a semistructured format. Although their milk came in promptly before discharge, 86% of mothers supplemented with formula, mainly at the urging of the infant's physician (69.6%). The major problems were inadequate milk supply and trouble latching. Nutritional deficiencies are a concern after bariatric surgery. Vitamin supplements are mandatory. Deficiency of vitamin B<sub>12</sub> is most commonly reported.<sup>97</sup> In experienced, responsible bariatric programs, it is not just about the surgery, but a complete change in lifestyle and attitude.

## DERMATITIS THAT INVOLVES THE BREAST

### Bacterial Dermatitis

Infections of the skin can also involve the breast. Impetigo is extremely contagious and spreads by contact. If it affects the breast, it should be vigorously treated locally and systemically. Breastfeeding should be interrupted until lesions are clear.

Milk should be pumped and discarded until systemic treatment has been under way for at least 24 hours. The infant should be inspected daily for possible lesions and treated vigorously if younger than 3 months of age. Local treatment may be adequate early in older children.

### Viral Dermatitis

In one case, an infant developed a lesion obtained from the father kissing the baby. Both mother and baby developed systemic herpes. The lesion on the breast was caused by the infant suckling. It subsequently became super infected with enterococcus. See discussion of herpes in [Chapter 13](#) for treatment.

Herpes simplex and herpes zoster lesions on the breast are a contraindication for breastfeeding (see [Figure 16-20](#) and [Chapter 17](#)). Unless the infant has already contracted the disease, chickenpox lesions similarly are a contraindication for breastfeeding until the lesions clear. When lesions of herpes are unilateral, breastfeeding can take place on the other breast. Herpes simplex in a neonate can be life threatening, so the source of the lesion should be determined to measure the risk for a lesion occurring on the other breast.

### Contact Dermatitis

Lesions from contact with irritating material usually do not affect the infant, so breastfeeding is not contraindicated unless the process interferes with maternal healing or puts the mother at risk for infection. Latex allergic dermatitis can usually be treated with cortisone ointment (by prescription to achieve adequate dosing), and breastfeeding can continue. The offending material should be eliminated. Latex may be in moisture-proof padding for nursing brassieres. Some nipple shields

are latex and have no purpose in lactation management. Silicone nipple shields can be used if indicated.

*Herpes gestationis* is a noncontagious, noninfectious bullous disease of the skin that occurs during pregnancy and the puerperium.<sup>89</sup> It occurs only when placental tissue is present, and so can occur with choriocarcinomas and hydatidiform moles. A genetic predisposition and increased frequency of HLA antigens as in autoimmune diseases exist. It begins with itching followed by erythema and edema of subcutaneous tissue. Within days or weeks, papules and plaques form that are somewhat urticarial. Lesions can be anywhere, including palms and soles, except face, scalp, or mucosa. Diagnosis is confirmed by biopsy. Onset is most commonly midpregnancy, but it can be immediately postpartum. It lasts for weeks. Neonatal *gestationis* occurs in 10% of cases and is transient and milder. It is believed to be related to placental exposure.

Breastfeeding is not contraindicated. Treatment is symptomatic, usually with corticosteroids. The itching is intense. It usually abates after delivery.

PUPP syndrome (pruritic urticarial papules and plaques of pregnancy) is the most common dermatosis of pregnancy (1 in 200 patients). Cause is unknown but no hormonal or autoimmune abnormalities have been found.<sup>89</sup> It is more common in primigravidae with prominent striae and uterine distention (twins, hydramnios). Lesions typically begin on abdomen as erythematous papules surrounded by a narrow, pale halo that coalesce into urticarial plaques. Lesions spread to thighs and arms in 2 to 3 days. Diagnosis is confirmed by biopsy to distinguish from *gestationis*. Treatment is symptomatic. PUPP syndrome is not contagious or infectious. Breastfeeding is appropriate. Lesions on the breast will have to be evaluated, but the disease does fade postpartum.

Mastocytosis is a local mast cell density and overactivity, resulting in a hive-like histamine-mediated reaction to any one of a variety of irritants, from simple physical contact to chemical contacts to drug reactions. The lesions are benign, often solitary, and tend to fade over time. It flares when it is mechanically stimulated. It presents as a recurrent hive and may have a hyperpigmented papule or plaque. Biopsy (which is rarely necessary) shows eosinophiles and mast cells. Mastocytosis does not interfere with breastfeeding. Serum tryptase levels are elevated, and leukotriene inhibitors such as Singulair have been used. Antihistamines are effective.

Poison ivy (*Rhus* infection) anywhere on the body, except the breast, poses no problem to the suckling infant. The toxin from the plant is dissipated from the involved skin within 6 hours after

**Figure 16-20.** Herpes of the breast. (Courtesy of Sue Cox, IBCLC, Rose Bay, Tasmania, Australia.)

contact. Toxic oils may remain on shoes or clothing until they are washed. The contents of the vesicles do not cause disease in others. The risk involved with continuing to breastfeed if the lesions are on the nipple or areola results from the possibility of secondary infection from infant to mother, which will cause skin breakdown and delayed healing. Treatment with hydrocortisone ointment 1.0% or Ultravate will hasten healing. Milk should be pumped and may be fed to the infant. Breastfeeding can resume as soon as lesions have healed, usually 4 to 5 days, and the risk for secondary infection is gone.

**Psoriasis and Eczema.** A flareup of psoriasis during pregnancy or lactation is not unusual. Since koebnerization or the development of new plaques of psoriasis occur in areas of injury or trauma, it is not surprising that the nipple and areola are affected during lactation. Psoriasis of the nipple is seen as well-demarcated, erythematous plaques with fine micaceous scales. Management is difficult, as many of the regular treatments for psoriasis may be too harsh for the nipple and areola and should be used sparingly. Each psoriasis victim has a different best therapy.

Eczema of the breast often affects not only the nipple and areola, but also the breast itself.<sup>110</sup> It presents as an acute erythematous eruption with oozing, crusting, and erosion, progressing often to chronic dry, lichenified, and scaly lesions. It can be very itchy and often painful at the same time. There are three types: endogenous atopic dermatitis, irritant contact dermatitis, and allergic contact dermatitis. Atopic dermatitis is seen in women predisposed to eczema. Irritant contact dermatitis occurs from something in contact with the skin, such as topical agents, detergents, clothing, or soaps. Allergic contact dermatitis is a delayed hypersensitivity reaction to an allergen contained in something. The list is vast. The distribution of the reaction may be a clue. A dermatology consult may be needed if simple treatments do not help.

## NONSPECIFIC NIPPLE PAIN

Nipple pain is a constant and often persistent complaint that does not fit the classic descriptions of pathology. The latch is good; usually several experts have confirmed this. It is not thrush; it doesn't look like it, the baby does not have it, and the mother has not had antibiotics and does not have vaginal thrush. It could be due to a bacterial infection and a course of an antibacterial ointment and, in persistent cases, systemic antibiotics might be considered. Other treatments to be considered are warm compresses, which were found to be the most effective in a group of 177 women who were assigned to

education, lanolin, local application of breast milk, or warm wet compresses. Pain assessment before treatment had been similar in all four groups.<sup>72</sup> The literature from 20 years was reviewed by Merland-Schultz and Hill<sup>182</sup> by checking computerized sources for prevention of and therapies for nipple pain. They found education about proper latch was most important. Warm compresses, expressed milk, teabags (usually not recommended), lanolin, hydrogel dressings, chlorhexidine (0.2%) in an alcohol spray, polyethylene film dressing, and glycerine gel were tested against controls. No one method was especially effective. Other unique treatments have been used. When the tissue is swollen, cabbage leaves are an historic remedy also used for swollen ankles in heart failure. Castor oil rubbed into the tissue (not taken by mouth) is also known to relieve swelling and pain and is used by persons with arthritis. It contains ricinoleic acid, a distant cousin of the toxin ricin. It is a purgative, so it should be wiped off the breast before breastfeeding begins. A study in Iran reported peppermint oil to be effective to prevent nipple cracks.<sup>180</sup>

Menthol essence was used to reduce pain and improve healing in another blinded controlled study in Iran of nipple fissures.<sup>3</sup> Four drops of menthol were applied to each nipple and areola after each feeding. The controls used 4 drops of their own milk. The menthol was dramatically more effective.

There is no apparent perfect treatment for idiopathic nipple pain. A Cochrane Review looked at the literature again in 2014<sup>66</sup> and reported a similar list of treatments studied, including glycerine pads, lanolin with breast shells, lanolin alone, expressed breast milk, and all purpose nipple ointments. All the studies included education to position the infant properly in both the intervention and control group. It was concluded that applying nothing or expressed milk was equally or more beneficial than any of the "treatments." Regardless of the treatment used, nipple pain was reduced to mild in 7 to 10 days after delivery, according to all reports.

## Anaphylaxis and Breastfeeding

Anaphylaxis can be associated with breastfeeding. Urticaria and angioedema can be triggered by a number of factors, including physical stimuli, bites, stings, hormones, collagen vascular disease, and cyclooxygenase inhibitors.

A patient reported by Mullins et al.<sup>191</sup> had symptoms when achieving let-down with breastfeeding. The first episode occurred at first feeding with the first infant. The events were restricted to the early postpartum period. The role of progesterone is not clear, although in other cases unrelated to lactation,

suppressing ovulation cleared the symptoms. Although the patient did not react to a skin test with oxytocin, manual expression of the breast precipitated laryngeal edema and hypotension, as did every attempt to breastfeed. Lactation was suppressed by bromocriptine, and there were no recurrences. The patient remained symptom free for 5 years until the birth of her fourth child. At 48 hours postpartum, urticaria, upper airway angioedema, and hypotension occurred within minutes of each breastfeeding. She was again given bromocriptine, lactation ceased, and she was symptom free.

Less dramatic urticaria reported during lactation usually occurs at onset of let-down. The itching may be intense. Some relief has been achieved by medicating the mother 15 minutes before breastfeeding with antihistamines. An alternative is a low-dose, sustained-release antihistamine preparation such as loratadine (Claritin), which does pass into milk, but at levels less than 0.03% of the maternal dose. Because it dries mucous membranes and decreases secretions, such a preparation could decrease milk supply over time. Low-dose corticosteroids taken before symptoms or daily are an alternative treatment.

## CEPHALGIA AND LACTATIONAL HEADACHE

The association of headache with lactation has been described in the literature and reported to our Lactation Study Center. Migraine headaches differ from lactational headaches.<sup>238</sup> Migraine is a unilateral, hormonally sensitive, episodic headache disorder that may worsen during pregnancy and lactation.<sup>265</sup> Women are reported to have frequent headaches between the third and the sixth day postpartum. Research on periparietal migraines fails to mention the mode of infant feeding. The relationship to prolactin is of interest to neurogenic theorists, because prolactin levels are high during migraine headaches. Hyperprolactinemic infertility is associated with increased headaches. The theory is that, although hyperprolactinemia does not cause headaches, per se, headaches and hyperprolactinemia reflect a derangement of neurotransmission.<sup>119,228</sup>

A detailed description of the onset of headache is provided by Askmark and Lundberg<sup>21</sup> in a 26-year-old woman who was gravida 4, para 2, and Ab 2. At her previous term pregnancy, she had intense headaches during the weeks before delivery. These increased in intensity, necessitating a complete diagnostic work up by 32 weeks. Because of the headache and facial edema, a cesarean delivery was done at 32<sup>5/7</sup> weeks. The headache and edema cleared in 2 days and recurred at 1 month, when 2 minutes into breastfeeding. Each event lasted for 2 to 7 minutes. On occasion the

headache would briefly clear while the infant interrupted feeding to burp or change breasts. No change in blood pressure and no effect of exertion occurred. Measurements of serum vasopressin, which is a vasoconstrictor, did not show a rise. Oral propranolol, given 1 hour before nursing, did not prevent the headache. Prolactin levels rose gradually and persisted long after the headache stopped. Oxytocin was not measured. The patient weaned the infant, and the headaches stopped. Wall<sup>265</sup> reported five milder, but similar cases. Tegretol has been used in severe cases.

Headaches are reported to occur during sexual intercourse, which is also associated with oxytocin, a vasoconstrictor. This condition is called benign orgasmic cephalgia. Serious vascular problems (stroke) with such events have been reported.

Medical evaluation of such a complaint requires the usual evaluation for headache. When associated with lactation, and after assessment of pulse and blood pressure, a trial of oxytocin can be given by nasal spray or injection to test the association with oxytocin. A prolactin level at baseline and after 10 minutes of breast stimulation might provide some information. With a negative work up for causes of headache, lactational headache can be considered. It appears to be self-limited. When lactational headache is seen in conjunction with pre-eclampsia, or hypertension and edema, a thorough review is essential to avoid an eclamptic crisis. Migraine headaches are not more frequent with lactation, but headaches that occur immediately postpartum can be severe. A study over pregnancy and postpartum, for weeks until 12 months after giving birth, confirmed that migraines do not usually occur during pregnancy (only 15% occurrence). After delivery, 50% have a return within the first month. For the first 6 months postpartum, breastfeeding was associated with a significantly lower recurrence rate of migraines than in bottle-feeders. The concerns are about using medications compatible with lactation and timing the dosing to minimize exposure of the infant. Package inserts are not reliable sources of information.<sup>173</sup>

## MULTIPLE SCLEROSIS

Studies historically have reported an increased risk for exacerbation in multiple sclerosis (MS) during the postpartum period but have not considered the impact of breastfeeding. A number of studies published in this century clearly demonstrate no relationship of breastfeeding to relapse. Exclusive breastfeeding and noncomitant suppression of menses significantly reduced the risk for postpartum relapses in MS in a large study by Langer-Gould et al.,<sup>160</sup> who called into question the forgoing of breastfeeding to start MS therapies.

Epidemiological characteristics of pregnancy, delivery, and birth outcomes in women with MS in Argentina (the EMEMAR study) also looked at breastfeeding. No evidence showed that breastfeeding increased relapses in the 79 mothers (76%) who breastfed. Argyrion and Makris<sup>19</sup> did a large literature review and concluded that breastfeeding and epidural anesthesia are not associated with increased incidence of postpartum relapses. In a study of 140 breastfeeding patients with MS and 35 patients with MS who did not breastfeed, significantly more otitis media, lower respiratory illness, constipation, milk intolerance, and allergy were seen during the first year in the nonbreastfeeding infants. The relapse rate was not increased in the breastfed group.<sup>100</sup> The discussion, however, continues; multiple small studies question results, but a large meta-analysis found no relationship to relapse and breastfeeding.

Patients may wish to start or resume therapy to decrease risks of exacerbation postpartum. The medication utilized is glatiramer (Copaxone). It is a mixture of polymers of four amino acids—L-alanine, L-glutamic acid, L-lysine, and L-tyrosine—and is similar to myelin. It has a large molecular weight, so it does not pass into the milk, and minimal oral bioavailability, so it would not be absorbed by the infants. It metabolizes into basic amino acids, which are already present in human milk. The mother receives the drug daily by injection because of its absent oral uptake. It is thus considered appropriate for use during lactation. There should be no hesitation to resume medication with glatiramer while breastfeeding.

The relationship between the mode of feeding in infancy and MS development in later life was examined by Pisacane et al.<sup>215</sup> Patients with MS were less likely than healthy control subjects to have been breastfed for a prolonged period. Of the 93 patients with MS and 93 control subjects, 76% of controls and 55% of patients with MS breastfed for 7 months or longer (odds ratio 0.38). In a study of 32 postpartum women with MS and 29 age-matched controls, it was observed that breastfeeding did suppress menses, but further breastfeeding lowered the risk for relapse.

Counseling a woman with MS regarding pregnancy should include discussion of the postpartum statistics. Breastfeeding is not contraindicated and newer work indicates that breastfeeding is protective.<sup>217</sup> It does allow a mother the opportunity to provide her infant with a special gift. Pregnancy and exclusive breastfeeding are strongly associated with low levels of 25(OH) D in women with MS. The lower levels of vitamin D were not associated with an increased risk of relapse of MS postpartum. The data suggest that low levels of vitamin D are not directly related to MS relapses.

A protective effect of vitamin D intake on risk for developing MS has been confirmed in the Nurses' Health Studies I and II, involving more than 238,000 women. It is further hypothesized that vitamin D supplementation will postpone or delay MS progression. Postpartum progression of MS may be related to vitamin D need in lactation and not lactation itself.

## *Psychologic Problems While Breastfeeding*

---

Early works, including those of Hippocrates in the Third Book of Epidemics from the fourth century BC, described the "mental derangements" of women who recently delivered and were breastfeeding. These disorders were considered to be etiologically linked to childbirth and lactation as a discrete disease entity. The women were described as febrile and toxic. With the introduction and liberal use of antibiotics, these symptoms disappeared. After the middle of the twentieth century, the incidence of infection and delirious reactions dropped precipitously. Some investigators now believe that no unique pattern of illness exists in puerperal compared with nonpuerperal women. Whereas childbearing might render certain predisposed women more vulnerable to an acute psychiatric episode, the pattern of mental illness in women in the perinatal period does not differ from that seen in other women or in men. The terms puerperal disorders and postpartum psychoses have been removed from the nomenclature.

What has often been suspected has now been proved by Eidelman et al.:<sup>77</sup> postpartum women have transient deficits in cognitive function, particularly in memory function. Test results on the Wechsler Logical Memory Test and the Wechsler Visual Reproduction Test were compared with results of similar, but nonpregnant, childless women, third trimester, high-risk pregnant women, and fathers of newborns. Intrapartum analgesics mitigated the cognitive deficit. These results should be considered in planning postpartum education.

Interest in the temporal relationship of the postpartum period to psychiatric disorders continues, however, especially because the incidence of mental illness is lower in pregnant women than in nonpregnant women matched for age, race, and socioeconomic status. The highest incidence of hospitalization for mental problems in women who are 15 to 44 years of age is 1 to 2 months postpartum.<sup>245</sup> Although the risk for mental illness increases fifteen-fold postpartum, most reviews never consider the distinction between mothers who breastfeed and those who do not. Elaborate

discussions of the influence of fluctuating hormone levels ignore lactation and the possible protective nature of the high levels of prolactin and oxytocin during lactation (Table 16-12).

Women who did not breastfeed or breastfed for less than 2 weeks had an associated increased risk for schizophrenia in the Copenhagen Perinatal Cohort. The authors<sup>245</sup> further hypothesize some protective effect of breastfeeding against the risk for later schizophrenia. The Copenhagen Perinatal Cohort includes 6841 women involved in the early weaning analysis. Other factors of socioeconomic status, single mother, and infant sex were ruled out.

The major clinical issue when significant mental illness occurs during breastfeeding is the question of medications. The use of lithium for bipolar disorders during lactation has been of concern because lithium does enter the milk, and lithium, in any dosage, has been considered a risk in an infant younger than 1 year of age. Infants have been reported to be hypotonic, flaccid, and "depressed" when the nursing mothers are taking lithium, whereas other infants have remained asymptomatic. The AAP has currently placed lithium on its acceptable in lactation list, but each case should be reviewed individually.

Lithium is a heavy metal and has pharmacologically unique properties. It is a small molecule, which crosses the placenta and into milk.<sup>40</sup> It is not protein bound and has a low volume of distribution. Milk/plasma ratios are 0.24 to 0.66. Levels in breastfed infants are one third of maternal levels, and infants receive about 0.1 mEq/kg/day. Toxic levels in the serum are 1.5 to 2 mEq/L. Lithium is excreted in the urine, so hydration is critical for breastfeeding infants, because renal clearance may be reduced in the neonate.<sup>268</sup>

Monitoring the infants is essential. Watch for symptoms of overdose, lethargy, hypotonia, and electrocardiographic changes. Blood levels can be quickly measured. No controlled studies have looked at breastfeeding infants of mothers taking lithium.

In a study of 147 postpartum women, 6 to 8 weeks after delivery of a normal, healthy infant, the Edinburgh, Montgomery-Asberg, and Raskin psychologic scales were completed. Fifteen percent of women were depressed on all three scales.<sup>85</sup> Significant correlations were seen between depression ratings and salivary progesterone and prolactin. Progesterone was positively associated with depression in bottle-feeding women and negatively associated in breastfeeding women. Prolactin levels

**TABLE 16-12** Timing of Onset, Symptoms, and Incidence of Material Psychologic Problems

Problem	Onset	Duration	Symptoms	Incidence
The "blues" or "baby blues"	3-5 days postpartum typically	A few days	Lability of mood; tearfulness; cognitive confusion; forgetfulness; headaches; depersonalization; negative feelings toward baby; restlessness; irritability; nightmares	30-84%; mean incidence across studies 55.75%
Postpartum depression	Within first postpartum year	At least 2 weeks, but usually longer	Tearfulness; despondency; feelings of inadequacy; numbness; suicidal ideation; sadness; reduced appetite and interest; insomnia; oversensitivity; feelings of helplessness and hopelessness; excessive dependency; anxiety and despair; irrational fears about infant's or mother's health	27% had depressive symptoms at 3-5 months postpartum 20% mild and 8% severe depression at 6 weeks postpartum; 40% mild and 17% severe depression at 12 months postpartum 12% major and minor depression combined at 9 weeks postpartum 10-14% experienced depression of clinical severity at 3 days postpartum 6.1% with major depression and 10.4% with minor depression at 8 weeks postpartum
Postpartum psychosis	Typically within 2-4 weeks or as late as 8 weeks postpartum	Depends on diagnosis and treatment prescribed	Heightened or reduced motor activity; hallucinations; marked deviation in mood; severe depression, mania, or both; confusion; delirium	1-2 per 1000 postpartum women

Modified from Kendall-Tackett KA, Kantor GK: Postpartum depression. In *Sage series in clinical nursing research*, Newbury Park, Calif., 1993, Sage.

were inappropriately low in depressed women who were breastfeeding. The authors suggest management should be different for breastfeeding and bottle-feeding women.<sup>108</sup>

Chlorpromazine or phenothiazine, used in psychotic disorders, appears in the milk in small amounts. Even at doses of 1200 mg, it does not appear to accumulate. Doses of 100 mg/day do not appear to cause symptoms in the infants. Fluoxetine (Prozac) appears in breast milk at one fourth to one fifth the levels in maternal plasma, and alternative therapies are recommended<sup>122</sup> (see Chapter 11).

Clinical experience with significantly depressed patients has shown that abrupt weaning from the breast may precipitate severe depression or even suicidal behavior. Whenever weaning is initiated in a woman with a psychiatric disorder, it should be initiated gradually and take place during 2 to 4 weeks or longer.

The impact of mental illness on the lactation process has been evaluated. Depressed mothers had more difficulties during breastfeeding than other women, and their attitudes were more negative. Depressed mothers complained more of too little milk or too much, of too much crying, of too little sleep, and of not getting enough support and help. It is difficult to determine cause and effect. Tamminen and Salmelin<sup>257</sup> noted frequent difficulties when they studied psychosomatic interaction between mother and infant during breastfeeding. They found that "depressed mothers in particular did not seem to understand that problems in nursing may be due to somatic rather than psychic reasons. Depressed mothers lacked satisfaction in the mother-infant relationship, failing to create reciprocity with their infant."

In assessing the relationship between infant-feeding method and maternal role adjustment at 1 month, studies find that women who breastfeed their infants have less anxiety and more mutuality; the adaptation of appropriate maternal behavior to the infant's state and behavioral cues, and the ability to adjust mothering activities to the infant's needs are improved.<sup>257</sup>

It is not possible with present knowledge to state definitely the impact of breastfeeding on the potential for mental illness in mothers, but breastfeeding clearly enhances mothering and mother-infant interaction and mutuality.<sup>200</sup> Under most circumstances, it is better to continue breastfeeding than to terminate it unnecessarily or prematurely.

## POSTPARTUM DEPRESSION

Much has been written in the lay press about the "baby blues," and many mothers, predominantly primiparas, will admit to a few hours or a day of

incredible emotional see-sawing in the first week after delivery (Table 16-12). Episodes in which a mother dissolves into tears when she has "so much to be thankful for" is the usual description. This is a transient state that has been attributed to the tremendous change in hormonal levels after the delivery of the placenta, although no studies confirm this belief. It is usually successfully treated with reassurance and rest. True postpartum depression does occur, however. Contrary to popular fantasy, it occurs in women who are breastfeeding, but usually only in women with a problem before pregnancy (Table 16-12).

Postpartum depression is not the baby blues, which have always been dismissed summarily as a transient reaction to hormonal change with a casual, "Buck up, girl, it's just baby blues." Postpartum depression is a crippling mood disorder that leaves a mother in fear, confusion, and silence. "Joy is not an option" for some women, according to Beck<sup>28,29</sup> (Figure 16-21).

Theme #	Theme
1	 Going to the movies: Please don't make me go!
2	 A shadow of myself: Too numb to try and change
3	 Seeking to have questions answered and wanting to talk, talk, talk
4	 The dangerous trio of anger, anxiety, and depression: Spiraling downward
5	 Isolation from the world of motherhood: Dreams shattered

**Figure 16-21.** Five essential themes of posttraumatic stress disorder due to childbirth. (Redrawn from Beck CT: Post-traumatic stress disorder due to childbirth: the aftermath, *Nurs Res* 53:216, 2004.)

Postpartum depression has been a catchall tag for many disorders. Misdiagnosis is common.

Postpartum panic disorder can occur for the first time after delivery. Panic attacks occur for brief intense periods, with extreme fear, palpitations, sweating, dyspnea, chest pain, dizziness, numbness, and even fear of death. Obsessive-compulsive disorder and bipolar disorder can occur postpartum and differ from the psychotic versions.

Postpartum depression is defined as five or more of the following symptoms for at least 2 weeks: insomnia or hypersomnia, psychomotor agitation or retardation, fatigue, changes in appetite, feelings of worthlessness or guilt, decreased concentration, and suicidality. Mothers who are depressed are less affectionate toward their infants and less responsive to their cries.<sup>112</sup>

Mothers with postpartum depression (Edinburgh Postnatal Depression score >12) at one week are more likely to wean by 4 to 8 weeks and be dissatisfied with their infant-feeding method, have breastfeeding problems, and report lower levels of breastfeeding self-efficacy. Findings were collected by questionnaires from over 500 postpartum mothers.<sup>65</sup>

A systematic review of the literature by Dennis and MacQueen<sup>66</sup> that identified 49 appropriate studies confirmed these findings. They concluded that postpartum depression results in poorer infant-feeding outcomes, including decreased breastfeeding initiation, duration, and exclusivity. There is need for early identification and treatment of postpartum women and breastfeeding mothers with depressive symptomatology to improve infant-feeding outcomes.

The incidence of psychiatric disorders during pregnancy is remarkably lower than age-adjusted rates in the general population. Rates in the postpartum period, however, increase dramatically to 1 to 2 per 1000, with 50% to 75% involving affective disorders, 10% to 20% schizophrenic illness, 2% to 12% organic psychiatric disorders, and 12% anxiety disorders.<sup>45</sup> Studies of clinically depressed postpartum women reveal that two of three have a major depression. With the introduction and use of antibiotics in the mid-1950s, many symptoms described as puerperal fever or milk fever, resulting in toxic-confusion or delirious behavior, no longer are reported.

A growing number of investigators have been unable to demonstrate significant evidence for a unique pattern of mental illness in puerperal compared with nonpuerperal psychiatric disorders. Although childbearing might make a woman more vulnerable to psychiatric stress, the patterns of illness symptomatology, course, and outcome are no different from those of nonpuerperal women or men. Prevailing views support a concept of

multifactorial causes or the summation of stresses. Factors of ambivalence or negative attitude toward pregnancy, primary role conflict, lack of emotional and practical support, and increased numbers of life events are all part of the picture.

The relationship between breastfeeding and depression was studied in mothers who totally breastfed and in those who totally bottle fed. No relationship was found between depression and feeding method. A prospective study following 103 women postpartum recorded a 13% incidence of marked postnatal depressive illness and an additional 16% of minor depressive illness of at least 4 weeks' duration. No correlation was made with method of feeding until the mothers were asked about their feeding methods and oral contraceptive use in an attempt to determine the influence of hormones on depression. The authors speculated that the prolactin, estrogen, and progesterone levels would vary with the amount of breastfeeding, amount of other foods consumed by the baby, and amount of hormones taken in the form of contraceptives.<sup>144</sup> In this study the women who bottle fed received estrogen and progesterone as contraceptives, but women who breastfed received only progesterone. Women who were totally breastfeeding and were not taking contraceptives were somewhat more likely to report depressive symptoms. Feelings of fatigue may have influenced this. The mothers least likely to be depressed were those who were likely to have normal hormonal levels, that is, partial breastfeeders not taking contraceptives. Clearly, breastfeeding women are not immune to postpartum depression.<sup>58</sup>

The impact of a mother's depression on her breastfeeding and nursing attitudes was reported by Tamminen and Salmeun<sup>257</sup> in a study of 119 healthy primiparous women using the Beck Depression Inventory attitude scales and other questionnaires. Eight percent of the participants were clinically depressed, but 25% did not return the questionnaire, which is possibly more common in depressed subjects. Depressed mothers had more difficulty with breastfeeding.

In a continuing study as part of a larger study, qualitative analysis of mother-infant interactions during breastfeeding showed depressed mothers to be less able to sense the infant's needs, cues, and problems.<sup>201</sup> Furthermore, they saw the problems in psychologic terms; that is, the infant did not want their milk or did not like it.<sup>257</sup> They did not understand that difficulties in breastfeeding could be somatic in nature. Depressed mothers achieved less satisfaction and mutual pleasure in breastfeeding.

The impact of postpartum depression on the emotional and cognitive development of infants was found to be adverse in several studies, because

depressed mothers are typically unresponsive to infant cues, which are manifest with flat affect or withdrawal.<sup>192</sup> Postnatally depressed mothers are likely to be socially isolated and emotionally unsupported. The relationship among family life events, maternal depression, and teacher and maternal ratings of child behavior up to age 6 years was reported. Both maternal depression and family life events made significant contributions to negative child behavior.<sup>189</sup>

The prevalence of postpartum depression varied between 7% and 14% during 34 weeks postpartum, based on the monitoring of a cohort of 293 women studied by Pop et al.<sup>216</sup> Peak incidence (14%) was at 10 weeks postpartum; in other studies the peak incidence has been as high as 40%. The symptoms of postpartum and other depressions are similar; however, the puerperium is a time of unique stress.<sup>213</sup> Table 16-12 lists major findings related to the "baby blues," postpartum depression, and psychosis.<sup>139</sup> The cause is uncertain, with hormonal change being a continuing theme. Other perinatal events have been noted to trigger true depression, especially negative birth experiences. At-risk infants, including premature infants, sick infants, and those with disabilities, are often triggers for maternal depressive episodes.<sup>216</sup>

Breastfeeding can be a source of distress for many new mothers who do not have a good support system at home, especially when no one knowledgeable about breastfeeding is available. The La Leche League International has made an enormous difference with their mother-to-mother program. Isolation often contributes to the depression, and having telephone contact with a League mother or resources such as a lactation consultant to assess the breastfeeding progress may be therapeutic.

The physician and other health care team members should be sensitive to the subtle signs and vague symptoms. When a woman says, "I am overwhelmed," "Nothing will ever be the same," or "I feel hopeless or out of control," the health care professional must listen to her. When she is anxious or nervous or has insomnia, especially waking in the early morning when she is exhausted, the professional must consider depression.<sup>139</sup> Use of a depression scale may be helpful when the mother answers general questions such as "How are things going?" with "Fine." A referral for professional psychiatric help or to a support program or hotline is the minimal response.

Studies support the recommendation that a primary care physician should identify the mother with depression using a simple inventory such as the 10-item Edinburgh Postnatal Depression Scale (EPDS) (Box 16-4). The EPDS has been validated and specifically designed for use by the primary

health care team during routine health care visits, and it relies on self-reporting.<sup>192</sup>

In a study conducted in the well baby clinic of a large teaching hospital, universal screening for postpartum depressive symptoms during the first year of an infant's life using the EPDS was administered at each well baby visit: 46% of visits had a filed completed form, 21% of completed forms had scores of 10 or greater, and 27% of all mothers who completed forms during the year had at least one score of 10 or greater (highly depressive symptoms). These clients were referred to social services. The authors concluded that pediatricians can play an active role in early detection and referral for postpartum depression.<sup>51</sup>

Appearing in the same journal was a report exploring maternal beliefs and perceptions about discussing the stress of parenting and symptoms of depression with their child's pediatricians. The population was from five community-based practices. The mothers were aware of the impact of their emotional health on their infants. Many were reluctant to discuss parenting stress and depressive symptoms with their child's pediatricians because of mistrust and fear of judgment. They liked open communication with their pediatrician and were receptive to written materials about parenting stresses and depression from their pediatrician, but did not want verbal counsel.<sup>111</sup>

The role of infant factors in postnatal depression and mother-infant interactions was evaluated in a large group of infants born to 188 primiparous women at risk for postnatal depression and a smaller group born to 43 mothers at low risk. By 8 weeks postpartum, poor motor scores and high irritability in the infants were strongly predictive of maternal depression. These factors also predicted less optimal infant behavior in face-to-face interactions with the mother at 8 weeks.<sup>187</sup>

When the crying behaviors of 3- and 6-month-old infants were compared, infants of depressed mothers cried significantly more per day than infants of nondepressed mothers at 3 months, but not at 6 months of age.<sup>187</sup>

A significant association exists with depressive disorder preceding the early cessation of breastfeeding, according to the results of two large, independent samples of puerperal women.<sup>53</sup> This was confirmed in a study in several large teaching centers, which examined the causes of early weaning, pointing out the effect of maternal depression and lack of clinical support.<sup>258</sup> Other factors associated with early weaning were low social class, low education, and young age of the mother. Depression is more common in winter in the Northern Hemisphere, when days are short and darkness is prolonged. The relationship of lower prolactin levels in the winter is not understood.<sup>209</sup>

**BOX 16-4 Edinburgh Postnatal Depression Scale (EPDS)**

The Edinburgh Postnatal Depression Scale (EPDS) has been developed to assist primary care health professionals to detect mothers suffering from postnatal depression, a distressing disorder more prolonged than the "blues" (which occur in the first week after delivery) but less severe than puerperal psychosis.

Previous studies have shown that postnatal depression affects at least 10% of women and that many depressed mothers remain untreated. These mothers may cope with their baby and with household tasks, but their enjoyment of life is seriously affected, and long-term effects on the family are possible.

The EPDS was developed at health centers in Livingston and Edinburgh. It consists of 10 short statements. The mother underlines which of the four possible responses is closest to how she has been feeling during the past week. Most mothers complete the scale without difficulty in less than 5 minutes.

The validation study showed that mothers who scored above a threshold of 12/13 were likely to be suffering from a depressive illness of varying severity. Nevertheless, the EPDS score should not override clinical judgment. A careful clinical assessment should be carried out to confirm the diagnosis. The scale indicates how the mother has felt during the previous week, and in doubtful cases it may be usefully repeated after 2 weeks. The scale will not detect mothers with anxiety neuroses, phobias, or personality disorders.

**INSTRUCTIONS FOR USERS**

1. The mother is asked to underline the response that is closest to how she has been feeling in the previous 7 days.
2. All 10 items must be completed.
3. Care should be taken to avoid the possibility of the mother discussing her answers with others.
4. The mother should complete the scale herself unless she has limited English or has difficulty with reading.
5. The EPDS may be used at 6 to 8 weeks to screen postnatal women. The child health clinic, postnatal check-up, or a home visit may provide suitable opportunities for its completion.

**EDINBURGH POSTNATAL DEPRESSION SCALE (EPDS)**

J. L. Cox, J. M. Holden, R. Sagovsky

*Department of Psychiatry, University of Edinburgh*

Name:

Address:

Baby's age:

As you have recently had a baby, we would like to know how you are feeling. Please UNDERLINE the answer which comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today. Here is an example, already completed.

I have felt happy:

Yes, all the time

Yes, most of the time

No, not very often

No, not at all

This would mean: "I have felt happy most of the time" during the past week. Please complete the other questions in the same way.

**IN THE PAST 7 DAYS:**

1. I have been able to laugh and see the funny side of things  
As much as I always could  
Not quite so much now  
Definitely not so much now  
Not at all
2. I have looked forward with enjoyment to things  
As much as I ever did  
Rather less than I used to  
Definitely less than I used to  
Hardly at all
- \*3. I have blamed myself unnecessarily when things went wrong  
Yes, most of the time  
Yes, some of the time  
Not very often  
No, never
4. I have been anxious or worried for no good reason  
No, not at all  
Hardly ever  
Yes, sometimes  
Yes, very often
- \*5. I have felt scared or panicky for no very good reason  
Yes, quite a lot  
Yes, sometimes  
No, not much  
No, not at all
- \*6. Things have been getting on top of me  
Yes, most of the time I haven't been able to cope at all  
Yes, sometimes I haven't been coping as well as usual  
No, most of the time I have coped quite well  
No, I have been coping as well as ever
- \*7. I have been so unhappy that I have had difficulty sleeping  
Yes, most of the time  
Yes, sometimes  
Not very often  
No, not at all
- \*8. I have felt sad or miserable  
Yes, most of the time  
Yes, quite often  
Not very often  
No, not at all
- \*9. I have been so unhappy that I have been crying  
Yes, most of the time  
Yes, quite often  
Only occasionally  
No, never

**BOX 16-4 Edinburgh Postnatal Depression Scale (EPDS)—cont'd**

*10. The thought of harming myself has occurred to me	Hardly ever Never
Yes, quite often	
Sometimes	

J. L. Cox, MA, DM, FRCP(Edin), FRCPsych, Professor of Psychiatry, Department of Postgraduate Medicine, University of Keele. Consultant Psychiatrist, City General Hospital, Stoke-on-Trent, formerly Senior Lecturer, Department of Psychiatry, University of Edinburgh (Correspondence to: University of Keele, Thornburrow Drive, Hartshill, Stoke-on-Trent, Staffs S177QB). J. M. Holden, BSc., SRN, HVCert, Research Psychologist. R. Sagovsky, MB, ChB, MRCPsych, Research Psychiatrist, Department of Psychiatry, University of Edinburgh.

\*Response categories are scored 0, 1, 2, and 3 according to increased severity of the symptom.

Items marked with an asterisk are reverse-scored (i.e., 3, 2, 1, and 0). The total score is calculated by adding together the scores for each of the 10 items.

Users may reproduce the scale without further permission, providing they respect copyright (which remains with the *British Journal of Psychiatry*) by quoting the names of the authors, the title, and the source of the paper in all reproduced copies (*Br J Psychiatry* 150:782, 1987).

Measurements of long-chain polyunsaturated fatty acids (LCPUFAs) in breast milk was done on the milk of 287 women enrolled in the Pregnancy, Infection, and Nutrition Study.<sup>138</sup> Levels were measured at <20 and 24 to 29 weeks in the mother and at 4 months postpartum in the breast milk. Multiple linear regression was used to examine association between depressive symptoms, as well as in the breast milk.<sup>138</sup> The authors express concern for early screening of LCPUFAs in the milk of depressed mothers and the nutritional value of their breast milk. Lower levels were found in pregnancy and associated with depressive symptoms, as well as in breast milk.

## POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder has now been described with childbirth.<sup>29</sup> It was first listed in the *Diagnostic and Statistical Manual of Mental Disorders* in 1980 following the Vietnam War. It has been defined as "direct personal experience of an event that involves actual or threatened death or serious injury or a threat to the physical integrity of self or others." The individual's response is one of extreme fear, helplessness, or horror, according to the American Psychiatric Association. The reported prevalence of posttraumatic stress following childbirth ranges from 1.5% to 6% of births. Mothers experiencing stress disorder with childbirth struggle to survive each day, while battling nightmares and flashbacks of the birth, anger, anxiety, depression, and painful isolation from the world of motherhood.

As more is learned about this devastating state, more will be learned about feeding choice and breastfeeding success.

## DYSPHORIC MILK EJECTION REFLEX

Dysphoric milk ejection reflex is described as a condition affecting lactating women that is "characterized by an abrupt dysphoria or negative emotions

that occur just before milk release and continuing not more than a few minutes." It was first identified and described by Alia Macrina Heise, who is a mother of three children, Certified Lactation Counselor, Certified Postpartum Doula, and a trained birth doula (<http://www.d-mer.org>). Hundreds of women have come forward describing similar experiences. The current belief is that the condition is due to inappropriate dopamine activity at the time of milk ejection. They have distinguished it from a psychologic response to breastfeeding, from nausea and headache and other physical manifestation, from postpartum depression, and from breastfeeding aversion. The dysphoria, or negative emotion, has been described as a churning in the stomach, a hollow feeling, dread, anxiety, and anger. The problem is that it is real, and it is all about let-down. It has been ranked mild, moderate, and severe, the latter often resulting in weaning. No research has been published yet, but clinicians need to be aware of this phenomenon. Natural herbal remedies have been suggested. Antidepressant therapy does not appear to help (<http://www.d-mer.org>).

# *Human Milk as a Prophylaxis*

---

## *The Natural History of Atopic Disease*

The association of allergy with cow milk has been documented in the literature for decades.<sup>25,52,71</sup> The incidence of this allergy in the general population has been noted to increase progressively since the original comments on the subject by Rowe<sup>74</sup> in 1931. The incidence has reportedly increased 10 times in 20 years. It has been attributed to increased recognition; increased incidence of exposure to known allergens; and a gradual decrease in infection as a source of morbidity, because the use of antibiotics and immunization revealed an underlying allergic component to chronic symptoms. Glaser<sup>31</sup> attributed this rapid increase in the development of allergic diseases to the abandonment of breastfeeding when safe, pasteurized milk became available. It was noted that 20% of all children were allergic by 20 years of age.

Studies of office pediatrics have shown that one-third of the visits are a result of allergy.<sup>87</sup> One third of all chronic conditions in patients younger than age 17 result from allergy and one third of lost school days from asthma. In the evaluation of 2000 consecutive, unselected newborns in pediatric practice, 50% had family histories of allergy. Gruelle et al.<sup>38</sup> observed, as early as 1934, that eczema was seven times more common in infants fed cow milk than in breastfed infants. McCombs et al.<sup>63</sup> reported in 1979 that asthma caused more than 2000 deaths and the loss of 94 million days of activity. It initiated 183,000 hospital admissions and more than 1 million hospital days in 1 year in the United States alone.

Asthma is the most common chronic disease of childhood, affecting an estimated 6.3 million

children, according to a Centers for Disease Control and Prevention (CDC) report in 2001.<sup>66,92</sup> These data indicate that, in the United States, people with asthma collectively have more than 100 million days of restricted activity and 470,000 hospitalizations annually, with more than 5000 deaths annually. Asthma hospitalization rates have been highest among black adults and children, with mortality rates consistently highest among black individuals ages 15 to 24 years. Asthma costs the American public billions of dollars every year. Decades of investigation have resulted in conflicting results. In a systematic review of the literature on how to prevent the development of food allergy,<sup>18</sup> there was one clear conclusion. Cow milk should be avoided for at least the first 4 months of life in children at risk for allergy. Maternal avoidance of allergens during pregnancy also produced conflicting results, except for the avoidance of cow milk during pregnancy when there was a family history. Maternal avoidance of cow milk resulted in lower levels of mucosal-specific IgA and a lower incidence of cow milk allergy in the infant.<sup>43</sup> The American Academy of Pediatrics (AAP) also agreed that cow milk and dairy products should be avoided in at-risk infants for the first year of life. The AAP and others have also declared that soy milk has no role in the prevention of allergy. The AAP is very supportive of breastfeeding for at least 6 months, as well as the delay in starting solids until 6 months.

Bone turnover is increased when mothers are on elimination diets that include cow milk, cow milk products, and eggs, even when they are on supplemental calcium. Mothers who were found to have some bone mobilization for 6 months recovered quickly when breastfeeding was discontinued.<sup>2</sup> Breastfeeding has increased in the new millennium. The incidence of allergy should diminish.

## The Question of Heredity

Heredity undoubtedly plays a part in the development of allergic disease, an observation first recorded by Maimonides in his Treatise on Asthma in the twelfth century. Most studies in the past 60 years have concurred with the concept of a recessive mode of inheritance.<sup>45</sup>

Kern<sup>51</sup> has noted that the outstanding etiologic factor in human hypersensitivity is heredity. He states that few diseases exist in which heredity is so clearly identified and so common.

Hamburger reported that children with two atopic parents had a 47% chance of developing atopic disease. One atopic parent meant a 29% chance of developing atopy, and the risk dropped to 13% with no allergic parent.

In a study of asthmatic monozygotic twins, Falliers et al.<sup>21</sup> observed similar serum immunoglobulin E (IgE), blood eosinophil counts, and positive skin tests to allergens in both twins. However, they had dissimilar responses to infection and methacholine. This finding suggests an acquired component to bronchial hyperactivity. Apparently several mechanisms are involved in antigen processing.

To identify infants at high risk for developing atopy, several approaches have been suggested. Cord serum total IgE levels of greater than 100 U/mL are associated with a five to ten times greater risk than lower levels. Eosinophilia and lymphocytes may prove to be markers, but, at present, only the family allergy history and the cord blood IgE have been significantly reliable predictors.<sup>9</sup>

In the 1930s, Glaser<sup>31</sup> speculated that if a child was at a high risk for developing allergy, prophylaxis should be able to change the outcome. The original work on prophylaxis was done by Glaser and Johnstone<sup>30</sup> and reported in 1953. Only 15% of a group of children whose mothers controlled their own diet in pregnancy and the infants' diets and environments at birth did develop eczema. In contrast, 65% of the sibling controls and 52% of the nonrelated controls who received cow milk developed similar allergic illnesses. As a retrospective study, it was open to some criticism, although it did begin to look at a significant issue—reducing the incidence of allergic manifestations in high-risk individuals by a new type of preventive measure: avoidance of known antigens.

A second study was designed and carried out prospectively by Johnstone and Dutton,<sup>46</sup> in order to investigate dietary prophylaxis of allergic disease. They observed a difference of more than 10 years in the incidence of asthma and perennial allergic rhinitis in those fed soybean milk (18%) and those fed evaporated milk (50%). No infant in this study of 283 children was breastfed,

however. A study of 1753 children fed breast milk, soy milk, and cow milk from birth to 6 months of age, who were followed until they were 7 years or older, was published. The children included those with high-risk, low-risk, and no-risk family histories for allergy. No difference in outcome was related to early diet, but a relationship to the family history was seen.

In a prospective study to identify the development of reaginic allergy, infants of allergic parents were placed in a study or control group. The study group followed an allergen-avoidance regimen, including breastfeeding. At 6 months and 1 year, the study infants had less eczema than the control infants, as well as lower serum total IgE levels.<sup>52</sup>

## Prophylaxis of Atopic Disease

Efforts to alter the incidence of atopic illness have continued to challenge investigators, who now have access to increased methodologic sophistication. Prevention of IgE-mediated disorders can be directed at the practice of interfering with any of the major forces responsible for the phenotypic expression of atopy. Practically, however, it is not yet possible to mask IgE genes or manipulate cellular components of the response organ. Clinicians are limited to manipulating the effect of the environment, by reducing the allergenic load.

Review of the plethora of studies directed at measuring the impact of dietary manipulations on the incidence of atopic disease demonstrates that retrospective studies show little or no difference in the incidence of asthma and eczema. Prospective studies, however, tend to demonstrate a significant reduction in atopic disease in the treated group (Table 17-1). In looking at these data, it is important to recognize that some studies did not consider the risk for the population developing atopic disease on a hereditary basis. In other studies, breastfeeding may have been carried out for only a few weeks or months.<sup>22</sup> The evidence is clear that exclusive breastfeeding for 6 months or longer makes a difference. None of these studies controlled for smoking in the household, and no data were reported on the incidence of respiratory syncytial virus. In addition, some studies did not control for the breastfeeding mother's diet, the weaning foods, or the use of cow milk beverages. However, when the long-term effects of breastfeeding, maternal smoking during pregnancy, and recurrent lower respiratory tract infections on asthma in children were examined, some discordance was observed. Breastfeeding for less than 3 months was not an effective deterrent. Breastfeeding reduced the effect of lower respiratory tract infections on asthma. Similarly, it reduced the effect of smoking.<sup>55</sup> The authors

**TABLE 17-1** Prevention of Atopy: Prospective Studies

Study	Year Published	No. of Years Followed	No. of Subjects*	Type of Milk/Feeding	Impact on Atopy <sup>†</sup>
Johnstone and Dutton <sup>12</sup>	1966	10	235	Soy, cow	↓ Asthma, rhinitis
Matthew et al. <sup>12</sup>	1977	1	53 (26)	Breast, soy	↓ Eczema
Chandra <sup>12</sup>	1979	>2	134	Breast	↓ Eczema, asthma

Kaufman and Frick <sup>12</sup>	1976, 1981	2	(94)	Breast	↓ Asthma
Hide and Guyer <sup>12</sup>	1981	1	843 (266)	Breast <6 mo, soy, cow (maternal diet not controlled)	↓ Eczema slight, rhinitis
Grusky <sup>12</sup>	1982	15	908 (328)	Breast 4 mo, soy, cow	↓ Breast symptoms; soy no effect
May et al. <sup>12</sup>	1982	1/2	67 normal	Soy, cow, modern formula	↑ Antibodies with no disease symptoms
Businco et al. <sup>12</sup>	1983	2	(101)	Breast <6 mo; soy, cow	↓ Asthma, eczema
Kajosaari and Saarinen <sup>12</sup>	1983	1	(135)	All breast milk <6 mo; half solid foods early	↑ Eczema/food intolerance in those fed solids
Moore et al. <sup>12</sup>	1985	1	525	Study—breastfed 3 mo; control—SMA	Not clear: 74% failed to breastfeed or gave cow milk in study group
Zeiger et al. <sup>12</sup>	1989	4	288	Maternal avoidance diet last trimester Controls unrestricted; mother's diet; infants given Nutramigen	↓ Atopy 16% in restricted infants ↑ Atopy in control infants (to 27%) ↓ Urticaria/GI symptoms in restricted group
Sigurs et al. <sup>12</sup>	1992	4	115	All breastfed; 65 mothers restricted diet for first 3 mo of lactation; 50 no restrictions	↓ Atopy/asthma among both groups ↓ Greater among restricted group

GI, Gastrointestinal. SMA, formula by Wyeth (no longer available).

\*Number in study; parentheses indicate number at risk for atopy.

<sup>†</sup>Arrows indicate decrease or increase compared with control group.

Modified from Businco L, Marchetti F, Pellegrini G, et al: Prevention of atopic disease in "at-risk newborns" by prolonged breastfeeding, *Ann Allergy* 51:296, 1983.

concluded that asthma in childhood can be prevented by promoting breastfeeding, preventing smoking in pregnancy, and avoiding recurrent lower respiratory tract infections in early childhood. Recurrent wheezing episodes were evaluated for associated risk factors.<sup>9</sup> Cigarette smoking in the household, heating mode (open stove), and breastfeeding for less than 6 months were significant.

Hamburger et al.<sup>41</sup> carried out prospective prophylactic studies to include measuring IgE and skin radioallergosorbent tests (RASTs) on mothers, fathers, and infants. They found a significant correlation between maternal IgE and infant IgE and potential allergy in the infants (Tables 17-2

and 17-3). This study was done by controlling the environment and the diet. The process was initiated in pregnancy, in order to begin by protecting the fetus, and was then continued at birth. Therefore, considerable attention was directed toward breastfeeding in this and other studies.

Human milk consistently contains antibodies, especially secretory immunoglobulin A (IgA), to major food proteins. The levels are influenced by the mother's own external antigen exposure.

In a study of 500 babies born to families at a high risk for allergies, one group was deliberately not given cow milk and was fed soy milk by random assignment.<sup>65</sup> No benefit resulted from withholding

cow milk, but breastfeeding, even for a short period, was clearly associated with a lower incidence of wheezing, prolonged colds, diarrhea, and vomiting. Smoking and environmental molds were also associated with wheezing. Merrett et al.<sup>65</sup> concluded from this that breastfeeding played a significant role in prophylaxis.

The effect of breastfeeding on allergic sensitization is both direct, through the elimination of nonhuman milk protein as an exposure to antigen, and indirect, by affecting the absorption of antigen through the intestinal tract.<sup>52,53</sup> Maternal antibodies are transferred to breastfed infants as part of what has been called the enteromammary immune system<sup>48</sup> (Figure 17-1). The secretory IgA antibody present in milk is the result of a mother's enteric immune response to antigens in her gut. Secretory IgA in a mother's milk provides protection against bacterial, viral, and toxic exposures. Prospective studies have shown that infants at a high risk for atopic illness,

**Figure 17-1.** Maternal serum antibodies affect passage of foreign antigens into milk and processing of antigen in infant's intestine. (Redrawn from Kleinman RE: The role of developmental immune mechanisms in intestinal allergy, *Ann Allergy* 51:222, 1983.)

from a hereditary standpoint, had significantly less disease when breastfed, especially if reared in a protected environment with delayed use of solid foods. This was compared with children of similar risk fed cow milk and regular solid foods. Serum IgE concentrations were also greatly reduced in infants younger than 6 months and 12 months of age in the breastfed group.<sup>89</sup>

Infants with a low incidence of T lymphocytes are at greater risk to develop allergies if fed cow milk rather than breast milk, according to Juto<sup>47</sup> and Juto and Bjorksten.<sup>48</sup> Infants with reduced T cells fed cow milk also demonstrated higher serum IgE levels and peripheral eosinophil counts. Juto<sup>47</sup> reported that with careful prophylaxis, more than 50% of infants who had both parents with IgE levels greater than 100 mg/mL showed elevated cord and 4-month IgE levels. More than 80% of those infants whose parents had IgE levels less than 100 mg/mL, however, had both low cord blood and low 4-month IgE levels. Such data confirm the genetic effect of both maternal and paternal genes.

Considerable work was reported from a laboratory in Newfoundland that promoted certain formulas as protective. This work has since been considered misleading.<sup>14</sup>

In a prospective study designed to examine asthma and atopy outcomes in male/female patients, Mandhane et al.<sup>62</sup> reported specific parental history of atopy and breastfeeding. The study members were born in New Zealand in 1972 to 1973 and followed to adulthood. Breastfeeding was considered positive if it lasted 4 weeks or more. There was no mention of exclusivity or when cow milk was introduced. Parental history was obtained.

Skin testing, spirometry, and bronchial challenge to methacholine was done from age 9 at intervals forward. They found that breastfeeding, in spite of its brevity, influenced development of atopy and asthma by sex and parental history. They found greater incidence of atopy in girls who were breastfed than boys who were breastfed and both who were bottle fed. They acknowledged the importance of a thorough breastfeeding history. The need to correlate the incidence of parental atopy, whose offspring were more likely to be breastfed, was also emphasized. Mai et al.<sup>61</sup> studied the relationship of breastfeeding, overweight, and asthma. They queried whether overweight and asthma shared common environmental influences, such as breastfeeding. They found that children who had been breastfed exclusively for less than 12 weeks had a risk for being overweight and of having asthma by 10 years of age. They also noted that they existed together but not separately. These mothers were obese in most cases, and the authors suggested that their obesity decreased their probability of successful breastfeeding. The long-term effects of maternal smoking during pregnancy and recurrent lower respiratory infections were associated with asthma in children. These effects were mitigated by breastfeeding in the long-term study of children in the Isle of Wight birth cohort.<sup>50</sup>

### *Long-Term Effects of Allergy Prophylaxis*

In an 18-month study of atopic outcome, atopic mothers were randomly allocated to an intervention group or an unrestricted-diet group, and both were compared with nonatopic mothers on unrestricted diets. The intervention was a milk/dairy product-free diet during late pregnancy and lactation. After 7 weeks of the diet, serum

$\beta$ -lactoglobulin and immunoglobulin G (IgG) levels in the mothers were collated to the levels in cord blood. The infants were examined at 12 and 18 months, utilizing a single-blind allergy assessment by a pediatrician. Infants born to nonatopic parents had significantly less allergy than those born to atopic mothers with unrestricted diets.<sup>58</sup> The "restricted-diet group" of infants had comparable levels to the atopy-free group and had significantly less allergy than the unrestricted-diet group. The nature of the parents' disease also played a role in the type of illness in both groups.

Mothers who consumed a diet similar to the Mediterranean diet, rich in fruits, vegetables, and fish and ample in vitamin D, showed greater impact on suppression of atopic disorders than those who did not.<sup>67</sup> The role of vitamin D has just been recognized as being important in lactating women, especially those with restricted diets. All breastfeeding women should consume at least 1000 units of vitamin D while lactating.<sup>55</sup> A prospective longitudinal study of 988 healthy infants, from birth to 6 years of age, recorded feeding-history episodes of lower respiratory tract infection in the first 3 years of life and recurrent episodes of wheezing.<sup>95</sup> Being breastfed was associated with lower rates of recurrent wheeze (3.1% vs. 9.7%,  $p < 0.01$ ) for nonatopic children. The authors concluded that recurrent wheeze at age 6 years is less common among nonatopic children who were breastfed as infants. This effect was independent of whether or not the child had a wheezing lower respiratory tract illness in the first 6 months of life (Table 17-4). These authors recorded smoking history, but it did not alter the compelling influence of breastfeeding on the outcome.<sup>95</sup>

Additional long-term studies have demonstrated that children who had ever been breastfed had a 50% lower incidence of wheezing than those who had not been breastfed. The effect persisted

**TABLE 17-4** Odds Ratios and Confidence Intervals for Recurrent Wheeze at Age 6 Years by Logistic Regression

Factor	Odds Ratio (Confidence Interval)*		
	Total Group ( $n = 970$ )	Nonatopic Children ( $n = 420$ )	Atopic Children ( $n = 280$ )
Not breastfed	1.49 (0.80-2.77)	3.03† (1.05-8.69)	1.36 (0.49-3.73)

for the 7 years of the study in nonatopic children.<sup>10</sup> The authors attribute this, in part, to breastfeeding's protective effect against respiratory illness. They did not distinguish minimal from prolonged breastfeeding.

In a 17-year prospective study of 150 healthy children, researchers did consider length of breastfeeding.<sup>75</sup> The three groups had been breastfed: less than 1 month or not at all, 1 to 6 months, or more than 6 months. Prolonged breastfeeding was associated with the least eczema at 1 to 3 years, as well as fewer food and respiratory allergies. At age 17 years, the trends continued, leading the authors to conclude that breastfeeding is protective against atopic eczema, food allergy, and respiratory asthma throughout childhood and adolescence<sup>75</sup> (Figures 17-2 and 17-3).

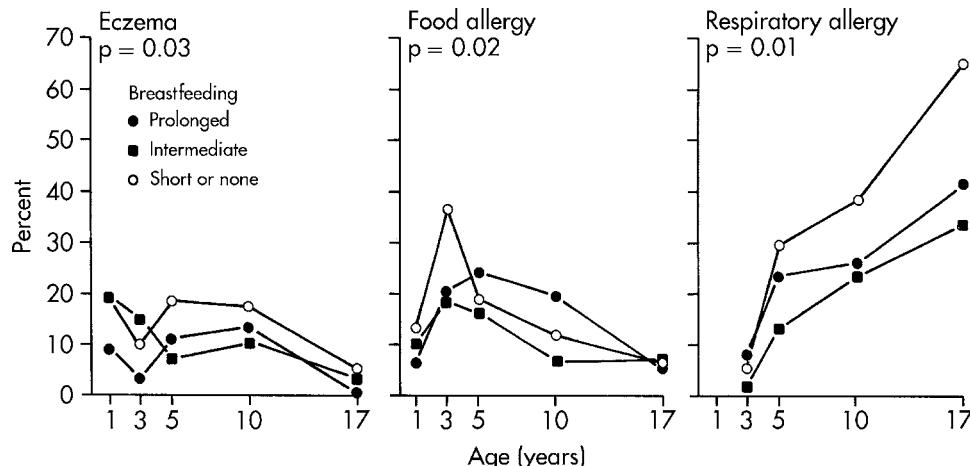

**Figure 17-2.** Prevalence of atopic eczema, food allergy, and respiratory allergy in full cohort of initial 236 children during follow-up for 17 years. ## RECOMMENDATIONS OF COMMITTEE ON NUTRITION AND SECTION ON ALLERGY AND IMMUNOLOGY OF THE AMERICAN ACADEMY OF PEDIATRICS<sup>16</sup>

The incidence of atopic disease, including asthma, atopic dermatitis, and food allergies, has increased in the past decade. Asthma at age 4 years has increased 160% and atopic dermatitis 200% to 300%. The literature and the research have been abundant, but evidence is hindered by inadequate study design. Prevention of disease by dietary restrictions in pregnancy and lactation have had limited attention.<sup>36</sup> The following statements summarize the available evidence within the context of these limitations. It is accompanied by an extensive bibliography that supports these statements.

1. At the present time, evidence is lacking for the assertion that maternal dietary restrictions during pregnancy play a significant role in the prevention of atopic disease in infants. Similarly, antigen avoidance during lactation does not prevent atopic disease. Eczema is a possible exception, although more data are needed to substantiate this conclusion.
2. For infants at high risk for developing atopic disease, evidence shows that exclusive breastfeeding for at least 4 months decreases the cumulative incidence of atopic dermatitis and cow milk allergy in the first 2 years of life. This is compared with the feeding of intact cow milk protein formula.
3. Evidence supports that exclusive breastfeeding for at least 3 months protects against wheezing in early life. However, in infants at risk for

**Figure 17-3.** Prevalence of atopic eczema, food allergy, and respiratory allergy in infant feeding groups during follow-up for 17 years. Tests for differences during the appropriate age periods (eczema 1 to 3 years, food allergy 1 to 3 years, respiratory allergy at 5, 10, and 17 years) were done by analysis of variance and covariance with repeated measures. (Modified from Saarinen UM, Kajossari M: Breastfeeding as prophylaxis against disease: prospective follow-up study until 17 years old, *Lancet* 346:1065, 1995.)

developing atopic disease, the current evidence that exclusive breastfeeding protects against allergic asthma occurring beyond 6 years of age is not convincing.

4. Studies were done of infants who were not breastfed exclusively for 4 to 6 months or were formula fed and were at a high risk for developing atopic disease. Evidence from these studies is modest that atopic dermatitis may be delayed or prevented by the use of extensively or partially hydrolyzed formulas, compared with cow milk formula, in early childhood. Comparative studies of the various hydrolyzed formulas have also indicated that not all formulas have the same protective benefit. Extensively hydrolyzed formulas may be more effective than partially hydrolyzed in the prevention of atopic disease. In addition, more research is needed to determine whether these benefits extend into late childhood and adolescence. The higher cost of the hydrolyzed formulas must be considered in any decision-making process for their use. To date, the use of amino-acid-based formulas for atopy prevention has not been studied.
5. No evidence is convincing to support the use of soy-based infant formula for the purpose of allergy prevention.
6. Solid foods should not be introduced before 4 to 6 months of age. However, no current evidence is convincing that delaying their introduction beyond this period has a significant protective effect on the development of atopic disease. This is regardless of whether infants are fed cow milk protein formula or human milk. This includes delaying the introduction of foods that are considered to be highly allergic, such as fish, eggs, and foods containing peanut protein.
7. For infants older than 4 to 6 months of age, data are insufficient to support a protective effect of any dietary intervention for the development of atopic disease.
8. Additional studies are needed to document the long-term effect of dietary interventions in infancy to prevent atopic disease, especially in children older than 4 years and in adults.
9. This document describes means to prevent or delay atopic diseases through dietary changes. For a child who has developed an atopic disease that may be precipitated or exacerbated by ingested proteins (via human milk, infant formula, or specific complementary foods), treatment may require specific identification and restriction of causal food proteins. This topic was not reviewed in this document.

Analysis of infant and maternal variables in the 6 year follow-up study of a cohort of U.S. children revealed that socioeconomic and atopic factors

were the most important predictors of probable food allergy at 6 years of age. Exclusive breastfeeding for 4 months or longer probably had a preventive effect on the development of food allergy after 1 year of age in non-risk children.

## *Immunologic Aspects of Allergy*

Interest in identifying the immunologic aspects of clinical allergy led to a number of additional studies on infant feeding.<sup>40,41</sup> Kletter et al.<sup>54</sup> reported that hemagglutinating antibodies to cow milk were present in the sera of some newborns but usually at levels lower than those of the mother. The earliest rise in titer was detected at 1 month, and a peak was seen at 3 months in infants given cow milk from birth. Antibodies belonged mainly to the IgG group, with their rise and fall paralleling hemagglutinating antibodies. IgA antibodies were in low titer, and IgM antibodies were rarely detected.<sup>60</sup> The delayed exposure to cow milk in breastfed infants resulted in lower mean values of cow milk antibodies. Peak values were attained more slowly. An inverse relationship exists between duration of breastfeeding and levels of titers of humoral antibodies.

Freed and Green<sup>23</sup> investigated antibody-facilitated digestion and its implications for infant nutrition. They suggest a model of digestion in which oligopeptides in the small bowel are bound to secretory antibodies, which hold them in contact with proteases. This facilitates the breakdown and utilization of the oligopeptides. They consider immunity and digestion to be closely related. Breastfeeding with colostrum and then mature human milk provides the immature gut of the infant with both immunity and "digestivity."

The presence of periods of transient IgA deficiency in saliva in the first 12 months of life has been identified as a possible risk factor for the development of asthma, bronchial hyperactivity, and atopy.<sup>33</sup>

Savilahti et al.<sup>77,79</sup> studied 18 patients with documented malabsorption of cow milk. They were improved by feedings of human milk after having challenges with powdered milk. Eight patients had clinical reactions; the number of IgA- and IgM-containing cells increased by approximately 2.5 times in the intestinal mucosa. When breast milk feedings resumed, the findings returned to normal. Serum antibodies of both hemagglutination and IgA increased. No change was seen in IgE antibodies or serum complement. Many other findings, including villous atrophy and round cell infiltration, were noted. After age 2 years, all the infants became tolerant of milk, which may indicate that immunologic immaturity is part of the

pathogenesis. Walker<sup>94</sup> presented similar arguments and conclusions in a symposium discussion.

When studying problems related to infant feeding, it is difficult to randomize groups to breastfeed or not. Many women with a strong family history of allergy are particularly adamant about breastfeeding. This was a factor in a study of 69 preterm infants and their subsequent allergic symptoms in childhood. A premature infant's intestine is also more permeable to proteins and their immune system more immature. The long-term incidence of atopy, however, was no different between the feeding groups at age 11 years, although those receiving breast milk had a strong family history of atopy.<sup>79</sup>

The low IgA content of milk, and the especially low colostral IgA, has been correlated with cow milk allergy in a group of 198 infants, seven of whom became allergic to cow milk.<sup>78</sup> All other measurements (immunoglobulins G, A, M; cow milk-specific antibodies;  $\beta$ -lactoglobulin) were similar among all 198 infants. The authors<sup>58</sup> suggest that an infant is more likely to develop cow milk allergy if the mother has insufficient protective factors, namely, IgA.

Some discrepancies among studies may be explained by measuring the concentration of bovine IgG in human milk using different methods. Levels were tested on the same milk samples using competition radioimmunoassay, competition enzyme-linked immunosorbent assay (ELISA), and sandwich ELISA. IgG levels were significantly higher using radioimmunoassay or ELISA.<sup>63</sup> Levels in the milk of mothers who went on a dairy product-free diet for a month still have measurable levels by radioimmunoassay and ELISA but not by sandwich ELISA.

Cantisani et al.<sup>14</sup> sought to resolve the question of the presence of specific secretory IgE for cow milk protein in the sera of breastfed infants who had never received cow milk. They measured secretory IgE in the sera of six breastfed infants with atopic dermatitis who were never in contact with cow milk. The secretory IgE to bovine  $\beta$ -lactoglobulin was not detected in any of the sera examined.

In the study of the role of heredity in allergy, unilateral family history was described as allergy in one parent and bilateral as involving both parents. Ninety-four infants were followed from birth for 24 months. Significantly more infants developed allergy if they were from a bilaterally allergic family. In the first 3 months, less atopic dermatitis occurred in the breastfed infants with unilateral history than with bilateral history. Businco et al.<sup>12</sup> presented similar relationships to family history in a study of breastfed infants.

These data are challenged by Murray's findings. Murray examined nasal-secretion eosinophilia in relationship to respiratory allergy, associated with a screening procedure for hearing loss. In a group

**TABLE 17-5** Some Diseases Possibly Preventable by Protecting Relatively Immunodeficient Infants From Adverse Antigen Experience

Disease	Status
Eczema	Established
Asthma	Probable
Hay fever	Probable
Infantile gut and respiratory infection	Probable
Intestinal allergy	Probable
Septicemia and renal <i>Escherichia coli</i> infection	Probable
Sudden death	Probable
Ulcerative colitis	Possible

From Soothill JF: Some intrinsic and extrinsic factors predisposing to allergy, *Proc R Soc Med* 69:439, 1976.

of children with a history of allergy in the immediate family, an association between the early introduction of solid food and the presence of a nasal secretion eosinophilia was significantly positive.

Although modern processing of cow milk has diminished the problem, it has not eliminated it. Given high-risk factors or strong family history of allergy, an effort to avoid unnecessary exposure to known allergens is an easy way to avoid some medical problems<sup>96</sup> (Table 17-5).

## The Role of Intestinal Flora in Allergy

Microbes are important in the Earth's ecosystems. They are important in overall health and especially in infants' health. At birth, infants, usually sterile, are colonized with the mothers' bacteria coming through the birth canal. First feeds affect the colonization of the intestinal tract. Breast milk supports the growth of *Lactobacillus* and *Bifidobacterium*, which, in turn, enhance the maturity of the gut and promote digestion and absorption. *Bifidobacterium* constitute up to 90% of an infant's intestinal microbiota. A healthy intestinal microbiota, established through breastfeeding, has been confirmed to reduce the risk for atopic disease. The composition of the intestinal bacteria is one of the major contributors to the development of immune functions in newborn infants, thus affecting the problem of allergies.<sup>37</sup> Maternal allergic status can alter the number of bifidobacteria a woman can pass on to her breastfed infant. Grönlund et al.<sup>37</sup> have shown that allergic mothers have a reduced bifidobacteria count, as do their breastfed infants. At the same time, investigators are looking at the role of probiotics in health and disease and, more specifically, in formula-fed infants. This is in an effort to change

the flora of the gut to the more physiologic bifidobacteria of the breastfed infant. The committee on nutrition and the section on gastroenterology of the AAP have released a clinical report on Probiotics and Prebiotics in Pediatrics, accompanied by a 110-item bibliography.<sup>16</sup> They affirm that human milk is a natural prebiotic. Breastfed infants have a preponderance of naturally occurring probiotic bacteria in their guts. They concede these bacteria are probably associated with a reduction in atopic eczema. They also suggest it is related to humoral immunity (T-helper 2 type) in infancy. In pregnancy, the cytokine inflammatory response profile is diverted away from cell-mediated immunity (T-helper 1 type). The risk for allergic disease may well be related to a delay in humoral immunity and an ultimate imbalance in T-helper 1 and T-helper 2 inflammatory responses. A study of 4031 subjects in 20 cohorts in Europe, Asia, and Australia was reported in a meta-analysis of clinical trials. Studies included 25 double-blind, randomized, and placebo-controlled trials. Probiotics were given prenatally and postnatally (10 studies), and directly to the child (9 studies). Atopic sensitization was measured by positive skin prick test or elevated serum-specific IgE level to any food or allergen. Asthma was diagnosed by physician or parent. Probiotics did not significantly reduce the prevalence of asthma or wheeze, although *lactobacillus* was associated with increased atopic sensitization, but not a reduction in the actual disease.<sup>20</sup>

A 7-year follow-up was done of a randomized controlled trial, where 184 Swedish children were given probiotic supplementation both prenatally and during infancy. All the children had a family history of allergic disease. At age 7 years, the children had a physical examination, a questionnaire, spirometry, and a measurement of fractional exhaled nitric oxide. An assessment of eczema, a skin prick, and IgE testing were also done. The outcomes of allergic diseases included symptomatic asthma, allergic rhinoconjunctivitis, allergic urticaria, or eczema in the previous year.

The probiotic and placebo groups did not differ long term, even though there was a transient effect of reduced risk of sensitization in infancy.<sup>1</sup> Other studies also report lack of effect of probiotics on eczema and allergy.

## *Patterns of Clinical Disease Associated With Cow Milk Allergy in Childhood*

Cow milk allergy affects 6% to 8% of infants younger than 3 years old. Many poorly defined illnesses and pathologic lesions have been associated with

the ingestion of milk, making clear diagnosis difficult. Definitions have been proposed by the American Academy of Allergy and Immunology and are described in a consensus paper,<sup>38</sup> as adapted by Anderson<sup>5</sup>:

- *Food intolerance* is an adverse reaction to the ingestion of a food related to an enzyme deficiency or metabolic or pharmacologic reactions.
- *Food adverse reaction* with unknown mechanism is an idiosyncrasy; no immunologic mechanism is associated.
- *Food allergy* or *food hypersensitivity* is an adverse reaction to food caused by one or more immune hypersensitivity mechanisms and is not confined to IgE.
- *Food anaphylaxis* reactions are immediate hypersensitivity involving the immunologic activity of IgE homocytotropic antibody and the release of chemical mediators that may be life threatening.
- *Anaphylactoid reaction* to food is an anaphylaxis-like reaction to food as a result of a nonimmune release of chemical mediators.
- *Food toxicity (poisoning)* is toxin from the food itself and not an immune reaction (e.g., scombrotoxic fish poisoning, botulism).
- *Pharmacologic food reaction* is a naturally derived or added chemical that produces a pharmacologic reaction (caffeine in coffee or sodas).

Symptoms associated with food allergy include asthma, eczema, urticaria, and rhinitis, as well as colic and failure to thrive with chronic respiratory and gastrointestinal disease.<sup>15</sup> Well-defined, but uncommon syndromes, including pulmonary hemosiderosis, bronchitis, protein- and iron-losing enteropathy, neonatal thrombocytopenia, and colitis, have been reported to result from cow milk allergy in both breastfed and formula-fed infants.<sup>15</sup> Sleep disturbances have been reported in a series of children evaluated with a prospective double-blind crossover design.<sup>49</sup> Another symptom, reported in two siblings, was insatiability despite adequate weight gain.<sup>19</sup> This was confirmed by history and reproducible reaction to dietary elimination and subsequent oral challenges.

The intestinal permeability test is a noninvasive but rigorous technique for detecting the deleterious effect of food on the intestinal mucosa of allergic children. It requires overnight fasting of 6 hours, test feeding, and nothing but water for an additional 5 hours to collect urine samples for analysis. A 1-month-old breastfed infant with a history of regurgitation, diarrhea, difficult feeding, and malaise did not respond clinically to the elimination of dairy products from the mother's diet.<sup>17</sup> When the intestinal permeability test was performed with the mother's milk before

and after dietary elimination of milk, no change occurred. When the mother eliminated pork and eggs, however, clinical and test results improved.

## Acute Reactions to Cow Milk in Breastfed Infants

Hippocrates and Gojen described classic cases of milk allergy.<sup>74</sup> External reaction to cow milk was first described in the literature in the nineteenth century and then by Schloss<sup>81</sup> in 1920 and Tisdale and Erb<sup>90</sup> in 1925. At that time, the reaction was noted to occur during the first feeding of cow milk, which was provided in an effort to wean from the breast at several months of age. The event included sudden crying as if in pain; swelling of the lips, tongue, and throat; stridor; and even generalized urticaria and wheezing lasting for up to an hour.

This type of cow milk allergy is the first of two types described by Gerrard and Shenassa<sup>27</sup> and others. The second type is the well-known reaction to large amounts of cow milk in a cow milk-fed infant and is manifested by vomiting, diarrhea, or colic. This second type is not associated with cow milk-specific IgE antibodies. It usually subsides over time. The acute anaphylactic reactions, however, are associated with  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, and casein immunity.

Schwartz et al.<sup>84</sup> studied 29 breastfed or soy formula-fed infants who had experienced acute urticarial reactions while being fed cow milk for the first time. One infant had the reaction in the newborn nursery, suggesting in utero sensitization. When charts were carefully reviewed, 16 infants were identified as having been given formula, often without an order, in the newborn nursery. Twelve could have been sensitized in utero or through the breast milk. The authors identified elevated serum IgE levels; positive RASTs for  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, and casein; and recurrent wheezing in 55% of infants (16 of 29).

In a follow-up study challenging this group of children with whey and casein hydrolysate products, Schwartz et al.<sup>84</sup> found that 69% had positive prick tests to whey hydrolysate and 38% were positive to casein hydrolysate. Children with reactions to cow milk and both hydrolysates had severe reactions, including urticaria, angioedema, and wheezing. Hydrolysates of cow milk protein are not, therefore, hypoallergenic. Breastfeeding with occasional small amounts of cow milk can be a major risk factor in the development of IgE-mediated cow milk allergy in the rare, susceptible infant. Early exposures may occur in utero, through the breast milk, or with inadvertent feeds. Schwartz suggests

that isolated cow milk not be given to exclusively breastfed infants in the newborn period.<sup>82,83</sup>

The study confirms the importance of heredity in this acute reaction by its occurrence in twins and human leukocyte antigen-identical siblings, as well as in children of 28 parent pairs (89%) also sensitive to cow milk. Genetic homogeneity could not be demonstrated by human leukocyte antigen typing.

A case of anaphylactic shock from cow milk hypersensitivity in a breastfed infant was reported by Lifschitz et al.<sup>57</sup> They describe three episodes of shock from two separate feedings of formula and one while breastfeeding. After a prolonged course and the diagnosis of colitis, associated with numerous eosinophils, the infant was able to breastfeed at 21 days of age without difficulty. This was after his mother had been placed on a cow milk-free diet. When challenged, however, with breast milk that was pumped and stored while the mother was still consuming dairy products, the infant went into profound shock. The child was finally stabilized on breast milk and meat-based formula. At 6 months, cereal was added to the diet. At 12 months, soy and cow milk were well tolerated.

Intrauterine sensitization and allergy in the newborn breastfed infant were described by Matsumura in Japan. Glaser<sup>32</sup> also identified that under certain conditions, an infant with a predisposition for allergy may become actively sensitized in utero because of the mother's overindulgence in certain foods during pregnancy. For example, Shannon<sup>86</sup> demonstrated the presence of egg antigen in human breast milk in 1922. Infants then responded to re-exposure with allergic symptoms on first contact with that same food.<sup>27,56</sup> Kuroume et al.<sup>56</sup> showed that with intrauterine sensitization, hemagglutinating antibody titers against lactalbumin and soybean in the amniotic fluid are high. They suggest using measurement of amniotic fluid as an instrument to predict future allergy. Infant colic associated with maternal ingestion of cow milk is discussed in Chapter 18.

Multiple studies continue to confirm the value of elimination diets in pregnancy for women at a high risk for having an allergic infant.<sup>13,24,42</sup> These studies not only report a significantly reduced incidence of symptoms in the infants but also a significant reduction in  $\beta$ -lactoglobulin-specific IgA and  $\alpha$ -casein-specific IgA levels in maternal serum and milk. Similar observations have been made with the elimination of egg. Consistently, breastfeeding was associated with reduced incidence of atopy in the infant with, and to a lesser degree without, dietary restrictions in mothers.<sup>26</sup>

Oral challenges must be physician-supervised for the diagnosis of food-allergic disease. In the case of an acute anaphylactic-type reaction that

lacks evidence of food-specific IgE for a food highly suspected of provoking the reaction, a physician-supervised challenge is indicated to reintroduce the food. This is done in case a skin/RAST test was false-negative.<sup>4</sup> In a technical review, the American Gastroenterological Association comments that breastfeeding is cost effective, but maternally ingested protein can elicit allergic symptoms in infants. Thus maternal dietary manipulation is required, which should be done to avoid expensive alternative formulas.

When Giovannini et al.<sup>28,29</sup> studied growth and metabolic parameters of infants fed special formulas for atopy prevention, they noted differences compared with infants who were exclusively breastfed. Lower body mass index values and higher blood urea nitrogen levels were seen at 3 months.<sup>28,29</sup> Plasma aminoacidograms showed higher essential amino acids but lower branched-chain amino acids. Furthermore, the plasma taurine levels were lower in the formula-fed infants, even though the formulas had added taurine. These observations have been confirmed by other investigators, who are most concerned about the elevated threonine levels.<sup>73</sup>

The allergens of specific foods ingested by the mother have now been identified in the milk. Cant et al.<sup>13</sup> found 49 eczematous infants who were solely breastfed to be sensitized to cow milk and egg protein; these researchers also concluded that infants can be sensitized by foods eaten by the mother. They were able to demonstrate ovalbumin in the breast milk of 14 out of 19 mothers, who were tested 2 to 4 hours after eating raw egg. This was whether or not their infants had tested positive to egg albumin.

Troncone et al.<sup>91</sup> collected samples of breast milk at various times after the mothers were fed 20 g of gluten, after a period of deliberate gluten avoidance. Gliadin was found in 54 of 80 samples; levels peaked at 2 to 4 hours. Gliadin could not be detected in maternal serum. The transfer of gliadin to infants through the milk could be one of the factors producing a protective effect, because breastfeeding is known to decrease the risk for celiac disease.<sup>34</sup>

## Allergies to Solid Foods

Foods ingested by a mother may present a problem for an allergic child. Well-known allergens have been discussed and include cow milk, bovine protein of any sort, eggs, and fish. In the hundreds of reports on children who develop atopy, eczema, and asthma in the first year of life, some authors claim restricting maternal diet prophylactically until a child is symptomatic is unnecessary.<sup>59</sup>

The increase in allergies to tree nuts is apparent even in breastfed infants. Peanuts (not tree nuts but legumes) belong to the same family as fenugreek, the ancient herb used a galactagogue. Mothers are taking large doses of fenugreek. Symptoms in the infants are usually colic, with and without diarrheal stools, fussiness, and crying. Stopping the fenugreek cures the symptoms. In a study of peanut allergies in children, 66% were boys, and 82% had a first-degree relative with atopy, including 68% with food allergy.<sup>35</sup> Median age of first exposure (known) was 14 months; median age of first reaction was 18 months. Children born before 2000 had the first reaction at 21 months; those born after 2000 had the first reaction at a mean of 14 months. It is recommended that children not be given peanuts in any form before the age of 3 years and that mothers of allergic children who are breastfeeding avoid peanuts. Allergy to tree nuts has been identified in breastfed infants whose mothers have ingested nuts on more than one occasion. Peanut allergy, in particular, can develop from skin contact and environmental exposure to the nut. Food protein-induced enterocolitis syndrome is commonly misdiagnosed as sepsis or a surgical abdominal emergency. The most common triggers are cow milk and soy milk, given directly or consumed by the breastfeeding mother. Rice, a food commonly thought of as "hypoallergenic" and given to highly allergic children, has now been identified as a significant cause of hemorrhagic colitis. In one report,<sup>64</sup> 14 children had 26 episodes of colitis, which was likely to be misdiagnosed. Rice caused more severe reactions than cow's milk or soy in this report.<sup>64</sup>

Timing of solid food introduction in relation to atopic dermatitis and atopic sensitization is a controversial topic. No evidence to date shows that delaying the introduction of solids beyond 6 months is beneficial.<sup>97</sup> The controversy dwells on the 4- to 6-month period. Prescott et al.<sup>70</sup> state that the rising rates of food allergies in early childhood reflect increasing failure of early immune tolerance mechanisms. They are concerned that the practice of delaying complementary foods until 6 months of age may increase, rather than decrease, the risk for immune disorders. They feel a critical window exists in development, when exposure to these allergens is tolerated. The window may be 4 to 6 months. They concede that favorable colonization and breastfeeding may promote tolerance. It is agreed that this issue needs study. Breastfed infants are, of course, exposed via breast milk to many flavors and some foods.<sup>3,70</sup> The Australian Society of Clinical Immunology and Allergy<sup>6</sup> states that previous allergy prevention strategies have been ineffective. They admit that more research is needed but recommend starting solids at 4 to 6 months but not beyond 6 months. They do not

recommend prophylactic avoidance of known allergens, in spite of family history (egg, peanuts, cow milk, etc.).<sup>6</sup> Allergic proctocolitis in the exclusively breastfed infant has been reviewed by the Academy of Breastfeeding Medicine, and a protocol has been developed.<sup>23</sup> The syndrome of allergic proctocolitis is increasing in the literature, wherein a group of exclusively breastfed infants develop bloody stools and colic but are otherwise well. The protocol describes the events, reviews the literature, and recommends prevention and management.

## *Recommendations*

1. If severe allergic proctocolitis is suspected based on any of the following:
  - Failure to thrive.
  - Moderate to large amounts of blood in the stool with decreasing hemoglobin.
  - Protein-losing enteropathy.
    - i. The infant should be referred to a pediatric sub-specialist (allergist or pediatric gastroenterologist) for diagnosis and treatment (III).
    - ii. While awaiting the appointment, begin an elimination diet in the mother, continuing her daily vitamins as suggested for all breastfeeding mothers, and adding calcium supplementation (1000 mg/day divided into several doses).
    - iii. In the majority of patients, it is reasonable and safe to continue breastfeeding through the elimination process while awaiting the appointment and thus to protect breastfeeding. However, if the hemoglobin or albumin level is significantly low (based on age-dependent published norms), the use of a hypoallergenic formula may be considered (III).
  - 2. If mild to moderate allergic proctocolitis is suspected based on the following:
    - Blood-positive stool or small amounts of visible blood in stool.
    - Weight gain and growth are normal.
    - Abdominal exam is benign; no abdominal distention or recurrent vomiting.
    - Stable hemoglobin and albumin levels (if measured).
      - i. The infant should continue breastfeeding. The mother should be started on an elimination diet, continue her daily vitamins as suggested for all breastfeeding mothers, and add calcium supplementation (1000 mg/day divided into several doses).
      - ii. The elimination diet trial for any given food or food group should be continued for a

minimum of 2 weeks and up to 4 weeks. Most cases will improve within 72 to 96 hours (II-2).

3. In cases of suspected mild to moderate allergic proctocolitis with improvement in response to maternal elimination diet:
  - Consider reintroducing the allergen back into the mother's diet.
  - If symptoms recur, the suspected food should be eliminated from the mother's (and infant's) diet until 9 to 12 months of age and for at least 6 months. Most babies/children will tolerate the offending allergen in the diet after 6 months "from the time of diagnosis," if at least 9 months old. For example, if a baby is diagnosed at 2 weeks, the food should be avoided until 9 to 12 months of age. In the rare circumstance that a baby develops allergic colitis at 5 to 6 months of age, the caregivers should wait a full 6 months (after diagnosis) to reintroduce. Therefore, the reintroduction would occur at at least 12 months of age, not at 9 months of age, or until the mother decides to wean, whichever comes first.
4. In cases of suspected mild to moderate allergic proctocolitis with no improvement in response to maternal elimination diet:
  - Consider introducing the allergen back into the mother's diet.
  - Breastfeeding may continue with monitoring of weight gain and growth.
  - Consider following hemoglobin and albumin levels if there is continued moderate degree of blood loss (blood is visible) in stools.
  - Consider use of pancreatic enzymes for the mother. Dosage is generally one or two capsules with snacks and two to four with meals, as needed, dependent on the baby's symptoms.
  - In severe cases with impaired growth, decreasing hemoglobin level, or decreasing serum albumin level, the use of a hypoallergenic formula may be considered; however, one should consider referral to a specialist.

## *The Impact of Early Feeding*

A multidisciplinary review of the literature (1966 to 2001) by a group of Scandinavian researchers was undertaken to assess the impact of early feeding in infancy and its impact on later atopic manifestations.<sup>93</sup> The early feeding modes were breast milk, cow milk, and/or formula. The search located 4323 articles; 4191 were eliminated because they lacked information on both exposure and health effects. The remaining 132 articles were analyzed in the

final analysis, and 56 were considered conclusive. The review group of 12 university scientists from Sweden, Norway, and Denmark concluded that breastfeeding seems to protect from the development of atopic disease. This effect was even stronger in children with atopic heredity. They further recommended that when breast milk is unavailable or insufficient, extensively hydrolyzed formulas are better than unhydrolyzed or partially hydrolyzed formulas to reduce the risk for some atopic manifestations.<sup>93</sup>

Once again, the definition of breastfeeding was important. Many articles that were included defined breastfeeding as any breastfeeding. Exclusive breastfeeding, as defined by the World Health Organization, meaning that no other food or drink be given, was critical to the analysis by these authors.

In an addendum to this article, these authors comment on two publications published after this review. They reported that, in a limited group of children, long-term breastfeeding by mothers with asthma may increase the risk for developing asthma.<sup>7,68,69,93</sup>

In a large study from Germany,<sup>3</sup> each week of breastfeeding increased the risk for eczema in children with atopic parents. In contrast, a large study from Australia<sup>61</sup> reported a protective effect of breastfeeding, unaffected by maternal asthma, atopy, or infection.

Van Odijk et al.<sup>93</sup> explain this apparent incongruity by the fact that maternal diets were not accounted for and that mothers' milk in Australia contains lower ratios of n5/n3 fatty acids. Considering reports by Jensen et al.<sup>44</sup> regarding fish oils, this is plausible (see Chapter 4).

The authors comment in their review that financial aid for the studies by formula companies seemed to show a bias. The original author was exposed for falsifying results that suggested that certain formulas were hypoallergenic and preferred over mother's milk.

The review was funded by grants from the National Institute of Public Health in Sweden and the Foundation for Research into Health Care and Allergy and the Swedish Council for Building Research. The article by van Odijk et al.<sup>93</sup> has an extensive bibliography. The authors provide the following consensus statement.<sup>93</sup>

For all children:

1. Exclusive breastfeeding reduces the risk for asthma. (Note: The definition of asthma is the author's definition.)
2. Any breastfeeding decreases the risk for recurrent wheezing. (Note: Recurrent wheezing is mainly caused by viral infection.)
3. These protective effects increase with the duration of breastfeeding up to at least 4 months.

4. The protective effects seem to persist at least during the first decade of life.
5. Breastfeeding protects against the development of atopic dermatitis.
6. Exposure to small doses of cow milk during the first days of life appears to increase the risk for cow milk allergy but does not affect the incidence of atopic diseases later on.

In children with atopic heredity:

1. The beneficial effects of breastfeeding seen in all children are particularly strong in infants with atopic heredity.
2. In addition, breastfeeding protects against cow milk allergy.
3. When breastfeeding is insufficient, extensively hydrolyzed cow milk formula, as opposed to nonhydrolyzed cow milk formula, reduces the risk for cow milk allergy.
4. Extensively hydrolyzed cow milk formulas also somewhat reduce the risk for developing atopic dermatitis and asthma or other wheezing.
5. Partially hydrolyzed cow milk formula also reduces this risk but to a lesser degree.

## *Recommendations for Management*

---

It has been suggested that for the first 6 weeks or so of life, the intestinal tract is immature anatomically and immunologically. The early absorption of protein macromolecules in young animals is well recognized.<sup>85</sup> The subepithelial plasma cells of the lamina propria mucosae and lymph nodes do not make IgA initially. Gradually, the levels increase until they reach adult values at 2 years of age. Children with a strong family history of allergy have a more prolonged deficiency of IgA, lasting 3 months or longer. The early introduction of foods other than human milk has been associated with a rise in antibodies in the blood and eosinophilia, as noted earlier. Providing infants with breast milk, so that they will not become sensitized to it, is the most direct way of dealing with the problem.<sup>29</sup>

The total approach to a potentially allergic infant involves exclusion of known common food allergens from the pregnant mother's diet and avoidance of products known to cause problems in members of that family<sup>88</sup> (Table 17-6). From birth to 6 months, the infant should receive no cow milk formula. In addition, the diet of the mother should be restricted, as in pregnancy, and the environment made as allergen free as possible. If not breastfed, the infant should receive hydrolyzed formula. Even though

**TABLE 17-6** Idealized Strategy and Mechanisms for the Prevention of Allergic Diseases in Humans

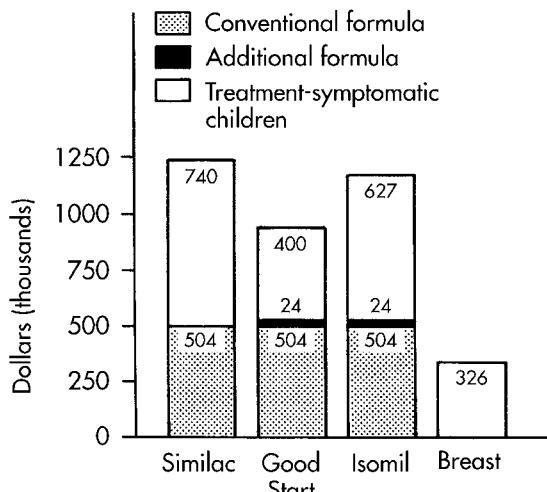

Strategy	Mechanisms
Identify at-risk families	Document IgE reactivity in parents with history of allergic disorders or with existing atopic child
Prevent intrauterine sensitization	Reduce maternal dietary allergenic load during last trimester, when potential for sensitization increases
Prevent postnatal sensitization to:	
1. Food allergens a. Transmitted through breast milk b. Ingested by infant	Continue maternal avoidance diet during lactation Withhold all non-breast milk foods except casein hydrolysate formula for at least 6 months
2. Environmental allergens	Encourage, instruct, and document avoidance of animals, mites, dust, and molds, as well as unnecessary medications
Maximize immunologic competence	Encourage, instruct, and support breastfeeding for at least 6 months
Minimize nonspecific enhancing factors	Discourage parental smoking; encourage avoidance of viral illnesses (?); delay pertussis immunization (?)

From Hamburger RN, Heller S, Mellon MH, et al: Current status of the clinical and immunologic consequences of a prototype allergic disease prevention program, *Ann Allergy* 51:281, 1983.

this regimen will not prevent all the potential for allergy, it will help to minimize the insults by foreign protein. Another compelling reason to consider prophylaxis is the costly medical care required for the affected individual<sup>13</sup> (Figure 17-4).

The possible alleviation of atopic eczema in a breastfed infant by maternal supplementation with a fish oil concentrate has been reported by Jensen et al.<sup>44</sup> A 6-week-old infant who had eczema from the first week of life, despite treatment, cleared when the mother, who was part of a study of effects of fish oil supplementation, began the supplementation. The eczema returned when the fish oil was stopped, and cleared again when the mother added fish to her diet.

This clinical experience has been corroborated in the laboratory. Essential fatty acids are important in promoting the renewal of the protective hydro-lipidic layer of the skin.<sup>22</sup> Altered essential fatty acid metabolism has been associated with atopic dermatitis.<sup>37</sup> Reduced levels of  $\gamma$ -linolenic acid and dihomo- $\alpha$ -linolenic acid appear in the plasma of patients with atopic dermatitis. The ratio of linoleic acid to the sum of its metabolites was found to

**Figure 17-4.** Estimated cost of management of symptomatic children with atopy in Newfoundland. Costs include physician fees, laboratory tests, hospitalization, and medication. For those fed Similac, cost of management until age 5 is \$740,000 per annum. Standard cow milk formula (e.g., Similac) during first 6 months of life for all infants with parental history of allergy would cost \$504,000. In those fed hydrolyzed formula (e.g., Good Start), cost is approximately the same as for standard formula but with savings of approximately 50% on management. An almost similar magnitude of reduction in allergic disease by feeding extensively hydrolyzed casein formula (e.g., Nutramigen) would cost three times more than in the cow milk group because of higher purchase value of such a formula. (Modified from Chandra RK: Five-year follow-up of high-risk infants with family history of allergy who were exclusively breast-fed or fed partial whey hydrolysate, soy, and conventional cow's milk formulas, *J Pediatr Gastroenterol Nutr* 24:388, 1997.)

be the relevant feature related to atopy. Increased marine fat consumption by a breastfeeding mother appears to improve the ratio of polyunsaturated fatty acids,<sup>11</sup> although this treatment has not been incorporated into routine care.

Human milk is a carrier of biochemical messages through its hormones, growth factors, cytokines, and whole cells.<sup>76</sup> Nucleotides, glutamine, and lactoferrin have been shown to influence gastrointestinal development and host defenses. Basically, three separate processes are involved in the reaction of the immune system toward allergen challenge.<sup>8</sup> Deregulation in each of them may increase the susceptibility to developing gastrointestinal allergy. It is speculated that breast milk may help to shift the balance toward tolerance, rather than sensitization, when the infant is exposed to an allergen.<sup>8</sup>

## Use of Pancreatic Enzymes

A novel treatment for allergic colitis, i.e., bloody diarrhea and colic in the breastfeeding infant, is the use of pancreatic enzymes by the mother.

The rationale for this treatment is that pancreatic enzymes will further break down the potential protein allergens in the maternal GI tract. Dosing is begun with the lowest dose of pancreatic enzyme (e.g., pancrelipase Creon® 6 in the United States or Kreon® in Europe, provided by Abbott Laboratories). There are 6000 USP units of lipase, 19,000 USP units of protease and 30,000 USP units of amylase.<sup>72</sup> Two capsules are taken with meals and one capsule with snacks. If necessary, doses can be doubled. No double-blind, controlled studies have been reported since Repucci first recommended this therapy. There are many reports of successful treatment. Schach and Haight have reported excellent results.<sup>80</sup>

Walker<sup>94</sup> summarizes his extensive research on the subject, by stating that antigens have been shown to cross the intestinal barrier in physiologic and pathologic states. He further states that it is most important to prevent excessive penetration of antigens, in patients who are susceptible to the disease, by implementing the following steps:

1. Identify the population at risk.
2. Encourage breastfeeding in infancy.
3. Decrease antigen load with elemental formulas.
4. Continue to conduct direct research at identification and prevention.

## Summary

The role of prophylactic management in pregnancy and the initiation of breastfeeding at birth have a major impact on the long-term incidence of reactive airway disease. Beyond the medical risks, the high cost of medical management must be considered when an infant is not breastfed.

## CHAPTER 18

# *Employment and Away from Home Activities while Breastfeeding*

---

Mothers are the fastest-growing segment of the labor force. Maternal employment has become more common in developed countries. Mothers who work and continue to breastfeed have also become more common. Part of the reason for this trend is the need for a second income in young households. Among professional women, the age of childbearing has been delayed to the 30s and early 40s, when a woman has established a career she wants to continue. Another reason for the increase of breastfeeding among employed mothers has been the exhaustive efforts by the United States Breastfeeding Committee, the Division of Nutrition Physical Activity and Obesity at the Centers for Disease Control and Prevention (CDC),<sup>37</sup> and the Center for Food Safety and Applied Nutrition of the Food and Drug Administration (FDA). The development of the Business Case for Breastfeeding campaign has been accomplished by their combined efforts. The Center for Economic and Policy Research reported on Parental Leave Policies in 21 countries, emphasizing their generosity, gender equality, the level of support provided to the parents, and the degree to which leave policies promote egalitarian distribution between mothers and fathers of the time devoted to child care. All 21 countries studied protect at least one parent's job for a period of weeks, months, or years at the birth of a child. Leaves vary from 14 weeks in Switzerland to over 300 weeks (about 6 years) in France and Spain. The United States is 20th out of 21, providing 24 weeks combined for both parents.

Switzerland also provides financial support of 80% of a mother's earnings.

In terms of money, most countries provide direct financial support between three months and one year at least for part of the protected leave time. The United States is one of two countries that provide a generous financial baby bonus but no paid leave; Australia is the other.

The Gender Equality Index is a single measure to examine the effect of parental leave policies on both the workplace and care giving. Sweden rated highest and the United States fell in the middle in terms of equality of gender in the workplace. Best practices require a generous, universal, gender-equalitarian, and flexible parental leave policy, financed through social insurance. There are states in the United States that provide some benefits but none provide generous benefits by international standards.

The issues of working women are no longer in the shadows. They are on the minds of federal legislators who are considering legislation to improve work environments, family leave, and accommodations for breastfeeding.<sup>38</sup> The Patient Protection and Affordable Care Act was signed into law in March of 2010; it includes an amendment to section 7 of the Fair Labor Standards Act (FLSA). This amendment requires employers to provide reasonable break time for an employee to express breast milk for her nursing child for a year after the child's birth.

Employers are required to provide a place, other than a bathroom, that is shielded from view and free

**TABLE 18-1** Select Elements of the Reasonable Break Time for Nursing Mothers Legal Provisions

Elements	Specifics
Time and location of breaks	<ul style="list-style-type: none"> <li>Provide a reasonable amount of break time to express milk as frequently as needed by the nursing mother.</li> <li>A bathroom, even if private, is not a permissible location.</li> <li>The location must be functional as a space for expressing breast milk.</li> <li>A temporarily created space is sufficient, provided it is shielded from view and free from any intrusion by coworkers and the public.</li> </ul>
Coverage and compensation	<ul style="list-style-type: none"> <li>Employers with &lt;50 employees are not subject to break time requirement if compliance with the provision would impose an undue hardship.</li> <li>“Undue hardship” is determined by looking at the difficulty or expense of compliance for the employer.</li> <li>Employers are not required to compensate nursing mothers for breaks taken for the purpose of expressing milk.</li> <li>If employers already provide compensated breaks, and an employee uses such times to express milk, she must be compensated in the same way that other employees are compensated for break times.</li> <li>The employee must be completely relieved from duty, or else the time must be compensated as work time.</li> </ul>
Fair Labor Standards Act prohibitions on retaliation	<ul style="list-style-type: none"> <li>It is a violation to discriminate against any employee because such employee has filed any complaint under or related to this act.</li> <li>Employees are protected regardless of whether the complaint is made orally or in writing.</li> </ul>

Abridged from the Fact Sheet #73, Wages and Hours Division, U.S. Department of Labor.

from intrusion from coworkers and the public, which may be used by an employee to express breast milk. The break time requirement became effective when the Affordable Care Act was signed into law on March 23, 2010. The Wage and Hour Fact Sheet #73 is available from the U.S. Department of Labor Wage and Hour Division ([Table 18-1](#)).

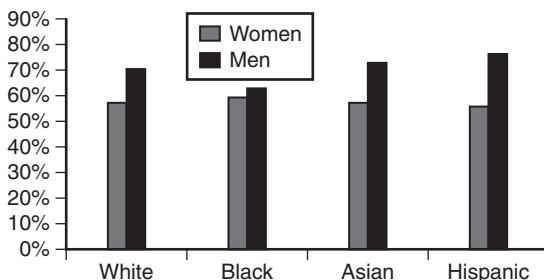

Low income women who are predominantly minorities (black and Hispanic) return to work earlier and to jobs that do not accommodate breastfeeding. The barriers in the workplace include inflexible schedules and lack of support from employers and colleagues.

There were 127.1 million working age women (16 years of age or older) in the United States in 2013 and 72.7 million were in the labor force. Of that number, 99.5 million were white, 16.6 million were black, 7.1 million Asian, and 18.7 million Hispanic ([Figure 18-1](#)). By 2022 it is projected that women

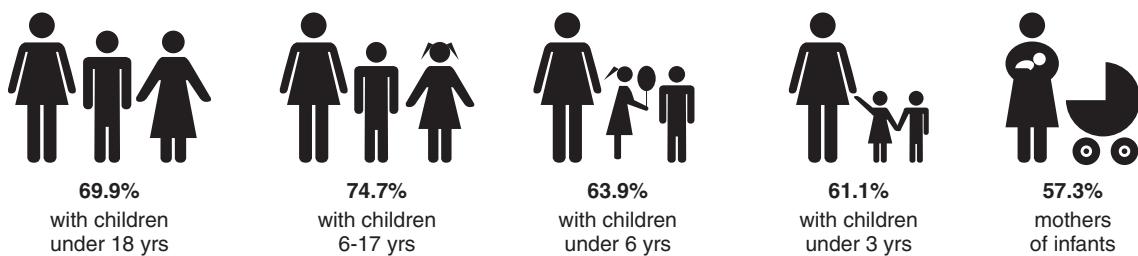

in the work force will increase by 5.4% compared to a 5.6% increase in the number of men. Women are expected to reach 46.8% of the labor force in 2022. The labor force participation rate of mothers with children under 18 years of age in 2013 was 69.9%, 74.7% for mothers with children 6 to 17 years of age, 63.9% for mothers with children under 6 years of age, 61.1% for mothers with children under 3, and 57.3% for mothers with infants ([Figure 18-2](#)). Of employed women, 74% worked full time (35 hours or more) and 24% worked part time compared to 86.9% and 13.1% of employed men. The largest percentage of employed women were in education and health services (36.2%), wholesale and retail trade industry (13.1%), professional and business services (10.5%), and leisure and hospitality (10.3%).

Education was a major factor with the over 64 million women 25 or older in the labor force; 6.7% had less than a high school diploma, 25.3% had no more than a diploma, 17.5% had some college, and 37.8% had a bachelor's degree or higher. The overall women-to-men ratio of earnings is 82.1%, with white women only 81.7% while black women are 91.3%, Hispanic women 91.1%, and Asian women only 77.3%.

Maternal employment, however, has been cited by many authors as the major reason for the decline in breastfeeding worldwide. International data do not actually support this conclusion. Year after year the Mothers Survey <sup>34</sup> in the United States confirmed that the highest percentage of women initiating breastfeeding in the hospital is among women who plan to return to full-time employment, the

**Figure 18-1.** Labor force participation by sex, race, and Hispanic ethnicity, 2013 annual averages. (Data from U.S. Department of Labor, Women's Bureau, <http://www.dol.gov/wb/stats/recentfacts.htm> (Accessed 12.05.14).)

**Figure 18-2.** Mothers' participation in the labor force. (Data from U.S. Department of Labor, Women's Bureau, <http://www.dol.gov/wb/stats/recentfacts.htm> (Accessed 12.05.14.).)

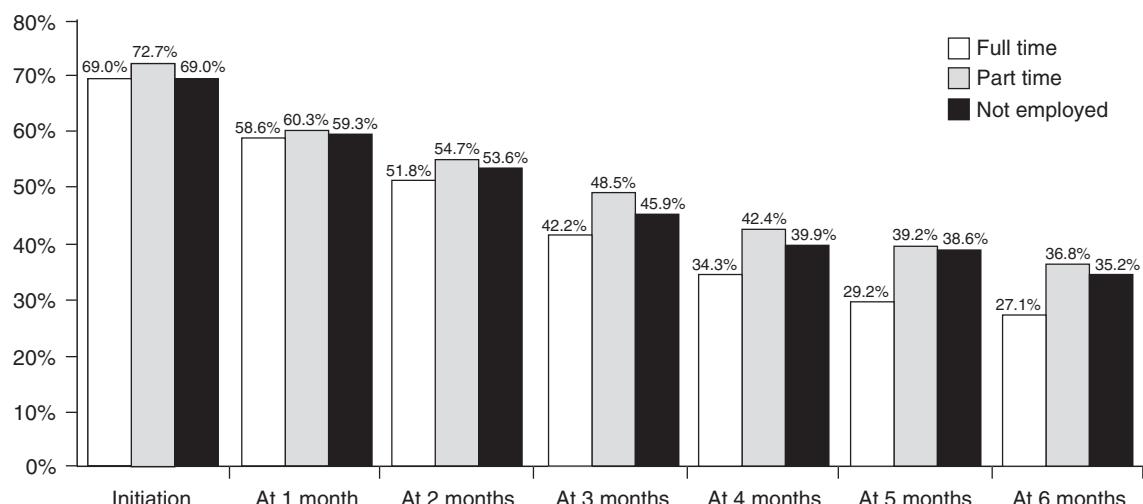

next highest among women who plan to return to part-time employment, and the lowest among those who plan to remain at home.<sup>34</sup> In 2002, initiation in the hospital was 69% among women fully employed, 72.9% among those employed part time, and 69% among those not employed. The duration, however, is affected by employment, with 36.8% of those employed part time still breastfeeding at 5 to 6 months, 35.2% of nonemployed women still breastfeeding at that point, and only 27.1% of those employed full time still breastfeeding at 5 to 6 months<sup>34</sup> (Figure 18-3). A mother who chooses to return to work and breastfeed is confronted by significant constraints, regardless of the statistical data. Although economic, cultural, and political pressures often confound decisions about infant feeding, the American Academy of Pediatrics (AAP) firmly adheres to the position that breastfeeding ensures the best possible health and the best developmental and psychosocial outcomes for infants.<sup>4</sup> Enthusiastic support and involvement of all physicians in the promotion and practice of breastfeeding are essential to the achievement of optimal infant and child health, growth, and development.<sup>4</sup>

The American College of Obstetricians and Gynecologists (ACOG) and the American Academy of Family Practice have made equally strong statements.<sup>3,5</sup>

## Historical Perspective

In modern cultures, a stigma has been attached to a mother earning money while her children are young, but no such stigma is associated with leaving her children for social interaction, personal reasons, or a volunteer job. All women work when work is defined as expending energy for a purpose, but not all women are employed when it is defined as earning money for labor. Before industrialization, working mothers were the rule and not the exception. Home and work were separated by industrialization, making parenting a separate role for women.

Women's work has been described as domestic or productive, public or private, traditional or modern. Domestic work, when performed for the family, is unpaid, thus undervalued, and not considered

**Figure 18-3.** Comparison of breastfeeding duration rates during first 6 months postpartum among mothers who are working full time, working part time, and not employed. (From Ross Products Division, Abbott Laboratories: *Mothers survey: updated breastfeeding trends through 2002*, Columbus, Ohio, 2002, Abbott Laboratories.)

productive work. Domestic work is performed in the private domain, and "productive" work is associated with the public domain. Women had previously worked in agriculture and cottage industries as well as in small-scale marketing, whereas today they participate in formal work (i.e., they are employees), including clerical, factory, and professional jobs, predominantly in urban settings.

More women are employed outside the home today than previously. In 1900, 20% of the labor force were women; in 1950, 29%; in 1997, 56.6%; in 2003, 57.5%; and in 2008 (at the onset of a recession), 59.9%. Women with children younger than 6 years old are the fastest-growing segment of the female work force; their numbers reached 59% in 1992 and more than 65% in 1996 but dropped to 59.4% in 2002 and 63.6% in 2008. Even more important is that the number of employed mothers with infants younger than 1 year old rose to 48% of all women in 1985 and has continued to climb. Many more women facing the decision about infant feeding methods must include early return to work in their considerations. In 1998, at least 50% of women employed in the United States when they became pregnant returned to the labor force by the time their children were 3 months old. U.S. Department of Labor statistics show that 54.3% of mothers with children younger than 1 year old were in the work force in 1996 and 57.3% in 2008. This figure rises to 63.3% for women with children younger than 2 years of age. In Australia, 27% of women with infants younger than 1 year old return to work and 49% of women with children younger than 5 years old are part of the paid work force.

Generations ago, the woman who worked violated the Victorian norms of role definition. Even when forced to work by sheer necessity, she was accused of neglecting her primary responsibility to her children. The new ethic proclaims work a cardinal virtue for liberated women, so that now women who can and do stay home may begin to feel inadequate.

Knowing why women enter the work force is important to understanding the trend. Before 1970, the need to earn money motivated 3 million women either because the woman was a single parent or because husband-fathers were unable to earn an adequate income. For women whose husbands earned "enough," there was the desire to have a higher standard of living or to provide the father with greater freedom of career choice. Few women sought employment for the sake of having a career because the need for income was the only socially acceptable, defensible reason for a mother to work outside the home.

Since that time many women have found that the full-time care of a home leads only to higher standards of cleanliness with no greater sense of

achievement or completion. Some believed that the exclusive investment of energy and emotion in the rearing of one to three children would involve a considerable hazard not only to a mother, but also to her children's ultimate achievement and ability to form a variety of responsive and satisfying personal relationships.<sup>26</sup> Women are responding to the pressures of a depressed economy, to the costs of higher education, to the opportunities for personal fulfillment, and to the growing market for service occupations.<sup>8</sup> Married women continue to carry at least 70% to 80% of the child care and household duties when both parents work.

Women have reached the point where marriage in itself has relatively little effect on the labor supply, according to Cohen and Bianchi. Educational differentials in the labor market have grown over time, widening the gap between more educated and less educated women, giving the former greater opportunities.<sup>32,33</sup>

## *Attitudes of Health Care Professionals Toward Working Mothers*

---

Professional and lay<sup>22</sup> books alike on child rearing have viewed working negatively except for economic necessity, thus enhancing a working mother's guilt and providing little substantial advice about how to balance or how to continue breastfeeding.

The AAP strongly states that pediatricians should "encourage employers to provide appropriate facilities and adequate time in the workplace for breast-pumping."<sup>4</sup> The AAP provides extensive recommendations for a mother to prepare for returning to work and maintaining her milk supply when she does return.<sup>36</sup>

The ACOG<sup>5</sup> has acknowledged the current trend to work throughout pregnancy and to return to work promptly after delivery by preparing a physician's guide to patient assessment and counseling, which has not been updated since 1987. ACOG also provides a patient occupational questionnaire for the practitioner. This forms a basis of discussion with a patient and provides an opportunity to counsel the patient and her husband about plans to maintain a healthy environment and any special needs for child care. With few exceptions, "the normal woman with an uncomplicated pregnancy and a normal fetus, in a job that presents no greater potential hazards than those encountered in normal daily life in the community, may continue to work without interruption until the onset of labor and may resume working several weeks after an uncomplicated delivery."<sup>5</sup> An obstetrician has a role in

facilitating continued breastfeeding after the return to work or school. This includes counseling regarding pumping and storing milk and avoiding exhaustion (**Tables 18-2** and **18-3**).

Physicians play an important role in guiding parents with information about quality and availability of child care facilities and with advice about coping strategies. Multiple studies have demonstrated the affect of clinician support and duration of breastfeeding.<sup>40</sup> As the family counselor, a physician can support mothers and fathers seeking to fulfill parental, occupational, and personal needs in a rapidly changing society. With the firm recommendation of the AAP to breastfeed throughout the first year and beyond, support from pediatricians will be critical.<sup>4</sup>

## Attitude of Employer and Employees Toward Working Women

Studies of employer attitudes toward working mothers, and specifically toward women who need accommodation to breastfeeding and to pump, reflected lack of knowledge. When employers understood the benefits of breastfeeding, attitudes changed.

Personal experience with breastfeeding had the greatest impact. Almost all at the managerial level were unaware of the existence of company policy. It appears that the greatest progress in supporting breastfeeding in the workplace has come when it has been mandated by state or federal policy.

Employers who accommodate lactating mothers can fear negative reactions from other workers. In a large U.S. corporation that provided a wide variety of accommodations for lactating mothers, 407 employees were studied by Suyes et al.<sup>39</sup> They observed that overall attitudes were favorable. Those who had previous exposure to a work colleague who was breastfeeding were associated with a positive attitude even after the investigators controlled for respondent's gender, length of employment, and personal exposure to breastfeeding. The authors concluded that lactation accommodations did not have a negative impact on the work environment or other employees.<sup>39</sup>

A program directed at the male employees has been functioning at the Los Angeles Department of Water and Power since 1990. There has been a full-time, on-site lactation program offered to the male employees. In addition to classes and individual instruction, information is available on the electronic pump and the pump kit and its use. Meetings with a lactation consultant and daily assistance for the mother when needed also are offered. It has grown by word of mouth, fathers' interest in the benefits of breastfeeding for the infant, and the female partners' interest in obtaining a free pump rental. It is a model that could well be implemented in any corporation.

## Outcome for Children of Employed Mothers

Numerous studies since the early 1930s have looked at the effects of maternal employment. Assessment of infant behavior, school achievement and adjustment, children's attitudes, adolescence, and delinquency have all been used as outcome measures.<sup>12</sup> Annotated bibliographies covering the range of research in areas of medicine, psychology,

sociology, and education are available.<sup>11</sup> The four major considerations are the variables that facilitate or impede maternal employment, the effect of maternal employment on children during the four developmental stages, the effects on the family, and the effects on society in general. Society is far more accepting of working mothers in the twenty-first century.

It has been emphasized that the presence of a mother in the home does not guarantee high-quality mothering. It has also been shown that well-educated (college) mothers, including those who are employed, spend time with their children at the expense of their own personal needs.<sup>18</sup> Because employed mothers encompass a large group of women with different educational levels, different reasons for working, and different opportunities for employment, it is difficult to generalize about effects. Literature reviews have emphasized critical factors that are more important than maternal employment, such as good substitute care, maternal role satisfaction, family stability, paternal attitude toward maternal employment, and the quality of the time spent with the children.<sup>17</sup> Despite the abundance of research on school-age children, there is still little reported about preschoolers because no school records or test results are available to use in large-population analysis.

To date, there is no direct effect of nonexclusive mothering per se. Studies of infants of adolescent mothers have shown that the children do better socially and academically if there are multiple caregivers instead of the adolescent mother alone.<sup>23</sup> No uniformly harmful effects on family life or on the growth and development of children have been demonstrated. Maternal employment may jeopardize family life when the conditions of the mother's employment are demeaning to self-esteem, when others are strongly disapproving of her work away from the home, or when arrangements for child care are not adequate.

Questions have been raised about the impact of separation of mother and infant and the timing of this separation.<sup>8</sup> Resumption of full-time employment when the child is younger than 1 year old has prompted studies. Using the Ainsworth "strange situation" validated techniques, no relationship between maternal work status and the quality of the infants' attachment to their mothers is reported.<sup>1,2</sup> Early resumption of employment may not impede development of a secure infant-mother attachment. A significantly higher proportion of insecure attachments to fathers in employed-mother families is reported for boys but not for girls. Boys are more insecurely attached than girls in most studies. It is believed that an infant's attachment relationship to mother emerges at approximately 7 months.<sup>14</sup> Other studies suggest

that maternal employment can have a positive effect on girls but not boys. Whether breastfeeding accounts for some of the variability in these studies is not stated.<sup>43</sup> No study recorded feeding method or considered the impact breastfeeding has on the mother-infant relationship or the infant's development. One of the strategies suggested is to advocate for infant care centers that provide breastfeeding facilities in the workplace, schools, and other locations serving working women.

## Breastfeeding and Employment

An important distinction must be made between work that separates mothers and infants for blocks of time and work that does not. In rural settings, women's work is usually compatible with all aspects of child care, including breastfeeding. Work in or around the home is usually flexible. If there are provisions for infants at the workplace, even formal urban work is compatible with child care and breastfeeding. The higher the education of the mother and the more advanced the job, the more opportunity exists for flexible arrangements that permit breastfeeding. Among the strategies available is pumping and saving milk while on the job to be fed to the baby by the babysitter the next day.

Overall, the breastfeeding rates for working women do not show that breastfeeding and employment are mutually exclusive. In Finland the incidence of mothers breastfeeding at 1 month is 78% among nonemployed and 80% among employed mothers. The duration is also unaffected: 29% of nonemployed and 32% of employed mothers are breastfeeding at 3 months, and 8% and 7%, respectively, at 6 months. Similar statistics are reported from Nigeria, the Philippines, and Chile.

An infant feeding practices study reported that those mothers at 6 months who were employed full time numbered 22,316 (26.6%), part time 12,186 (14.5%), and not employed 49,483 (58.9%). The same proportion (55%) of employed mothers as not employed mothers were breastfeeding when they left the hospital. Only 10% of full-time employed mothers were breastfeeding at 6 months compared with 24% of those who were not employed, however. The highest incidence of breastfeeding at birth and at 6 months was among mothers older than 30 years who are well educated and in a higher socioeconomic group. In 2002, the duration of breastfeeding at 6 months was as follows: of those mothers employed full time, 27.1% were breastfeeding, of those employed part time, 36.8% were breastfeeding, and of those not employed, 35.2% were breastfeeding—not a remarkable rate for those at home. At 6 months,

42.3% of women older than 30 years were still breastfeeding; those with a college education were at 44.6%.<sup>43</sup>

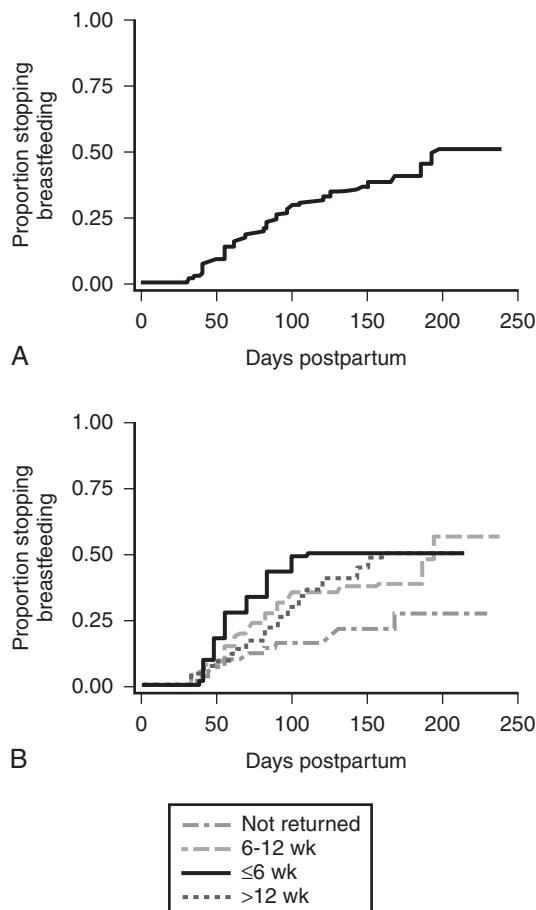

Although there was no association between planning to be employed within the first 6 months and initiation of breastfeeding, there was a significant association with cessation of breastfeeding as early as 2 to 3 months postpartum, even with adjustment for demographics. Among employed mothers, working 20 hours a week or less was protective for continuation of breastfeeding. When the factors influencing the duration of breastfeeding at 6 months were examined by postal questionnaire in Edinburgh, only 5 of 116 mothers listed "return to work" as a reason for discontinuing.

Employment among black women around Johannesburg, South Africa, after the birth of a baby strongly influenced duration of breastfeeding. Although 97% had initiated breastfeeding, only 30% continued for 20 weeks; duration of breastfeeding had a direct association with return to work because these women did not consider it feasible to do both. Similar findings were reported in Washington, District of Columbia, where 80% of black women worked during pregnancy and those who planned to return to work part time only were more likely to breastfeed.<sup>21</sup> In this study, those who returned to a professional occupation had a longer duration of breastfeeding than those who returned to sales or technical jobs, regardless of whether the individual was black or white.<sup>34</sup>

Although work has been listed as the primary cause of early weaning, women seldom give employment as a reason for terminating breastfeeding. A review of the world literature documenting reasons for weaning, starting bottle-feeding, or not initiating breastfeeding rarely mentioned employment. In studies of the effect of mother's employment on the nutritional status of her children, poverty, not mother's work, was associated with poor nutrition.

The effect of employment on the duration of breastfeeding may be influenced by the fact that breastfeeding can be carried out while a mother performs other tasks around the house so that it is easier to breastfeed when she is home. Many studies have found that employment has little or no effect on the duration of breastfeeding, especially where cottage industry was prevalent.<sup>6</sup> The greatest problems are the difficulties encountered finding a place to pump and store the milk on the job. Those women who work outside the home must schedule and plan carefully and are motivated to continue once the complex schedule is established. They also are more able to accommodate themselves to the stresses involved (Figure 18-4).

In times of economic downturn, work patterns are influenced by money. More women feel forced to return to work for economic reasons. Thus more

**Figure 18-4.** Breastfeeding cessation, Kaplan-Meier failure assessment. **A**, All subjects; **B**, According to length of maternity leave. (From Guendelman S, Kosa JL, Pearl M, et al: Juggling work and breastfeeding: effects of maternity leave and occupational characteristics, *Pediatrics* 123:e38, 2009.)

women with less flexible jobs find it impossible to handle the job, the home, the baby, and breastfeeding. As a result, returning to work or inability to combine work and breastfeeding appears as a reason for early weaning.

In a study in Canada, monthly semistructured interviews were conducted with 61 mothers who intended to continue breastfeeding after returning to work.<sup>27</sup> Maternity leaves in Canada vary from 17 to 37 weeks. Mothers were hesitant to commit themselves to continuing to breastfeed because they believed too many factors were beyond their control despite elaborate plans and backup plans. The authors<sup>27,29</sup> concluded that financial constraints, increased education, and professional preparation were forcing women back to work in greater numbers, but few could manage to continue to breastfeed because there were no accommodations in the workplace. When the final results were reported, 36 of the 61 mothers successfully

combined breastfeeding and work for a mean of 18 weeks.

The introduction of a bottle at 2 weeks of age for 4 weeks before returning to work was studied by Cronenwett et al. In a prospective study of 121 women who were committed to at least 6 weeks of breastfeeding, the mothers were randomly assigned to the "add-a-bottle" group or to the exclusive breastfeeding group. Some of the mothers pumped and gave their own milk by bottle. The mean breastfeeding duration for both groups exceeded 6 months, although there was a slight difference in rates between the two groups at 12 weeks. The most important predictor of duration of breastfeeding was the mother's goal. The authors saw no evidence that a single daily bottle in the early weeks was incompatible with prolonged breastfeeding in women committed to breastfeeding. Mothers who returned to work in the early postpartum period were likely to wean earlier. The conclusion in this study was that no evidence supports the "nipple confusion" hypothesis because the infants went back and forth between breast and bottle without difficulty.

## **IMPACT OF STRESS ON MILK SUPPLY**

The stability of a milk supply is an individual matter. Some women can cope with extreme pressures and maintain an abundant milk supply, whereas other women find milk production to be volatile. In the early weeks of lactation, the effect of external factors is much greater, but fatigue is consistently the most detrimental factor to milk production.

## **THE WORKPLACE**

Pumping milk at work has been identified as a critical element in the successful return to work for women who work full time outside the home. In a report of over 500 mothers, it was observed that mothers who expressed milk one or more times a day while away were less likely to stop breastfeeding before 6 months. When the problems in the workplace that interfered with pumping and continued lactation were studied by Slusser et al.,<sup>38</sup> it was observed that a mother expressed milk twice a day when the infant is 4 months old and less when the infant is 6 months old. The mother spent a total of less than an hour a day in the process of pumping, usually divided in two sessions. Pumping facilities at work that are readily accessible are critical for a successful breastfeeding support program.<sup>38</sup>

Although working mothers are common, companies who make working mothers comfortable are still uncommon. Efforts to increase parental leave, even unpaid leave, have not been widely established, although laws requiring minimal parental leave have been passed and have been applied to

both parents. In the interest of equality, institutions have established family leave to provide for other family needs; care of elderly parents is an example.

Some major companies, however, have been recognized by *Working Mother* magazine's annual survey as making some efforts to support mothers in the workplace.<sup>47</sup> The yardstick includes everything from the number of female vice presidents to fair advancement and equal pay for equal work. No company has been nominated for its support of breastfeeding, although maternity leave policies are considered important. The 2003 report of the Eighteenth Annual Survey named JFK Medical Center, King's Daughters Medical Center, Pittsburgh County Memorial Hospital, and St. Mary's Medical Center in the top 100 companies, but none were in the top 10, even though hospitals should be the model workplace. The top 10 included pharmaceutical houses Abbott Laboratories and Eli Lilly (best in the industry). Hospitals employ a number of professional women in their childbearing years as physicians, nurses, therapists, psychologists, laboratory technicians, and child life specialists.

A significant contribution could be made by allocating space and providing staff for daycare centers.<sup>40</sup> This would allow mothers to interact with their infants and breastfeed them during the work day. Small experiments providing daycare have shown a decrease in tardiness and absenteeism and a general increase in job satisfaction among employees who are mothers. For hospitals, where highly skilled and trained staff require as much as 6 months of costly on-the-job training, daycare has been shown to be cost effective for reducing turnover.

Physicians who serve as consultants to large and small industries, unions, not-for-profit agencies, and daycare centers are in important positions to influence corporate trends, which are changing slowly. In a study of Women, Infants, and Children (WIC) program employees, it was hypothesized that WIC employees would initiate and continue breastfeeding at significantly higher rates than the national averages because there has been a major breastfeeding campaign at WIC in the past decade.<sup>46</sup> Six Los Angeles WIC agencies participated; 99% of WIC employees began breastfeeding and 68.6% continued to 1 year. Key variables that contributed to the outcome were (1) intention to breastfeed for a year, (2) delayed use of formula, (3) breastfeeding support groups, and (4) availability of pumps at the worksite. Thus it was proved that full-time employment and breastfeeding are compatible if the worksite is supportive.

The welfare-to-work program, a central theme of welfare reform, requires recipients to engage in work, even mothers whose newborns are only a few months old, decreasing the incidence of breastfeeding. The

negative consequences of these requirements were studied by Haider et al.<sup>15</sup> They indicate that the national breastfeeding rate would have been 5.5% higher at 6 months in 2000 without this mandate. They further suggest that the negative consequences of this policy should be considered because the potential benefits of breastfeeding these at-risk infants are so great.<sup>15</sup>

A comparison of maternal absenteeism and infant illness rates among breastfeeding and formula-feeding women showed breastfeeding reduced absenteeism.<sup>10</sup> In two corporations with on-site lactation programs, one had 100 births among 2400, and the second had 30 births among 1200 female employees. Of the 101 mother-infant dyads studied, 59 were breastfed and 42 formula fed. The company provided lactation counseling as well as pumping and storing facilities. Of the 28% of the infants who had no illnesses, 86% were breastfed and 14% formula fed. Among mothers who were absent because of infant illness, 75% were formula feeding and only 25% were breastfeeding (Figure 18-5).

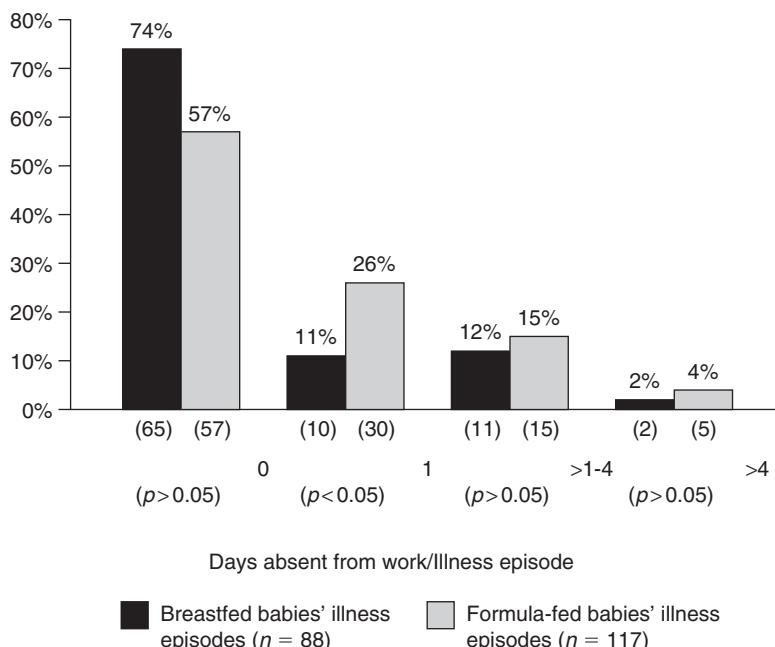

After a mail panel questionnaire study in which questionnaires were sent in late pregnancy and 10 times during the first year, mothers' work patterns were clarified. Working full time at 3 months decreased breastfeeding duration by 8.6 weeks relative to not working. Part-time work for 4 hours or less per day did not decrease duration of breastfeeding; part-time work more than 4 hours per day decreased breastfeeding duration only slightly. The authors concluded that part-time work is actually a good

strategy to help mothers combine breastfeeding and work.

Planning to return to work before 6 weeks postpartum reduced the likelihood of initiating breastfeeding in a study of more than 10,000 mothers of singleton term infants.

Most of the studies concerning employment and breastfeeding were retrospective, relied on voluntary responses, and did not clearly define breastfeeding in terms of exclusivity or working in terms of part time or full time. A prospective study reported by Kurinij et al.<sup>21</sup> involving more than 1000 women confirmed the reports of others that women with professional occupations breastfeed longer than nonprofessionals and that part-time work is more conducive to longer duration than full-time jobs. Both groups of women found equal satisfaction from breastfeeding. The duration of breastfeeding was evaluated in a separate study in the same two corporations mentioned previously. Cohen et al.<sup>9</sup> reported that of the 187 participants, 75% who returned to work breastfed for 6 months or longer. The average duration for breastfeeding was 8.1 months. These rates were equal to the statistical norms for the region among women not employed outside the home.

The general consensus has been that returning to work diminishes breastfeeding. As the number of women who work outside the home increased and breastfeeding increased in the last decade, the trends have changed. A large study of U.S. mothers found that initiation rates among mothers who were not working after childbirth compared

**Figure 18-5.** Distribution of illness episodes and maternal absenteeism by nutritional groups. (Modified from Cohen R, Mrtek MB, Mrtek RG: Comparison of maternal absenteeism and infant illness rates among breast-feeding and formula-feeding women in two corporations. *Am J Health Promot* 10:148, 1995.)

with mothers who were working part time were not different.<sup>35</sup> In 2001 to 2003 it was estimated that 67% of mothers of first children worked during the pregnancy, and most of them held full-time jobs.<sup>19</sup>

The Infant Feeding Practice Study II (IFPSII) was conducted by the FDA with the CDC from 2005 to 2007. It was a longitudinal study of women from late pregnancy through the infant's first year of life.<sup>24</sup> Similar to IFPSI conducted in 1992 to 1993, over 1400 mothers were involved. The expected number of hours she planned to work was used to categorize each dyad. The actual number of hours worked and baby's age at onset of work were categorized along with demographics, length of maternity leave, past breastfeeding experience, hospital experience, and degree of social support at home. This study showed that compared to not expecting to work, expecting to work less than 35 hours was not associated with breastfeeding initiation. Expecting to work full time, however, decreased breastfeeding initiation. Returning to work within 12 weeks, regardless of hours worked, was associated with less breastfeeding. Returning to work after 12 weeks but working more than 34 hours per week was also associated with shorter breastfeeding. The authors conclude that longer post partum leave and part-time work promote breastfeeding.<sup>24</sup>

The Early Childhood Longitudinal Study-Birth Cohort utilized a sample of singletons whose mothers had responded to a survey and had worked the 12 months before delivery. The study included 6150 women and classified them by the length of their maternity leave. Almost 70% initiated breastfeeding, which was not influenced by paid maternity leave. Those who returned to work within 1 to 6 weeks were less likely to initiate breastfeeding. Duration of breastfeeding was impacted by time of return to work. Those returning to work at or after 13 weeks were more apt to breastfeed for 3 months or longer.<sup>30</sup>

The dilemma every woman faces, whether breastfeeding or bottle-feeding, is leaving one's child. Mother's milk in a bottle given by any of several staff members at daycare is not equal to nursing at the breast. The decision to work or not work is a personal one and does not separate women into good and bad mothers. The role of the health professional is to discuss the mother's plans nonjudgmentally and assist her in adjusting her infant and herself to the process.

## COUNSELING BREASTFEEDING MOTHERS WHO CHOOSE TO WORK

The AAP periodic survey of members that included questions about breastfeeding was conducted in 2004 and results were compared with a similar

survey taken in 1995. Pediatricians in 2004 were less likely to believe that the benefits of breastfeeding outweigh the difficulties or inconveniences. Pediatricians with personal experience were much more likely to be supportive. Personal experience seemed to mitigate poor attitudes.

Part of a physician's counseling session before the birth of a baby should include inquiry about a mother's plan to work postpartum. Open discussion about work, breastfeeding, child care arrangements, and general stress will be helpful. Most well-educated women who plan to return to a career have thought out the entire process carefully but may want some reassurance or alternative suggestions. Physicians should know what services are available locally. It may be helpful to have a list of other working mothers who are willing to share experiences and knowledge of resources. It is often helpful for a woman to know another person who has experienced similar career choices. The physician, however, should not assume that personal experience should be the model recommended to the patient.

Some women have no experience with newborns and are totally unrealistic about the new responsibility and what it entails. Even pediatricians in training may be unrealistic. Pediatricians may have to recommend a more realistic view of parenting and urge the parents to plan carefully and practically for working and parenting. A new mother needs to appreciate that events occur that cannot be totally controlled. Even for a woman who has been an efficient career woman in total control of her destiny, an infant with normal needs may be overwhelming. Women who have jobs that are rigid from the standpoint of work hours and workplace will not find a few glib remarks in a pamphlet helpful when they want to maintain their milk supply.

Physicians may need to discuss specific issues of child care while a mother is working, as follows:

1. Child care arrangements should be sought that permit sufficient time for feeding an infant inexperienced with a bottle and sufficient time for extra cuddling of an infant who is used to a closer relationship with the "feeder." A child care specialist should be familiar with breastfeeding and sympathetic to the philosophy.
2. The advantages and disadvantages of child care in an infant's home, in a sitter's home, with or without a sitter's children, and with or without other children should be discussed. Is daycare a good arrangement for this family, and what centers take young infants and will work with breastfeeding mothers? Despite low costs, nursery "warehousing" should be avoided.

3. Are child care facilities available close to the workplace so that a mother could leave work on her breaks to breastfeed?

Plans for feeding an infant while the mother is working depend on the infant's age and feeding pattern. If an infant is totally breastfed and younger than 6 months of age, the mother can breastfeed if she can leave work and go to the infant or if the infant can be brought to the workplace. If a mother cannot leave work to nurse, she may choose to pump her milk at work and save it for the following day. This necessitates having a reasonably sanitary place to pump, such as a lounge or clean locker room, and a means of storing the milk until she gets home, either in a refrigerator at work or in a portable refrigerator system. Mothers have used insulated containers with ice, reusable cold packs, or dry ice. If no such arrangement for chilling can be made, the milk can be stored in a sterile container for 8 hours without refrigeration if collected under clean conditions.

A woman who is away from her breastfeeding infant past feeding time may need to pump to maintain her milk supply. A mother may also anticipate the infant's needs before she returns to work. She can practice pumping and storing a small amount of her milk daily for several weeks in her home freezer so that a stockpile is available while she is at work (see [Chapter 21](#)).

A mother should be instructed to introduce the baby to the bottle and an alternate caregiver before the first day of work. Developing a plan of organization and practicing it before the first day of work may avoid initial disaster. Also, returning to work part time at first may help minimize the adjustment. In addition, returning to work on a Wednesday or Thursday allows the first week to be a short one.

No evidence indicates that it is necessary to introduce a bottle sooner than 10 days before returning to work. Unless a mother is returning to work immediately after delivery, a bottle should not be introduced before lactation is well established (at least 4 weeks for most primiparas) because it interferes with a mother's milk-making rhythm. Furthermore, it may confuse the infant. Although some infants readily go back and forth between breast and bottle, no way exists to identify the infant who will develop sucking difficulties and "nipple confusion," ultimately resulting in preference for the bottle if it is introduced too early. Babies given a bottle well before 3 months may easily reject the breast after 3 months. For the infant who does not accept the bottle gracefully, the following techniques may facilitate the process:

1. Someone other than the mother should give the feeding.
2. The mother should be out of sight and hearing range, preferably out of the building, so the infant does not await her arrival.
3. The infant should be held by the "feeder" in the same position as for breastfeeding, that is, slightly elevated and close to the chest wall at about breast level. The bottle can be slipped down against the caregiver's chest wall.
4. Use a soft nipple and a small bottle at first for easy handling. A Volufeed, the clear plastic cylinder used for premature infants, allows a better view of the infant.
5. Create a soothing atmosphere; use a rocking chair, quiet music, and muted light.
6. The initial bottle-feedings, if not all of them, should contain warm mother's milk to reduce the elements of change being introduced.

If the bottle feedings do not go well and alternate feedings are needed, milk can be provided by medicine cup feeding (see [Chapter 15](#)).

If an infant is older than 6 months of age, a physician may consider introduction of other foods. The feeding given by the caregiver can be solids by spoon and liquids from a cup so that no breastfeeding is actually missed. A health professional can anticipate these issues and tailor feeding counseling accordingly. Some infants quickly learn the mother's schedule and may adjust their sleep pattern to allow a long stretch while mother is away. This may result in feedings during the night instead, but if the mother is informed of this phenomenon, she may be less anxious if it occurs.

Formula-fed infants have more infections and illnesses, which is another reason to encourage a mother to continue breastfeeding. This is especially important during the first weeks of adjustment to the transient, recurrent separation of mother and infant associated with the mother's return to work.

## MATERNAL CONSIDERATIONS

Counseling a breastfeeding family when the mother returns to work should also include attention to mothering the mother. Fatigue is a significant problem for all postpartum women and many nursing mothers. It can easily become a major stress when the mother adds outside employment to her schedule. Several days or more of adjustment are necessary for a major change in one's schedule. If the mother can focus on a few essential concerns (infant, job, own well-being) as opposed to housework, fancy meals, or a social schedule, she will weather the transition without despair. The first casualty of fatigue may be breastfeeding unless some anticipatory action is taken.

Once the schedule has been adjusted and a routine established, breastfeeding may offer

1. Someone other than the mother should give the feeding.

tremendous satisfaction for both mother and infant in terms of a sustained relationship as well as a reaffirmation for the mother of the quality of her parenting. One of the most difficult adjustments to motherhood is the need to set priorities and eliminate some chores of lesser urgency. Physicians need to reinforce this when a mother returns to work. Whether a mother continues to breastfeed, holding and cuddling her baby cannot become a lower priority. The mother's nourishment is also important and can be consumed during the time spent pumping. A mother should plan to have a beverage available every time she sits down to nurse or pump.

When mothers were asked what works for them when combining employment and breastfeeding, 43% pumped milk at work only, and 31% breastfed the baby while at work. Those mothers who neither fed nor pumped had the shortest duration of breastfeeding and working. Those who fed the baby either took the infant to work, went to the baby at daycare to feed the infant, or had the infant taken to the mother. These latter options require daycare that is nearby, a car, or a flexible caretaker who can take the baby to the mother.<sup>13</sup>

## DAYCARE

Infants in daycare have created a special concern for parents, pediatricians, social scientists, and policymakers. Early published information did not discuss the impact of breastfeeding before or during an infant's involvement with daycare. Haskins and Kotch<sup>16</sup> first reviewed the literature (172 articles) and concluded, "Children in day care, especially those under three years old and sometimes their teachers and household contacts, have higher rates of diarrhea, hepatitis A, meningitis and possibly also otitis media than children not in day care." The data are less clear for respiratory illnesses and cytomegalovirus. Parents choosing daycare facilities for their children need to select them with consideration for health and safety. More than 60% of the children younger than 6 years of age of women who work are in out-of-home care, approximately 8 million children in the United States. In some situations, daycare may actually improve an infant's potential, especially when the mother is young, immature, depressed, overwhelmed, or without family support.

Concern about infant illness should result in the pediatricians' involvement in ensuring quality daycare in the local community. For an infant of an age appropriate for breastfeeding, one possible preventive measure would be to encourage a continuation of breastfeeding when possible. Furthermore, daycare policy and procedure should encourage and facilitate breastfeeding. Mothers should inquire

about daycare centers' policies toward breastfeeding. Physicians who consult for daycare centers should be well informed as well. Breast milk can safely stand at room temperature for 6 to 8 hours and need not be discarded if the first feeding attempt is incomplete. In contrast, formula must be refrigerated and discarded after the first feeding attempt because it contains no antibodies or infection protection factors. No infant feeding of any kind should be warmed in a microwave oven. Protective gloves are not necessary to feed breast milk. The accidental feeding of a different mother's milk is not cause for alarm, although it should be reported to the parents for public health reasons. One feeding of milk produced by a mother who is positive for human immunodeficiency virus (HIV) will probably not transmit the disease. Women who are HIV positive in developed countries, including the United States, are prevented from breastfeeding.

## RESOURCES FOR PARENTS

The popular press has been inundated with books on child care and child rearing, with a significant number on breastfeeding, specifically breastfeeding and employment. These volumes can be extremely helpful to young parents, providing detailed information about how to manage. Many recognize that mothers, fathers, infants, jobs, child care arrangements, and support resources are all different. A disturbing number, however, are dogmatic and single-minded, giving the impression that the author's method is the only recipe for successful lactation. Pediatricians should become familiar with a few of these guidebooks and certainly not recommend any without reading them first. A few of these books have produced guilt in a working woman about leaving her infant.

The brochure *Working and Breastfeeding: Can You Do It?* was prepared by the National Healthy Mothers, Healthy Babies Coalition and is available free by calling the coalition in Alexandria, Virginia, at 703-837-4792. It is also available through local WIC nutritional programs. It is simple and direct, providing directions for managing a job and breastfeeding as well as collecting and storing breast milk.

Women in health care head the list of authors because many women physicians (especially residents), nurses, and hospital employees return to work while breastfeeding and then share their experiences in print. Even the worst setup in a hospital may surpass the resources available to the women working in another industry. Certainly hospitals and health care centers should provide models for other workplaces in supporting optimal daycare sources and making it possible for a mother-employee to return to work and maintain

her milk supply.<sup>20</sup> Independent lactation practitioners provide an additional resource. Women should contact the International Lactation Consultants Association for consultants in their area (see Chapter 22). Some industries have hired certified lactation consultants to provide assistance to their employees in maintaining their milk supply. The company also usually provides "a pumping room" and equipment. As pointed out by Cohen et al.,<sup>9</sup> this also reduces absenteeism because an infant who is provided the mother's milk has fewer illnesses.

In a survey conducted by the Women's Health Resource Center of 1000 working mothers in 2007, overall, 32% of new mothers gave up breastfeeding in less than 7 weeks after returning to work. When looked at by age, 51% of mothers younger than 24 years of age gave up and only 21% of older mothers gave up. They also noted that not meeting their breastfeeding goals and work was the reason more than 25% of the time. Mothers who were in retail jobs, were younger, and had lower paying jobs met the most significant barriers. Barriers at work were a lack of private space, a place to pump, a place to store milk, and an inflexible work schedule. Emotional barriers included discomfort about storing supplies in front of coworkers and anxiety about discussing this with supervisors.

Responding to parental needs, Brazelton<sup>7</sup> captured the quintessential challenge to parents in the title and the text of *Working and Caring*. It is possible for parents to both work and care! The two most powerful requirements for human existence are "love" and "work." Our culture had suggested that men work and women love in relation to family obligations. Today, it is possible not only for a mother to love her children and work, but also for a father to work and love his children.

## SURGEON GENERAL'S WORKSHOP

The Report of the Surgeon General's Workshop on Breastfeeding and Human Lactation,<sup>32</sup> published in 1984, clearly enunciated that strategies need to be developed to reduce the barriers to breastfeeding while employed. All six categories of the report address the issue in some capacity. Twenty-five years later a summit on breastfeeding was convened to review the progress and reset the strategies.<sup>33</sup> The workgroups were the same: work, professional education, public education, health care systems, and support services. The issues were similar, as were the strategies. The urgency of legislative support, workplace support including day-care, paid maternity leave, child care, alternative work schedules (flexitime), and job sharing were on the list for the workgroup on work. The workshop report also states that successful initiation and continuation of breastfeeding will require a

broad spectrum of support services involving families, peers, care providers, employers, and community agencies and organizations.<sup>32</sup> Although little has been accomplished toward these specific goals, the U.S. Breastfeeding Committee has been formed in concert with the Innocenti Declaration recommendations.<sup>41</sup> The U.S. Breastfeeding Committee has undertaken as a major activity the improvement of the atmosphere for breastfeeding, working women. The Committee's policy paper on the subject states the following benefits for employers that adopt a breastfeeding support program<sup>41</sup>:

- Cost savings of \$3 per \$1 invested in breastfeeding support
- Less illness among the breastfed children of employees
- Reduced absenteeism to care for ill children
- Lower health care costs (an average of \$400 per baby in the first year)
- Improved employee productivity
- Higher morale and greater loyalty
- Improved ability to attract and retain valuable employees
- Family-friendly image in the community

Each company or employer should tailor a program to its unique needs.

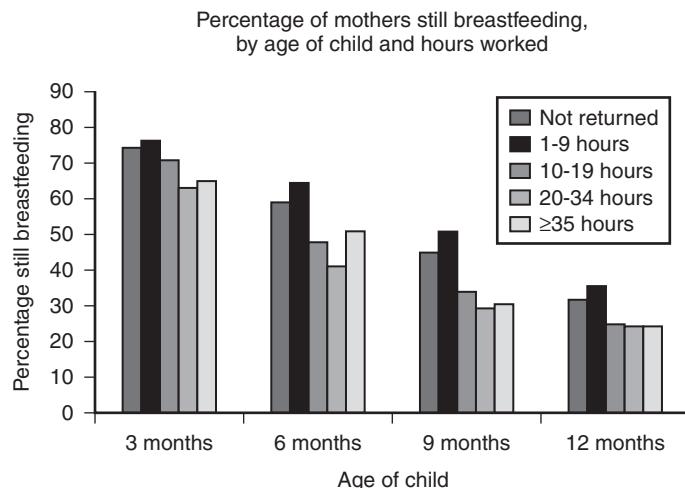

The Committee has suggested that several strategies are feasible, safe, and relatively easy to implement. They include developing a breastfeeding support program, distribution of support policy, consideration of a flexible scheduling option, sufficient break time to feed or pump, and providing useful information. The full statement is available at <http://www.usbreastfeeding.org>.

## WORKPLACE KIT FOR AUSTRALIA

Women in Australia face the same challenges to working while breastfeeding as reported in many other countries. McIntrye et al.<sup>25</sup> report on a project that promoted balancing breastfeeding and paid work through the development, distribution, promotion, and evaluation of suitable materials to workplaces, employers, and employees. Materials for employees were translated into Arabic, Chinese, Turkish, Spanish, and Vietnamese.

In this project targeting employers, women, and workplaces in Australia, 500,000 information kits were distributed with preference for places that had women of childbearing age and women of diverse cultural backgrounds. The project was widely publicized in all media.

The kit contained a poster to display key points and a booklet to provide more detailed information in an easy-to-read format. The contents had been tested in focus groups and evaluated by other key

**Figure 18-6.** Percentage of mothers still breastfeeding, by age of child and hours worked. (From Cooklin AR, Donath SM, Amir LH: Maternal employment and breastfeeding: results from the longitudinal study of Australian children, *Acta Paediatr* 97:620–623, 2008.)

stakeholders, including a working mother and a lactation consultant.

The evaluation of the project included a simple survey sent via email or fax to 1571 organizations. Only 202 (12.8%) were returned. Those who responded thought it was excellent, more than half thought it would be useful, and two thirds thought the kit would provide suitable solutions to support balancing breastfeeding and work at their organization. The authors recognize the need for further work to implement the policies and procedures to support breastfeeding in the workplace. To investigate the effect of maternal postpartum employment on breastfeeding duration in Australia in the first 6 months after birth in 2008, Cooklin et al.<sup>10</sup> performed a secondary analysis of the Longitudinal Study of Australian Children. Data on 3697 children were completed. Multivariable logistic regression was used to measure the effect of the timing of a mother's return to work and the effect of employment on breastfeeding status. Maternal age, history of smoking during pregnancy, and socioeconomic status were adjusted for. Breastfeeding rates dropped to 39% at 6 months among employed mothers compared with unemployed mothers at 56%. Full-time employment before 6 months had a major impact; 44% of those who were employed part time were breastfeeding at 6 months. The authors concluded that in spite of controlling for risk factors, employment before 6 months had a negative impact on dedicated breastfeeding (Figure 18-6).

## THE BUSINESS CASE FOR BREASTFEEDING

The *Business Case for Breastfeeding*<sup>42</sup> contains the steps for creating a breastfeeding-friendly worksite. This

was developed by the U.S. Department of Health and Human Services (HHS), Health Resources and Services Administration's Maternal and Child Health Bureau (MCHB). It is a comprehensive resource kit that targets a broad spectrum of individuals and groups involved in supporting breastfeeding women. The kit provides a train-the-trainer approach that results in improving workplace lactation support for employed breastfeeding women. It is intended to provide training for reaching out to local businesses and is working with state breastfeeding coalitions and Healthy Start programs. Healthy Start is a HHS-funded program providing community-based initiatives to reduce infant mortality rates and to improve the health of women, infants, and children and their families. The training content is based on the MCHB workplace lactation resource kit in a community-based outreach program. Training is targeted at breastfeeding coalitions, Healthy Start Staff, International Board Certified Lactation Consultants, health care professionals, La Leche League Leaders, and WIC staff. It is a step-by-step program complete with script and slides. Format includes role play. Those who complete the course should be ready to approach employers with why and how to start a program that supports breastfeeding by their employees. The kit is well referenced. The bibliography is extensive. Materials are readily available.

The National Business Group on Health is a not-for-profit membership organization for large employers whose mission it is to identify and share best practices, link science and evidence to health benefit plan design, and be a national voice for large employers.<sup>28</sup> Membership includes half the Fortune 500 and 40% of the companies who made

*Working Mother's* Top 100 Best Companies to work for. Employers' budgets for health care benefits are limited, so that breastfeeding competes with smoking cessation, obesity prevention, and worksite wellness programs. The annual health care coverage costs will double in 10 years. Worksite breastfeeding programs have increased to cover more than 25% of large companies.<sup>31</sup> The number who offer breastfeeding programs is greatest among large employers. It has been shown that absenteeism is twice as high among mothers who bottlefed. Employee retention rates in companies who implemented breastfeeding support programs were 83% to 84% compared with the national average of 59%.<sup>31</sup> Other benefits of the programs beyond cost savings for health care are earlier return from maternity leave, higher productivity, morale, loyalty, and recognition as a "family-friendly" worksite. Employers decide what health benefits they will select based on medical evidence of effectiveness, impact on productivity indicators, cost savings, and good will. When making decisions about what health benefits to provide, employers often rely on a variety of sources of information, including the health plan itself and research they gather themselves. They do not consult government agencies or peer-reviewed academic journals.<sup>28</sup>

## MATERNAL BENEFITS

In 1919 the International Labour Organization established the Maternity Protection Convention for working women. This document provided for two half-hour nursing breaks per day. It also recommended that employers provide crèches (day nurseries, especially European) or daycare when more than a given number of women are employed, but few countries hold to its tenets today. Maternity benefits vary from country to country and may include maternity leave with or without pay, nursing breaks, provision of daycare facilities, and prohibition of dismissal. Physicians who care for mothers and infants should take a leadership role in ensuring that mothers can continue breastfeeding even when the mother is employed.

The World Alliance of Breastfeeding Actions has stated that breastfeeding is a right of mothers and is a fundamental component in assuring a child's right to food, health, and good care. Recognition of the importance of maternity leave as a social function should be supported by public funds. The International Labour Organization in the document "Maternity Protection at Work" states, "Maternity protection is a precondition of genuine equality of opportunity and treatment for men and women." In the renewal of the Innocenti Declaration in 2005 one of the declarations was a charge to nations to "adopt maternity protection

legislation and other measures that facilitate 6 months exclusive breastfeeding for women employed in all sectors."

Efforts in the United States, headed by the United States Breastfeeding Committee, include legislation for:

- Fully paid maternity leave with benefits and job security followed by paid breaks upon return to work (14 weeks' minimum paid leave recommended by the International Labour Organization)
- Cost sharing with state and federal funding tax incentives and legal mandates and protection of breastfeeding mothers (Civil Rights Act 1964)
- Provision of adequate facilities to feed one's infant or pump one's milk and store it safely

Many women, especially when faced with coping with a second or third child, reexamine the working issue in light of the needs of their children, even though they may have previously managed to breastfeed and work at one time. No one else can or should decide for a woman how she will handle parenting, especially in the early years of a child's life. No woman should be embarrassed to stay home or should apologize for working part time or not at all. Breast milk is not a substitute for good parenting, any more than "quantity parenting" is synonymous with quality parenting. It is possible to work and to care, however.

## PHYSICIAN'S ROLE

The primary role of a pediatrician is as an advocate for children, but all physicians can help support fathers and mothers alike who are faced with fulfilling the roles of parent, employee, and citizen in a rapidly changing society. Physicians should be able to provide understandable information concerning a child's growth and development combined with a realistic view of the issues in parenting and family life. They should show an openness and willingness to discuss nonjudgmentally with the parents their specific situation, options, and choices for caring for their child.

If a physician is the medical consultant to the daycare program, the role can be to assure mothers who want to provide their milk that they will be supported by the staff. The physician should develop policies and procedures for the storage and use of the breast milk provided. In addition, space and facilities (at least a rocking chair and a screen) should be available for a mother to nurse the infant before leaving the child and on her return later before going home. If a physician is in the medical department of a large company or the pediatrician for a working breastfeeding mother, he or

she can advocate for time and resources for pumping while at work as part of good preventive care.

The success of breastfeeding depends to a degree on ever-widening circles of support for the breastfeeding infant-mother dyad. Support should come first from the husband/father, then from other family members, other caregivers in the home, daycare facilities, employers and other employees, and community members to help the mother and family comfortably and safely breastfeed, work, and care for their child as they choose. Breastfeeding is not just a woman's issue. It is a family issue and a public health issue as well. Articles abound in the medical and lay literature describing how one can achieve success in breastfeeding and returning to work. Most authors list pumps and milk storage as important items. Each mother has to plan her own approach based on her job requirements, her own resources, and her support system, as well as her infant's needs. Although it is not easy to balance a job and breastfeed, it can be done, with adequate strategizing and planning, which is appropriate with or without breastfeeding and returning to work postpartum.

A physician's role in achieving a successful return to work for the breastfeeding mother includes the following steps:

1. Discuss the mother's plans for returning to work in advance.
2. Recommend appropriate local child care facilities that are "breastfeeding friendly."
3. Suggest that the mother discuss breastfeeding with her employer or supervisor.
4. Have a licensed, certified lactation consultant available in the practice or office, or if not, know where one can be contacted.
5. Provide recommendations for collecting and storing breast milk, which can be additionally covered in an office handout.
6. When medical problems arise, seek adequate information so that an appropriate solution can be recommended that supports continued breastfeeding.

## CHAPTER 19

# *Induced Lactation and Relactation (Including Nursing an Adopted Baby) and Cross-Nursing*

---

As breastfeeding has returned to being the preferred form of nourishment for the infant, there has been an increased interest in induced lactation. Induced lactation is the process by which a nonpuerperal woman is stimulated to lactate—in other words, breastfeeding without pregnancy. Relactation is the process by which a woman who has given birth but did not initially breastfeed is stimulated to lactate. This may also apply to a mother who may have initially breastfed her infant, weaned the infant, and then chooses to reinstitute lactation. Relactation can also involve a woman who previously breastfed a biologic child, even years before, and now is adopting a newborn. There are no blinded controlled research studies about either induced lactation or relactation. There are occasional observation reports about successes in a small series of dyads. The process has not been confirmed by clinical trials.<sup>41</sup> The literature is actually meager and predominantly in the animal research field.

### *Historical Perspective*

Induced lactation and relactation are not new concepts but rather are well known to history and to other cultures. The motivation historically has been to provide nourishment for an infant whose mother has died in childbirth or is unable to nurse for some

reason. A friend or relative would take on the care of the child and with it the responsibility to nourish the infant at the breast because no other alternatives were available.

Relactation has been used in times of disaster or epidemics to provide safe nutrition to weaned or motherless infants. Numerous historical accounts of induced lactation are recorded in the medical literature and reviewed in the writings of Brown.<sup>8</sup> Mead<sup>27</sup> recorded the occurrence of relactation in her writings about New Guinea in 1935. Other anthropologists have made similar observations in other preindustrialized societies of women who have not borne children and, after a few weeks of placing the suckling infant to the breast, produce milk adequate to nourish the infant.<sup>36</sup> Until recently, Western world literature reported the phenomenon as an anecdotal report as part of the discussion of aberrant lactation. In 1971, Cohen<sup>13</sup> reported a patient who had been nursing an adopted child successfully for weeks when first seen in his pediatric office.

Today, the interest in induced lactation in the industrialized world stems from a desire on the part of adopting mothers to nurture an adopted child at the breast even though they were unable to carry the infant in utero. The interest in relactation comes from mothers of sick or premature infants who want to breastfeed their infants after the days

and weeks of neonatal intensive care are over. These mothers, although postpartum, have not been lactating.

## Induced Versus Inappropriate Lactation

The process of induced lactation is separate from galactorrhea, or inappropriate lactation, which has been described in the medical literature for more than 100 years.<sup>44</sup> Abnormal lactation has been observed in a number of circumstances in nulliparous and parous women and even in men. There are many eponyms for these conditions, usually based on the name of the physician who first described the syndrome, such as Chiari-Frommel and Ahumada-del Castillo.

Normally in the absence of suckling, lactation ceases 14 to 21 days after delivery. Milk flow that continues 3 to 6 months after abortion or any termination of pregnancy is termed *abnormal* or *inappropriate lactation*, or *galactorrhea*. Galactorrhea also refers to lactation in a woman 3 months after weaning or the secretion of milk in a nulliparous woman in association with hyperprolactinemia and amenorrhea. Although these cases are pathologic in nature and, therefore, different from the groups under discussion, it is noteworthy that some knowledge of the initiation and maintenance of lactation has been gained from the study of these syndromes. A nonpregnant woman who develops spontaneous lactation should be evaluated for hormonal disease. The most common cause is a prolactinoma of the pituitary. Spontaneous lactation should not be ignored.

## Animal Studies

Information on the incidence of nonoffspring nursing in 100 mammalian species has been assembled by Packer et al.<sup>32</sup> The incidence of nonoffspring nursing is increased by captivity. It is more common in species with large litters (polytocous taxa) and differs from that which occurs with single young species (monotocous taxa). In the latter, it is more common for females to continue nursing after they have lost their own young. Among nondomesticated animals, spontaneous lactation has been observed repeatedly only in the dwarf mongoose (*Helogale parvula*).

Lactation has been induced for scientific and commercial purposes in nonpregnant and nonparlurient animals by the continual systematic application of a mechanical milking apparatus to the mammary gland of the animal.<sup>25</sup> The response is

effected through the release of a mammotropic hormone from the anterior pituitary gland. This effect is abolished if the pituitary stalk is transected. Ruminants respond to the addition of estrogen or estrogen-progesterone combinations, which facilitate mammary growth. Experiments in goats involved applying ointment containing estradiol benzoate to the udders of virgins, which resulted in development of the udder and milk yield almost comparable to normal postpartum animals.<sup>14</sup> It was subsequently shown, however, that a combination of estrogen-progesterone not only resulted in better milk yield, but histologically the lobuloalveolar growth was normal, whereas with estrogen alone growth was cystic and irregular. It was also demonstrated that ovariectomized goats could be stimulated to lactate with these two hormones, with resultant normal histology of the udder and good milk production. Initiation of regular milkings had a significant impact on production of milk.

Because lactation can be stimulated when the ovaries have been removed but not when the pituitary stalk has been severed, this has significance for understanding some of the postpartum lactation failures in women. Again in ruminants, growth hormone and thyroid hormone have been shown to increase milk yield, although prolactin does not. This suggests that prolactin is not deficient in ruminants. Because the motivation, goals, and physiologic problems may be slightly different, induced lactation and relactation in women are discussed separately.

## Induced Lactation

When a mother chooses to nurse her adopted infant, the goal is usually to achieve a mother-infant relationship that may also have the benefit of some nutrition. In that perspective, success can be evaluated on the basis of whether an infant will suckle the breast and achieve some comfort and security from this opportunity and close relationship with the new mother. As has been well described by Avery,<sup>5</sup> this is nurturing with the emphasis on nurturing, not on "breastfeeding" or nutrition. A mother who is interested in inducing lactation to nurse an adopted infant may need to understand that she may never be able to sustain the infant completely by her milk alone without supplementation. Neither the physician nor the mother should be disappointed. The nurturing goal is still achieved. An adoptive mother induced lactation for premature twins who were exclusively breastfed by 2 months of age. The mother succeeded due to careful planning and support of the health care team.<sup>38</sup>

## PREPARATION OF THE BREAST

Normally the breast is prepared by the proliferation of the ductal and alveolar system throughout pregnancy in anticipation of the time when lactation will begin, when the infant delivers and the placenta is removed.<sup>24</sup> Thus it is appropriate to assume that a period of similar preparation should take place in induced lactation. It has been suggested that a woman should begin systematically to express the breasts manually and stimulate the nipples for up to 2 months before the arrival of the infant, if time permits. A hand pump or other pumping devices can be used, but manual expression may work as well or better. Sometimes some secretion can be produced in this manner if it is carried out systematically on a uniform schedule throughout the day. The schedule should be practical, that is, include times when a mother could take a moment for this activity, such as morning and night plus any times she uses the bathroom or can conveniently handle her breasts.

A more aggressive approach involves hormones and medications. During pregnancy, the breasts are prepared by the hormones generated by the pregnancy, estrogen, progesterone, and human placental lactogen (see *Figure 3-2*).

To mimic this environment, it has been suggested that starting a course of estrogen and progesterone would be appropriate, namely, prescribing oral contraceptive dosing that suppresses ovulation (such as Ortho-Novum). This dosing should be maintained without a pause as it would be during pregnancy.<sup>30</sup> Unfortunately, women who are adopting typically do not have 9 months to prepare, so priming the breasts with hormones may not be possible because the hormones need to be discontinued a month before anticipated lactation.

Concomitant with hormone therapy should be breast stimulation with systematic pumping with a good electric double pump. Timing should begin gradually, 5 minutes three times per day, then 10 minutes, increasing to every 4 hours. Pumping about the same time every day is helpful. It usually takes about a month before drops of milk appear. This is a good time to start domperidone (not available in the United States).<sup>2</sup> The schedule adopted by Newman<sup>29</sup> in Canada is 10 mg three times per day, increasing during a month's time to 20 mg four times per day. Newman suggests using domperidone from the beginning.<sup>29</sup> Without a placenta, the adoptive mother does not have "prolactin inhibiting" hormone to block the breast from responding to the prolactin secreted because of the breast stimulation. When domperidone is initiated, milk should appear in increasing quantities. Many women have achieved success by pumping alone initially and then adding galactagogues.

In other cultures in which lactation is induced as a survival tactic for the infant, no period of preparation is available. An infant is put to the adoptive mother's breast and allowed to suckle. Emphasis has been placed on herbal teas as galactagogues and good nourishment for the mother, and the infant is also given prechewed food, gruel, or animal milk. Mead<sup>27</sup> attributed much of the success of induced lactation to the ingestion of ample supplies of coconut milk by the new mother. Coconuts are well known in herbal medicine; the oil pressed from ripe fruit is used for wound healing and inflammation.<sup>34</sup> Adoption is not an easy process, and, in fact, it can be quite stressful to become an instant parent. In assisting such a mother, consideration should be given to the infant's age, previous feeding experience, and any medical problems that may exist. Provision for additional nourishment during the process of establishing some milk secretion is most important. Onset of lactation varies from 1 to 6 weeks, averaging about 4 weeks after initiation of stimulation with the appearance of the first drops of milk. When the infant is actually nursing at the breast and being nourished by supplements, milk may appear as early as 1 to 2 weeks.

Some infants are easily confused by switching back and forth between breast and bottle because the sucking technique is slightly different. Other nourishment can be offered by dropper, by small medicine cup, or as solid foods. A unique system is available, however, for providing nourishment for the infant while suckling at the breast. It involves the use of a device to provide a source of nourishment while the infant suckles at the breast, thus stimulating production. It is further described later in this chapter and is called the Lact-Aid Nursing Trainer System (Lact-Aid International Inc., Athens, Tennessee) or Supplemental Nursing System (Medela Inc., McHenry, Illinois).

## OTHER DRUG SCHEDULES TO INDUCE LACTATION

As described in *Chapter 3*, estrogen and progesterone stimulate the proliferation of the alveolar and ductal systems. These hormones work in association with an increase in prolactin production. Although the prolactin level is high during pregnancy, milk secretion is inhibited by the presence of the estrogen, progesterone, and placental lactogen, the prolactin inhibiting hormone. After delivery has occurred and the placenta is removed, these hormone levels fall, and prolactin initiates milk production. Efforts to stimulate this hormonal response have had variable success and are not usually recommended because of the possible effect on an infant through the milk. Women taking oral

contraceptives have been noted in some cases to have breast enlargement. In addition, although estrogen and progesterone may enhance proliferation, they may inhibit lactation per se, so they must be discontinued well before lactation is planned to begin.

The dosage of conjugated estrogens recommended by Waletzky and Herman<sup>47</sup> is 2.5 mg twice per day for 14 days beginning on the fourth day of a regular menstrual cycle. Giving 0.35 mg norethindrone once daily for the morning dose of estrogen prevents breakthrough bleeding. Medication is given for 2 weeks and is comparable in dosage to 2 weeks of oral contraceptives. This therapy may be accompanied by some side effects. The regimen should include direct efforts to stimulate lactation by pumping the breasts.

A report from Papua New Guinea, where inducing lactation is critical to adequate infant nutrition, recommends priming the breast tissue of nulliparous women or those who have not lactated with 50 mcg ethinyl estradiol three times per day for a week.<sup>21</sup> Medroxyprogesterone (Depo-Provera) has been used to initiate lactation in nonpuerperal women. A dose of 100 mg is given intramuscularly a week before stimulating the breast with massage and pumping. Galactagogues, such as metoclopramide, domperidone, or herbs, can be introduced. This approach was reported in Papua New Guinea, and success was claimed in 24 of 27 women.<sup>28</sup> When relactation is the goal in women who have previously lactated, pumping and massaging alone are initiated.

Growth hormone and prolactin have considerable genetic similarity, as reflected in some overlap of function.<sup>12</sup> High concentrations of growth hormone can cause lobuloalveolar development and casein expression. Growth hormone may play a role in optimization of milk production during lactation and even an accessory role in the induction of lactogenesis. Both natural and recombinant human growth hormones are potent inducers of milk synthesis in pregnant and lactating rats. This effect is attributed to their effect on the prolactin receptor.<sup>12</sup>

Oxytocin is a critical component in the milk-ejection reflex and may be helpful in the early initiation of ejection. Physiologically, stimulation of the nipple in the lactating woman results in the release of oxytocin by the hypothalamus, which then triggers the release of milk by stimulating the contraction of myoepithelial cells and the ejection of milk (see Chapter 8). The effect of intranasal administration of oxytocin on the let-down reflex in lactating women was well described by Newton and Egli.<sup>31</sup> (Oral administration by tablet is not as effective because oxytocin is destroyed in the stomach; therefore, oral administration must be

sublingual.) Oxytocin nasal spray has been used in cases of nonpuerperal lactation with some success in enhancing let-down but not necessarily altering the volume produced. The original oxytocin product, Syntocinon, is no longer available, but a pharmacist by prescription can place the intravenous preparation in a dropper bottle or a nasal spray container. The intravenous preparation (10 units/mL) is one quarter the strength of the old nasal spray (40 units/mL). Therefore, the dose needs to be increased four-fold: 4 to 6 drops per dose in one nostril and feed the infant or pump immediately (see Chapter 8). The dose can be repeated. Continued use of oxytocin for weeks has been associated with diminished effect or even suppression of lactation.

In a randomized, double-blind trial of oxytocin nasal spray in mothers expressing breast milk for preterm infants, there were only marginal differences in the pattern of early milk production. The use of oxytocin nasal spray did not significantly improve outcome. Most of the subjects thought they were receiving the real medicine, which demonstrates the power of the placebo effect. All the mothers had been pregnant, and their breasts had responded to the pregnancy. These data should not be extrapolated without further study to women who had never been pregnant.

The chief benefit of oxytocin is often to break the cycle of failure and instill a feeling of confidence once it has been demonstrated that some secretion can be produced.

Chlorpromazine has been observed to act as a galactagogue as well as a tranquilizer when given to patients in large doses (as high as 1000 mg). The effect has been observed in both male and female patients in mental institutions. The drug has been reported to increase pituitary prolactin secretion several fold. It acts via the hypothalamus, probably by reducing levels of prolactin inhibitory factor (PIF). Using this information, women well motivated to lactate who have attempted induced lactation by suckling a normal infant have had the process enhanced by small doses of chlorpromazine (Tables 19-1A and 19-1B).

In a program to induce lactation in refugee camps in India and in Vietnam, nonlactating women were given 25 to 100 mg of chlorpromazine three times per day for a week to 10 days while infants were initially put to breast. Brown<sup>9</sup> reports apparent enhancement of lactation with this treatment. Chlorpromazine has the added pharmacologic effect of acting as a tranquilizer. The program of management in these women was supportive in other ways and also included the usual herbal medicines associated with lactation in these Eastern cultures. There was no control group.<sup>9</sup> It is possible that the drug contributed to both the

<b>TABLE 19-1A</b> Pharmacologic Agents to Induce Lactation				
	Domperidone	Fenugreek	Metoclopramide	Silymarin*
<b>Possibly effective for selected indications</b>				
Chemical class or properties	Dopamine antagonist	A commonly used spice; active constituents are trigonelline, 4-hydroxyisoleucine, and sotolon	Dopamine antagonist	Flavolignans (presumed active ingredient)
Level of evidence	I (one study); other studies have inadequate methodology or excessive dropout rates	II-3 (one study in lactating women—abstract only)	III (mixed results in low-quality studies; effect on overall rate of milk secretion is unclear)	II-I (one study in lactating women)
Suggested dosage	10 mg, orally, three times per day in the Level I study; higher doses have not been studied in this context	"3 capsules" orally (typically 580–610 mg), three to four times per day; strained tea, 1 cup, three times per day (1/4 tsp of seeds steeped in 8 oz of water for 10 minutes)	10 mg, orally, three to four times per day	Micronized silymarin, 420 mg orally per day; anecdotal: strained tea (simmer 1 tsp of crushed seeds in 8 oz of water for 10 minutes), 2–3 cups/day
Length/duration of therapy	Started between 3 and 4 weeks postpartum and given for 14 days in the Level I study. In various other studies the range was considerable: domperidone was started between 16 and 117 days postpartum and given for 2–14 days	1 week	7–14 days in various studies	Micronized silymarin was studied for 63 days
Herbal considerations	—	Need reliable source of standard preparation without contaminants	—	Need reliable source of standard preparation without contaminants
Effects on lactation	Increased rate of milk secretion for pump-dependent mothers of premature infants of less than 31 weeks' gestation in neonatal intensive care unit	Insufficient evidence; likely a significant placebo effect	Possibly increased rate of milk secretion; possible responders versus nonresponders	Inconclusive
Untoward effects	Maternal: dry mouth, headache (resolved with decreased dosage), and abdominal cramps. Although not reported in studies of lactation, cardiac arrhythmias due to prolonged QTc interval are a concern and are occasionally fatal. This may occur with either oral or intravenous administration and particularly with high	Generally well tolerated. Diarrhea (most common), unusual body odor similar to maple syrup, cross-allergy with Asteraceae/Compositae family (ragweed and related plants), peanuts, and Fabaceae family such as chickpeas, soybeans, and green peas—possible anaphylaxis	Reversible CNS effects with short-term use, including sedation; anxiety; depression/anxiety/agitation; motor restlessness; dystonic reactions; extrapyramidal symptoms. Rare reports of tardive dyskinesia (usually irreversible), causing the FDA to place a boxed warning on this drug	Generally well tolerated; occasional mild gastrointestinal side effects; cross-allergy with Asteraceae/Compositae family (ragweed and related plants)—possible anaphylaxis

*Continued*

**TABLE 19-1A** Pharmacologic Agents to Induce Lactation—cont'd

	<b>Domperidone</b>	<b>Fenugreek</b>	<b>Metoclopramide</b>	<b>Silymarin</b>
	doses, or concurrent use of drugs that inhibit domperidone's metabolism (see Interactions, below). Neonatal: very low levels in milk and no QTc prolongation in premature infants who had ingested breast milk of mothers taking domperidone	Theoretically: asthma, bleeding, dizziness, flatulence, hypoglycemia, loss of consciousness, skin rash, wheezing—but no reports in lactating women		
Interactions	Increased blood levels of domperidone when combined with some substrates metabolized by CYP3A4 enzyme inhibitors (e.g., fluconazole, grapefruit juice, ketoconazole, macrolide antibiotics)	Hawthorne, hypoglycemics including insulin, antiplatelet drugs, aspirin, heparin, warfarin, feverfew, primrose oil, many other herbs	Monoamine oxidase inhibitors, tacrolimus, antihistamines, any drugs with CNS effects (including antidepressants)	Caution with CYP2C9 substrates—may increase levels of the drugs. Possible increased clearance of estrogens (decreased blood levels). Possible increased levels of statins
Comments	In the United States, the FDA has issued an advisory <i>against</i> the use of domperidone for lactating women  Do not advise exceeding maximum dosage; no increased efficacy but increased untoward effects  Licensed for use as a drug for gastrointestinal dysmotility in some countries (but not in the United States), where for this indication in some regions it is accepted that if no response at the initial dose may increase the dose. Some areas use as drug of choice when prolactin stimulation is felt to be needed. However, there are no studies of the safety or efficacy of this practice in lactating women	If patient develops diarrhea, reducing the dose is often helpful	Some studies suggest tapering off the dose at the end of treatment	No prescription required
	<b>Human Growth Hormone</b>	<b>Sulpiride</b>	<b>Thyrotropin-Releasing Hormone</b>	
<b>Controversial or not recommended, although possibly effective</b>				
Chemical class or properties	Protein-based polypeptide hormone: stimulates multiple	Substituted benzamide (antipsychotic, antidepressant); antagonism of	A tripeptide hormone that stimulates the release of TSH

**TABLE 19-1A** Pharmacologic Agents to Induce Lactation—cont'd

	<b>Human Growth Hormone</b>	<b>Sulpiride</b>	<b>Thyrotropin-Releasing Hormone</b>
Level of evidence	growth, anabolic, and anticatabolic effects I, II	presynaptic inhibitory dopamine receptors II-I (only two studies)	and prolactin by the anterior pituitary I
Suggested dosage	0.2 IU/kg/day, given intramuscularly or subcutaneously	50 mg orally, two times per day; do not use higher doses because of sedation of mother and baby	1 mg four times daily by nasal spray
Length/duration of therapy	7 days, starting anywhere from 8 to 18 weeks postpartum	4-Day course starting at 3 days postpartum; no evidence to use for a longer course of treatment	10 days
Effects on lactation	Increased milk secretion in a selected population of normally lactating women with no feeding problems and with healthy, thriving infants between 8 and 18 weeks postpartum	Increased milk secretion in a selected population: primiparous women with total yield of milk not exceeding 50 mL for the first 3 postpartum days	Increased milk secretion in selected population of primiparous women with insufficient milk supply at 5 days postpartum
Untoward effects	None observed in mothers or infants studied to date. Potentially: joint swelling, joint pain, carpal tunnel syndrome, and an increased risk of diabetes, heart disease	Severe drowsiness; extrapyramidal effects same as for metoclopramide (above); weight gain	Elevated TSH and hyperthyroidism
Interactions	Other hormones including contraceptives, insulin, cortisol, and others	Levodopa, other drugs with CNS effects	Other hormones including contraceptives, insulin, cortisol, and others
Comments	Insufficient study; not practical—requires injection and is very expensive	Concern about untoward effects	Insufficient study, very expensive, no commercial product available

\*Silymarin (micronized silymarin) or *S. marianum* (milk thistle).

physiologic and the psychologic well-being of the women wanting to lactate. It has been suggested that the desire to lactate is a strong component of success because women whose breasts are frequently stimulated sexually do not begin to lactate.

Theophylline can also increase pituitary prolactin secretions.<sup>45</sup> Therefore, both tea and coffee should enhance prolactin secretion and thus lactation. Excessive amounts may inhibit milk let-down, however.

Because the role of prolactin is the initiation and maintenance of lactation, whereas oxytocin regulates the glandular emptying through the milk-ejection reflex, it is reasonable to speculate that enhancing prolactin release would be productive in inducing lactation. The exact activating mechanism of the neuronal reflex arc from breast to brain has not been deciphered. Secretion of prolactin appears to be influenced, if not controlled, by changes in hypothalamic dopamine turnover. Correspondingly, suckling has been observed to deplete dopamine stores.

Investigation of other drugs that are known to stimulate prolactin release has identified some possible therapeutic materials. Kramer<sup>21</sup> and McNeilly et al. have reported that metoclopramide induces prolactin release regardless of the route of administration. Prolactin levels are increased three to eight times normal levels within 5 minutes when a 10-mg dose of metoclopramide is given either intravenously or intramuscularly. The effect is achieved within an hour when metoclopramide is given orally. The effect persists for 8 hours. The suggested regimen is 10 mg of metoclopramide, four times per day for a week.<sup>16</sup> This is then gradually tapered (see Chapter 12).

Metoclopramide also is used in neonates with esophageal reflux. The side effects are irritability and diarrhea. Rarely, susceptible infants experience dystonic reactions, which have been described in adults. Metoclopramide has also been used in combination with chlorpromazine, 25 mg four times per day, in Papua New Guinea.<sup>21</sup> Metoclopramide has been used to enhance lactation as well, especially among mothers of premature infants.<sup>16</sup>

The regulation of prolactin secretion in humans has been studied to further the understanding of abnormal lactation as well as to provide information on the regulation of pituitary function of the brain.<sup>15</sup> It has been shown experimentally that the hypothalamus secretes PIF, which acts on the mammotropin-releasing cells of the pituitary to inhibit release of the hormone prolactin. The hypothalamus can also regulate prolactin secretion by a stimulatory mechanism, the secretion of thyrotropin-releasing hormone (TRH). When human volunteers (non-pregnant, nonlactating) are given infusions of TRH, increases in thyrotropin and prolactin are observed within minutes of injection, with values peaking in 20 minutes. The level of thyroid hormone in the volunteers initially influences the results. Patients with hypothyroidism have been observed to secrete excessive amounts of prolactin, whereas patients with hyperthyroidism are relatively insensitive to TRH. This may explain some of the variable results obtained with prolactin-stimulating drugs used to enhance lactation. Studies using TRH have been done of relactation but not of newly induced lactation. Thyroid activity has not been measured. Table 19-2 summarizes the influence of drugs on prolactin secretion. The ABM Protocol #9 discusses the use of galactagogues and their effects and side effects (see Tables 19-1A and 19-1B).

Any pharmacologic regimen to stimulate milk production is most effective if it is initiated after the breast tissue has responded to mechanical stimulation because the hormones that act as the prolactin-stimulating compounds are thought by

TABLE 19-2 Influence of Drugs on Prolactin Secretion

Pharmacologic Agents	Plasma Prolactin Concentration	Mechanism of Drug Action
L-Dopa	Decrease	Increase in hypothalamic dopamine-catecholamine levels, leading to enhanced activity of PIF
Ergot alkaloids (ergocornine, ergocryptine)	Decrease	Direct inhibition of adenohypophyseal prolactin secretion; possible increase of hypothalamic PIF activity (continued PIF function)
TRH (pyroglutamyl histidyl-prolinamide)	Increase	Direct stimulation of adenohypophyseal lactotroph for increased prolactin secretion
Theophylline phenothiazines (chlorpromazine)	Increase	Decreases in hypothalamic dopamine-catecholamine levels, leading to diminution of PIF activity
Metoclopramide	Increase	Inhibition of hypothalamic PIF secretion through dopamine antagonism
Sulpiride	Increase	Increase in hypothalamic prolactin-releasing hormone
Growth hormone	Increase	Causes lobuloalveolar development and casein expression
Recombinant human growth hormones	Increase	Affects prolactin receptors

Modified from Vorherr H: Human lactation and breast feeding. In Larson BL, editor: *Lactation*, New York, 1978, Academic Press.

many to be ineffective in unprimed breast tissue. Jelliffe<sup>19</sup> points out that the most important factor for continued production of milk is not drugs or hormones but "mulging." He explains that *mulging* (stimulation) is a word created by N. W. Pirie to mitigate the confusion between the words *sucking* and *suckling*. The word comes from the Latin *mulgere*, to milk. *Suck*, according to the dictionary,<sup>18</sup> means to draw into the mouth by means of a partial vacuum created by action of the lips and the tongue. *Suckle*, however, refers specifically to the breast and means "to give suck to," as at the breast, or to take nourishment from the breast; thus by definition a bottle is not suckled.

## COMPOSITION OF INDUCED MILK

Concern has been expressed that the composition of the milk produced by stimulation of suckling rather than as a result of pregnancy might differ from "normal human milk."<sup>39</sup> Such induced milk is not different in other species that have been studied extensively, including bovine and rat. In developing countries, the fact that the infants showed normal growth and weight gain was taken as evidence that induced milk is adequate.

Vorherr<sup>44,45</sup> reported the analysis of the galactorrheal secretion produced by the breast after hyperstimulation; Table 19-3 lists the comparative

**Figure 19-1.** Total protein changes over time: biologic versus nonbiologic mother's milk, protein value  $\pm$  standard deviation. (From Kleinman R, Jacobson L, Hormann E, et al: Protein values of milk samples from mothers without biologic pregnancies, *J Pediatr* 97:613, 1980.)

analysis. The induced lactational milk did not differ from puerperal milk. Brown<sup>8</sup> reported higher values of fat, protein, and lactose in galactorrheal milk, but the volume of secretion was small in these subjects (Figures 19-1 and 19-2).

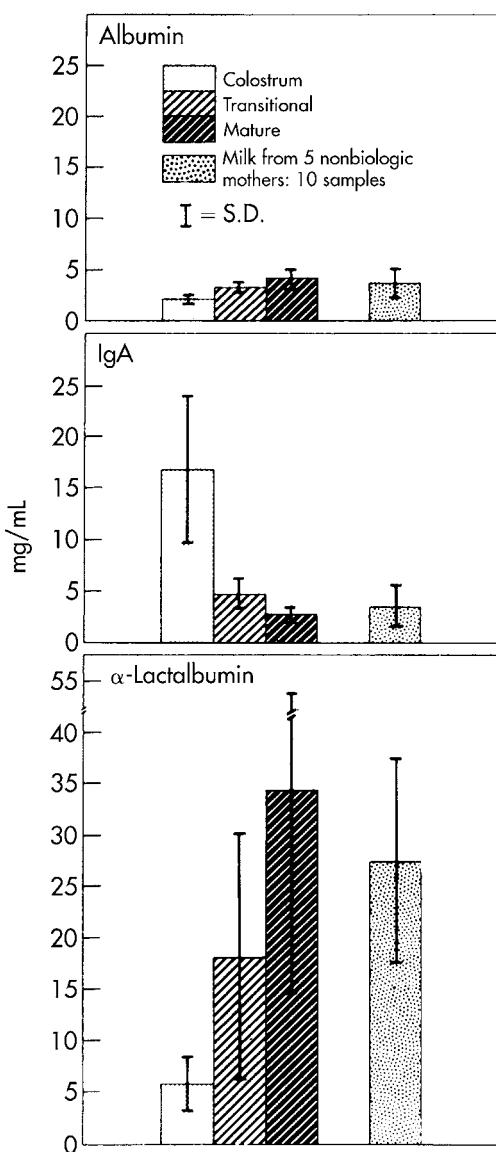

The composition of the breast secretion produced by two women who induced lactation artificially by breast hyperstimulation was close to the composition obtained for women with normal lactation, according to Kulski et al.<sup>23</sup> (see Table 19-3). These investigators also examined the milk of a woman in whom lactation had occurred when medicated with a psychotropic drug (haloperidol). She had been pregnant 4 years previously. Her galactorrhea lasted 38 months. Her milk had a composition like that of colostrum for a week but resembled mature milk at 1 month. A woman with hypothyroidism and elevated prolactin and thyrotropin-stimulating hormone (TSH) had colostrum-like milk for 53 days of sampling. Two women with galactorrhea and amenorrhea associated with pituitary tumor and hyperprolactinemia had transient colostrum-like secretion, which changed to mature-appearing milk.

Protein values of milk samples from five mothers without biologic pregnancies were measured by Kleinman et al.<sup>20</sup> Two of the mothers had nursed previous babies, and three had never been pregnant and had never breastfed. These authors did not distinguish between them. The mean total protein concentration of milk samples from the "nonbiologic" mothers differs from the "biologic" mothers (see Figures 19-1 and 19-2). If the goal of induced lactation is nurturing, these differences are clinically less important. However, a clinician needs to keep these values in mind when counseling a

mother-infant dyad about induced-lactation nutrition, especially if the infant was premature or small for gestational age. A creamatocrit test for fat and energy content is an appropriate first step (see Chapter 21).

In tandem nursing, when a mother continues to nurse an older child and puts an adopted newborn on the breast simultaneously, the composition of milk will not return to colostrum as it does with a biologic pregnancy.

Lactation has been induced in men, usually when a father tries to replace the mother who

has died suddenly. A young married man collected and froze several liters of normal appearing milk during a year's time of taking estrogen and progesterone and using mechanical breast stimulation.

## MANAGEMENT OF MOTHER AND INFANT

The collected experiences of counseling women in the Western world who want to induce lactation have resulted in reports on several thousand women. The request for information and advice is increasing and becoming widespread throughout the United States and other Western countries.<sup>39</sup>

Because simple means of supplementing the nutritional needs of an infant are available, counseling should center on the relationship and the nurturing aspects. When the process is undertaken in preindustrialized nations, the antiinfective properties become important even though total nourishment may not be possible. Success is measured by having the infant content to nurse at the breast.

A woman should be encouraged to go to a physician's office for a counseling visit before the arrival of the adopted infant to discuss the process of induced lactation. The physician ideally has a lactation-friendly office. There are physicians who specialize in breastfeeding and lactation. They can be located by contacting the Academy of Breastfeeding Medicine at 140 Huguenot Street, New Rochelle, New York 10801; telephone: 800-990-2115; fax: 914-740-2101; e-mail: [abm@bfmed.org](mailto:abm@bfmed.org); website: [www.bfmed.org](http://www.bfmed.org).

A couple who is planning to adopt an infant should have at least one visit with a pediatrician so that parenting can be discussed, just as any couple should do before the birth of a first child. At this visit, while discussing lactation with the couple, it is helpful to explore the motives and general concepts of what is involved. All authors on the subject have pointed out that a husband's interest in, and support of, lactation is critical to success. His participation in the preparation of the breasts may be a means by which the father can share intimately and constructively in the process.

Equally important is to engage the services of a licensed, board certified lactation consult (IBCLC) who is preferably associated with the physician's office. The LC will need to spend time in the day-by-day, week-by-week counsel and support of the mother.

Instruction of a mother in preparation of the breasts for suckling is critical in induced lactation, whereas with puerperal lactation it may not be necessary at all. Exercises to stimulate the nipples should be undertaken several times per day and will be most successful if they are scheduled for times

when, and situations in which, it is easy, feasible, and readily remembered. A few minutes multiple times per day is more successful and less likely to overemphasize milk versus mothering than rigid excessive exercises once or twice per day. Manual manipulation with gentle traction or horizontal and vertical stretching can be suggested. Avery<sup>5</sup> suggests that a father be encouraged to assist in breast massage and other techniques. She notes that "many adoptive parents felt that this technique (fondling and sucking of the breasts by the husband) added to the mutual sharing in preparation for adoptive nursing similar to the closeness many couples experience in preparing for natural childbirth." Raphael<sup>35</sup> reports that among 40 nursing adoptive mothers, dozens of variations on the theme of preparation were used. A positive attitude seemed to be the only consistent factor.

The need for dietary counseling is obvious. Lip service on behalf of well-balanced nutritious meals is not enough. Discussion should center on the absolute needs in kilocalories, fluids, and nutrients to produce milk (see Chapter 9).

A physician should point out that stimulation of the nipples may cause amenorrhea. Although the variation in menses is not uniform, decreased flow, irregular cycles, and total cessation of menstrual flow are possible. Conversely, the menstrual cycle may be maintained and the flow of milk may seem to vary during menses. Changes in breast size, heaviness, and feeling of fullness should accompany the induced lactation. A woman may have an associated weight gain of 10 to 12 lb (4.5 to 5.4 kg), on average,<sup>5</sup> attributed to the response of the body to developing stores for lactation, just as in pregnancy (i.e., increased fluid retention and appetite increase). The weight gain may be a simple phenomenon of excessive intake. There is no need to gain excessive weight, however, during this experience. Mothers (who may be nutritionally depleted) in non-Western countries who induce lactation are given added diet, nourishment, and herbal teas but do not usually gain weight. Failure to experience change in breast size, menstrual regularity, or weight should not be construed as a failed response as it might be in pregnancy.

Auerbach and Avery<sup>4</sup> reported a retrospective questionnaire study of 240 women: 83 had never been pregnant or lactated, 55 had been pregnant but never lactated, and 102 had breastfed one or more biologic children before the adoptive nursing (lactation). Most respondents used more than one technique to stimulate their nipples. These mothers stated that the most effective method of nipple stimulation was nipple exercises combined with infant suckling. Hand-operated pumps caused soreness and irritation. The nipple exercises included nipple stroking, massaging the breast, and rolling the nipple between thumb and finger.

In this study, infants' willingness to suckle improved over time and was related to the age at which the infant was first put to breast. Infants who were less than 8 weeks of age had more than a 75% success rate; those more than 8 weeks of age had only 50% success. No infants failed to thrive, but nearly all needed some type of supplementation. Mothers who had nursed a biologic baby before were able to wean from supplementation partially or completely. This group was also more disappointed if they had to supplement.<sup>4</sup>

Following personal experience, Bryant<sup>10</sup> prepared a review, "Nursing the adopted infant." As a physician she is able to see the issue more clearly as a physiologic, pharmacologic, and psychologic challenge.

The initiation of lactation and establishing relactation in an outpatient setting with mothers whose infants are less than 6 weeks old in India is described by Banapurmath et al.<sup>6</sup>—over a thousand mothers were followed with 91.6% succeeding in establishing lactation within 10 days. Proper latch was reported to be essential for success. Focus was on understanding the process, positioning, and building confidence. Medications were not used. Establishing lactation in India for mothers who are adopting babies usually in social crises is challenging. A report was done of 23 mothers, all of whom were given metoclopramide 10 mg twice a day for 15 to 20 days. They put the baby to breast immediately upon receipt of infant.<sup>24</sup> Motivation was critical to success. Lactation has been induced in a primiparous woman with Sheehan's syndrome (see Chapter 16), which is usually described as a delivery where there is excessive loss of blood and maternal shock that also shocks the pituitary. Most of these women develop permanent hypopituitarism. A patient of our Lactation Study center suffered such an event. The mother had an emergency hysterectomy. She wished desperately to breastfeed. She was given daily oxytocin by nasal spray and pumped the breasts with increasing frequency. She began producing milk in 2 weeks and fully lactating in 4 weeks. The infant was 36-weeks premature when admitted to the NICU. She nursed the infant for a year, although she was hypopituitary.

Early successful relactation in a case of prolonged lactation failure was reported by Agarwal and Jain.<sup>1</sup> The case was a mother with hemorrhage and shock at delivery. At 3½ months the infant was very ill with diarrhea, dehydration, and shock due to formula intolerance. The mother induced lactation with the drip and drop method. A tube is used along the breast just beyond the nipple and an assistant presses on the syringe causing milk to drip as the infant suckles, similar to the Lact-Aid device. Supplement was given by cup and spoon until the mother's milk supply was sufficient to sustain the infant.

The following simple guidelines, developed as a result of experiences reported by several authors and many mothers, may be helpful to physicians in counseling mothers to induce lactation:

1. Before arrival of the baby, initiate frequent, brief manual stimulation of nipples and breasts, increasing time gradually to approximately 10 minutes per session. Initiate mechanical pumping stimulus after 2 weeks or so of manual stimulus, if time permits. Hand pumps usually cause more soreness. Modern electric pumps with milking action and pressure cycling are most effective. Pumps that can be controlled in cycle frequency and strength are best. Double-sided pumps maximize stimulus and save time.
2. On arrival of the baby, depending on the infant's age, limit sucking to breastfeeding, using a lactation supplementer if necessary.
3. Breastfeed before any other nourishment is provided for a given feeding.
4. Avoid stressing baby with hunger.
5. When supplementing, use donor human milk or prepared formula, not cow's milk, with its long stomach-emptying time and potential for allergic response.
6. Avoid rubber nipples and pacifiers to encourage appropriate suckling at breast.
7. Provide other supplements by dropper, spoon, cup, or supplementer.
8. Create a positive atmosphere, "mother the mother."

A trial of oxytocin nasal spray once the infant is established at the breast may facilitate let-down and even encourage prolactin release.

Rigid conformity to a system of feeding may be a symptom of a more serious problem. Women who are rigid and compulsive may have trouble lactating because of the inability to have a good ejection reflex, which can be inhibited by stress and emotional conflict. Mothers who demonstrate an inordinate attention to volume of production of milk more than the value of the relationship may feel as if they have failed.

## WHEN ADOPTING MOTHERS ARE A SAME-SEX COUPLE

- As inducing lactation for an adopted infant by same-sex couples has become more common, so has the desire to breastfeed the infant by both women in a lesbian relationship.
- Physiologically inducing lactation is usually possible for both women although often one is more successful than the other. A case is reported by Wilson et al. in which both adopting women and the biologic mother breastfed the infant.

Milk induction was stimulated with hormones, domperidone, and scheduled breast pumping. Defining parental roles was complex and maintenance of milk production was difficult.

- Considerations are complex when the infant of a same-sex couple has been born to one member of the couple by artificial insemination, and both women plan to breastfeed the baby, one by lactation induction.
- A case is reported as an ethical issue when the physician refuses to assist the patient inducing lactation.<sup>46</sup> The conclusion of the ethics consults was that the physician's objections were unfounded. The value to the infant outweighed any objections. It was felt that the objection showed a troubling unfamiliarity with the clinical facts of lactation and a double standard for treating LGBTQ patients and heterosexual patients.<sup>46</sup>

## NUTRITIONAL SUPPLEMENTATION

The need to supplement an infant's intake while the milk supply is being developed should be discussed. An older infant who has already been receiving solid foods can be continued on solids by spoon with careful attention to nutritional content so that the diet includes a balance of protein and other nutrients. Supplements with milk or formula should be appropriate to the age of the infant. The infant younger than 12 months should receive infant formula rather than whole milk if donor breast milk is not available. The milk supplements should be full strength, 20 kcal/oz, and provided during the feeding by dropper or supplementer or after the nursing by dropper, spoon, or cup in preference to artificial nipple, which may confuse the infant during adaptation to nursing at the breast.

## POSTMENOPAUSAL LACTATION

Women have had infants after menopause thanks to modern fertility techniques and hormone therapy. The question, "Can they breastfeed?" arises. They will require maintenance hormone therapy paralleling levels in postpartum lactating women. The oxytocin and prolactin should respond with removal of the placenta and suckling of the infant at the breast. Three cases have been reported to the lactation center in which producing milk was successful. No long-term follow-up was available.

A postmenopausal woman may wish to induce lactation. Some of these women are young and had surgical menopause; however, most of them had emergency hysterectomies and still retain their ovaries. The situations are different; the treatment is different.

In natural menopause, the woman may be on hormone replacement therapy, which should be modified to match pregnancy levels of estrogen and progesterone. A program of regular systematic dual pumping should be initiated with the addition of galactagogues, such as domperidone, after the breast has responded with enlargement and turgescence and the first drops of milk. The woman who has retained her ovaries can be managed in the same manner as a premenopausal woman.

## SUPPORT SYSTEMS

The process of induced lactation requires considerable commitment and determination.<sup>48</sup> It is far more arduous a task than initiating postpartum lactation, but it is possible and worth the effort, according to the many mothers who have attempted it. The situation is better managed if a doula is available. It is appropriate for a physician to suggest that, in addition to medical support, the mother seek counseling from a licensed, certified lactation consultant experienced in induced lactation. Day-by-day contact for verbal support may be helpful, and these needs may be beyond the scope of a busy office practice unless there is a lactation consultant on staff. A nurse practitioner may be invaluable in this situation, particularly if home visits are made.

Ensuring that the child grows appropriately is the responsibility of a pediatrician; however, this task is best carried out in a nonthreatening way so a mother can concentrate on nurturing and nourishing the infant.<sup>17</sup> Monitoring the usual growth parameters of weight and height as well as the patterns of voiding and stooling is essential.

## PROTOCOLS FOR INDUCED LACTATION

The Newman-Goldfarb protocols were developed by Dr. Jack Newman and Ms. Lenore Goldfarb and are on the website Ask Lenore at [http://www.asklenore.info/bfg/induced\\_lactation/regular](http://www.asklenore.info/bfg/induced_lactation/regular). Also available are protocols for induced lactation with accelerated menopause. The protocols use hormonal stimulus using birth control pills and domperidone initially until the breasts have responded and enlarged; pumping is initiated within 1 month of the beginning of feeding. Various herbs recognized as galactagogues are also added.<sup>31</sup> Domperidone is not available in the United States by FDA mandate.<sup>43</sup> The authors point out that starting 9 months before the baby arrives is ideal preparation time. They also provide information for more rapid induction. They do not recommend pumping until the hormone treatment has been effective. They recommend stopping the

hormones as pumping is begun. Domperidone is maintained throughout. A woman should always consult her own physician before starting any protocol or trying any medication, hormones, or herbs.

## Relactation

Relactation has assumed new significance as the plans for disaster preparedness are reviewed. World attention has been drawn to major disasters, hurricanes, earthquakes, tsunamis, tornadoes, and fires that leave infants without their mothers to nurse them. The drama has allowed people to recognize the value and safety of human milk and breastfeeding when simple things like clean water, sanitation, heat, and light are not available. Brown<sup>8</sup> recalls the 100,000 orphans in the city of Saigon, many of whom were newborns. In times of disaster surrogate mothers were housed in orphanages, fed well, and received a daily dose of chlorpromazine for a week. Many women were able to nourish two babies.

The need to relactate exists in a number of circumstances, including the following:

1. A sick or premature infant cannot be fed initially, or at all, until several weeks or months old (*Figure 19-3*).
2. An infant is weaned prematurely because of illness in the infant or in the mother.
3. An infant who was not previously breastfed develops an allergy or food intolerance.
4. A mother who has lactated weeks, months, or years earlier wants to nurse an adopted infant.
5. A mother who is nursing a biologic child wants to nurse an adopted child (without benefit of pregnancy).
6. A town or village is in a time of crisis in the area and infants need clean safe food.

Historical reviews provide many examples of infants suckled in times of crisis by women who have not lactated for years. The process of reestablishing lactation under these circumstances is generally easier than that of nonpuerperal lactation. Investigations have shown that a breast that has been previously primed by pregnancy to respond to prolactin will produce milk more readily (*Table 19-4*).

Relactation was reported in a series of 15 mothers being managed in a clinic in Davangere, Karnataka, India, who had stopped breastfeeding for 2 weeks or more.<sup>6</sup> The mothers had stopped because they thought they did not have enough milk and began supplementing. The management began immediately with putting the infant to the breast 10 to 12 times per day for at least 10 to 15 minutes on each breast. Key to success was the pouring of milk (formula or donor milk) by

**Figure 19-3.** Premature infant at breast: infant weighed 1300 g at time of photograph.

\*Mothers were asked if their brassiere size was different from that before this pregnancy.

†Estimated on the basis of a decrease in formula intake.

‡Ceased to suckle her infants after 28 days in the study to return to full-time employment.

From Bose CL, D'Ercole J, Lester AG, et al: Relactation by mothers of sick and premature infants, *Pediatrics* 67:565, 1981.

spoon or small cup by a helper (a nurse or relative). The amount of milk dripped over the breast was reduced as a mother's supply increased until the process could be stopped. The group of mothers included two with premature infants and two surrogate mothers who had not breastfed for 16 and for 6 years, respectively. Milk appeared at 7 and 8 days of pumping and exclusive breastfeeding was accomplished in 45 and 40 days. Follow-up and support was intense. Babies were seen and weighed weekly. Ten of the 15 were exclusively breastfed and five continued with some supplementation. The authors encourage clinicians to initiate relactation whenever a mother thinks her supply has dwindled.

These protocols have not been tested with placebo-controlled blinded studies but reflect the experience of a number of practitioners.

## PSYCHOLOGIC FACTORS

Although the general process of nipple stimulation, having the infant suckle the breast, and setting the stage for lactation is similar, a woman who has experienced successful lactation previously may have not only the physiologic but also the psychologic edge. As Jelliffe<sup>19</sup> wrote, "Breastfeeding is a confidence game."

A prospective study of mothers whose infants were in the neonatal intensive care unit in Durham, North Carolina, was reported by Bose et al.<sup>7</sup> The profile of the mothers is listed in Table 19-4. Mother and baby were admitted to the clinical research unit, where they were assisted with relactating, including help using the Lact-Aid. The infant's nutritional intake was recorded. Mother and infant were discharged when the mother was comfortable with the Lact-Aid and feeding was established (approximately 3 days). Follow-up occurred every week or two. All but one infant were initially reluctant to suckle, but all received their entire nutritional intake at the breast, with or without Lact-Aid, within the first week of the study. Most of the mothers had trouble initiating suckling, with the most significant factor being the length of separation from their infants and not the degree of prematurity, postnatal age, weight, or feeding regimen. Nipple tenderness occurred in all mothers, but it was transient. All the mothers (except number seven, who was an adoptive mother) produced milk in 1 week, with maximum milk production occurring from 8 to 58 days, proportional to the time since delivery.

Although it was done with a small population, this study established some important information. Given appropriate techniques and support, many women appear to be able to relactate, and premature infants can learn to breastfeed after initial bottle feeding.

A retrospective study of relactation was reported by Auerbach and Avery<sup>3</sup> in which 366 women

responded with a completed questionnaire of more than 500 contacted from a list of names obtained from manufacturers' lists, magazine ads, and requests to breastfeeding support groups. The bias was in favor of well-educated, affluent women who had probably obtained their lactation goals. The population included those who had untimely weaning ( $n=174$ ), after delivery of low-birth-weight infants ( $n=117$ ), and after hospitalization of mother or baby or both ( $n=75$ ).

An infant's willingness to nurse was related to previous suckling experience, but responses in the first week of effort were not directly correlated with ultimate successful suckling. After 1 month, 50% of mothers were able to discontinue supplementing; however, 24% were never able to eliminate supplements completely. Once established, the nursing patterns were similar to those of ordinary breastfeeding. The authors<sup>3</sup> point out that keeping the baby hungry in the mistaken notion that the infant will nurse more often and for longer periods does not help and may negatively influence outcome. It is of interest that fewer than 10% of respondents felt that they had received helpful advice from health care professionals.

Relactation in mothers of children older than 12 months of age was reported.<sup>33,41</sup> Six Australian children 12 to 18 months of age had been weaned by the mothers, with no further stimulus to the breast, and then were reinitiated to breastfeeding. The length of time without breastfeeding ranged from 1 week to 6 months (Table 19-5). All the

**TABLE 19-5** Relactation in Mothers of Children Older Than 12 Months of Age

Case No.	Age of Child	Length of Time Off Breast	Methods	Evidence of Presence of Milk	How Long from Relactation to Weaning	Age at Final Weaning
1	48 mo	4 mo	Child suckled from breast Mother relaxed, not anxious over outcome	Child verbally reported presence of milk Mother saw whitish milk	After milk appeared	48 mo
2	12 mo	1 wk	Child took four feeds daily	Milk had not quite dried up	1 yr	2 yr
3	20½ mo	2½ mo	Mother gave in to demands of child and suckled her	Mother noticed child's swallowing while breastfeeding	>10 mo	Sometime after 2½ yr
4	2 yr	1 mo	Child suckled from both breasts avidly	Mother saw the milk flow was enough to soak the bed next morning Mother heard swallowing	Approx. 1 yr	>3 yr
5	>3 yr	6 wk	Child suckled from both breasts	Mother saw the milk Mother noticed swallowing	Approx. 2 yr	5 yr
6	Approx. 2 yr	Approx. 6 mo	Mother attached child to breast to demonstrate	Mother began to feel let-down of milk	12 mo	Almost 3 yr

From Phillips N: Relactation in mothers of children over 12 months, *J Trop Pediatr* 39:45, 1993.

children had been actively weaned and initiated the suckling, although the mothers did not forcibly resist. All the mothers reestablished milk supplies and nursed for 48 months to 5 years.<sup>31,40</sup>

## TANDEM NURSING

Tandem nursing an adopted child is a phenomenon in which the adoptive mother is still nursing a biologic child and puts an adopted infant to the breast and intends to nourish the newcomer totally. Usually the older child is a toddler and feeding only a few times per day or for comfort and receiving the major nourishment from other food and drink. In biologic tandem nursing, the milk returns to colostrum-like constituency with the birth of the new baby; in the absence of a pregnancy, however, the milk volume may increase with increased nipple stimulus while the constituents do not change. Data on milk constituents beyond a year postpartum or in the case of relactation have been noted earlier. In most cases reported anecdotally, the adopted infant is several weeks or months old, so the absence of colostrum is less of a problem. On the other hand, the active state of lactation in terms of immediate availability of milk is an advantage.

An additional concern, as in any situation of tandem nursing, is the development of the younger child. The physician will need to be alert to these issues in counseling the family and ensuring adequate total nutrition for the adopted child.

Eighteen respondents to the survey on adoptive nursing by Auerbach and Avery<sup>4</sup> reported tandem-nursing experiences; 11 of these mothers were able to discontinue supplements totally (two within the first month). Most of the infants were started on solids by 4½ months, which may be the most effective method of supplementing if nutritional value is maintained. For physicians, it is important to be knowledgeable about tandem adoptive nursing and to support the family accordingly.

## DRUGS TO INDUCE RELACTATION

Some medications that have been tried in relactation seem to work only when the breast has been primed by mammogenesis, that is, by pregnancy.<sup>42</sup>

Thyroliberin (TSH) has been used by Tyson<sup>42</sup> and others to induce lactation (see Table 19-2). Each woman in the study was primed with estrogens beforehand. Thyroliberin stimulates the pituitary to release both TSH and prolactin. Drugs that produce a decrease in hypothalamic catecholamines, such as phenothiazines, reserpine, meprobamate, amphetamines, and  $\alpha$ -methylldopa, cause an increase in prolactin secretion by blocking hypothalamic PIF.

The feasibility of pharmacologically manipulating puerperal lactation was demonstrated by Canales et al.<sup>11</sup> using bromocriptine and thyroliberin sequentially. They suppressed lactation using bromocriptine orally for 8 days in four mothers whose infants were premature or ill and could not be nursed. These mothers did not lactate during this time. On the 8th day, they were given thyroliberin intravenously and then orally daily for 4 days (8th to 12th postpartum days). On the 14th day, they initiated breastfeeding by putting the infants to the breast. Prolactin levels were measured from the day of birth. Levels were depressed by bromocriptine and rose when the thyroliberin was given. The mothers subsequently nursed successfully.

Bose et al.<sup>7</sup> also studied thyroliberin and the basal and stimulated serum prolactin concentrations. Prolactin concentrations were measured followed by levels at 15 and 30 minutes after intravenous infusion of 200 mg (range 100 to 500 mg) of thyroliberin. Prolactin levels were also measured before and after suckling at weekly intervals. Serum prolactin levels rose 15 minutes after infusion of thyroliberin (Table 19-6). The absolute rise in prolactin concentrations did not appear to be related to establishment of milk production. The change over time in the basal prolactin levels was not predictably related to lactation progress.

Lactation can be reestablished with metoclopramide, according to Sousa et al.<sup>37</sup> Metoclopramide is a derivative of procainamide, as is sulpiride (see Chapter 16).

Metoclopramide and sulpiride are potent stimulators of prolactin release. A marked increase in prolactin is seen when metoclopramide is given, as noted previously in this chapter. Sousa et al.<sup>37</sup> used metoclopramide to reestablish lactation in women who had experienced diminished milk supply (Table 19-7). All five mothers experienced increased production of milk when 10 mg was given orally every 8 hours for 7 to 10 days. No side effects were noted, although this drug is known to cause cardiac arrhythmias and extrapyramidal signs in some adults. No side effects were noted in the infants either, but the level of drug was not measured in the milk. The results were encouraging, but further study is needed to determine the minimum dosage necessary to produce the effect and the amount passed into the milk.

In a controlled double-blind study with a placebo, Lewis et al.<sup>26</sup> found no difference in the success rate of induced lactation in 10 patients medicated with 10 mg metoclopramide orally three times daily for 7 days compared with 10 matched patients medicated with lactose capsules. Successful lactation was attributed to the special advice and support provided equally for these women by the nursery staff. Before conducting the study,

4	35	3	30	7	None	Same as above	University
5	20	2	20	7	None	Same as above	High school

From Sousa PLR, Barros FC, Pinheiro GNM, et al: Reestablishment of lactation with metoclopramide, *J Trop Pediatr Environ Child Health* 21:214, 1975.

these authors measured the amount of drug that appeared in the milk of 10 women after a single 10-mg dose of metoclopramide given orally at 7 to 10 days postpartum. The mean 2-hour post-dose plasma level was  $68.5 \pm 29.6$  ng/mL. The simultaneous mean concentration in the breast milk was  $125.7 \pm 41.7$  ng/mL. If an infant consumed a liter of milk per day, the dose to the infant would be calculated at 130 mg or 45 mg/kg, a subtherapeutic dose. These data do not address possible accumulation in the infant, however, when multiple doses are given to the mother.

Domperidone has a better track record anecdotally for stimulating lactation but has not been studied in induced lactation or relactation. Herbals such as fenugreek have not been studied for this purpose either but could be used as an adjunct to protocol.<sup>33</sup>

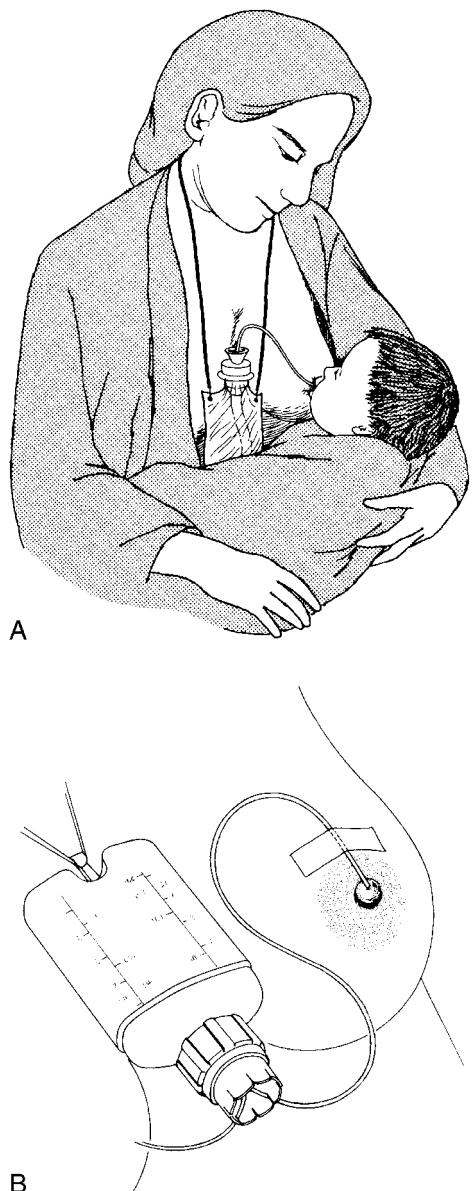

## Special Devices

Although many mechanical devices have been developed since Roman times to augment lactation and give other feeding opportunities, lactation-supplementing devices provide a unique ability to

adequately nourish an infant while it is suckling at the inadequately lactating breast (Figure 19-4). The suckling stimulates the mother's own supply. On the other hand, the infant continues to suckle the breast because milk is available. The devices have been carefully engineered to provide a source of milk that is obtained by suckling, not by gravity. The capillary tube through which the milk flows can be placed along the human nipple without interfering with suckling. The plastic containers that serve as reservoirs for the supplemental milk are sterilizable or disposable. The milk is naturally warmed by hanging the bag beside the mother's breast, as shown in Figure 19-4.

Gradual weaning from the supplementer can be provided by putting less and less in the container each day. Thus the infant can obtain milk from the breast in increasing amounts because the nipple stimulation affects milk production.

An increasing number of mothers want to nurse their sick premature infants; however, it is often not possible for the infant to breastfeed for weeks. Meanwhile, the mother may pump but only obtain minimal volume. When the infant is finally ready for discharge from the hospital, it is mandatory that

**Figure 19-4.** **A.** Lact-Aid Nursing Trainer System (Lact-Aid International Inc., Athens, Tennessee). **B.** Supplemental Nursing System by Medela (McHenry, Illinois), which provides additional nourishment to infant while suckling at underproducing breast.

the baby continue to receive reliable nourishment every day. Starving the infant into submission is inappropriate and dangerous. A lactation supplementer is an excellent alternative.

For years, mothers of premature and sick infants have been assisted in breastfeeding their infants in preparation for discharge from the hospital and during the early weeks at home by using dropper feeding, complementary feeds by bottle after each breastfeeding, or solids. The success rate

was low and the aggravation for the mother often insurmountable.

Weaning from the device is usually not a problem for most of the infants. It was a problem, however, for an occasional mother who could not nurse without the supplementer even though it contained less than an ounce of formula per feeding and the breast was supplying the rest. Because the mother may use this as a "crutch," careful anticipatory counseling should address this issue.

Special equipment should be started with a full understanding of its role in nourishment of infants as well as with a plan for weaning from it that begins the first day. Weaning should be appropriate to an infant's age and nutritional needs. The nourishment provided should be donor human milk or regular-strength formula, 20 kcal/oz, and not just water, sugar water, or diluted formula. Starvation, even for a day or so, in a premature infant compromises growth, especially of the brain. An infant who has been in the intensive care nursery is in special jeopardy (see Figure 14.3).

Several alternative devices have been suggested by professionals interested in the transient supplementation of lactation while a mother increased her milk supply for her full-term baby. Usually in these situations, lactation failure has been the result of inadequate initial advice. The devices are rigged from readily available feeding tubes and syringes but lack the special engineering and safety features of the supplementer. Special precautions are advised when employing such handmade equipment to avoid milk aspiration by the infant, which is the chief hazard. Because they will allow milk to flow without sucking, they do not stimulate the infant to suck. Other devices, such as hand pumps and a variety of electric pumps, which are useful in initiating relactation or induced lactation as well as in puerperal nursing, are illustrated in Chapter 21.

## SUMMARY

Careful medical management of an adopted infant who is breastfed is important. Many times the prenatal care of this infant as a fetus in utero and the biologic mother has not been optimal. Any failure in growth should be identified quickly so that appropriate supplementation can be provided. In cases of relactation to provide for sick or premature infants, close follow-up is mandatory. A child who does not have a powerful suck may appear to be content yet be underfed.

Relactation and induced lactation are special events requiring the positive support of medical personnel.<sup>48</sup> A physician can serve as a well-informed stable resource in a process that will require considerable effort and commitment by the participants and will go better if there is an

experienced licensed IBLCL available as a supporter. A pediatrician is responsible for monitoring adequate growth, nutrition, and adjustment of the child.

#### *Mother-initiated preparation*

1. Nipple stimulation: hand massage and nipple exercise, hand pump, electric "milkers"
2. Diet supplementation: fluids and calories, especially protein
3. Reading, learning, and communicating with others with similar experience

#### *Physician-initiated preparation*

1. Knowledgeable, sympathetic support
2. Preparatory hormones and lactagogues to promote mammogenesis for prescription
3. Induction of let-down: oxytocin nasal drops to initiate or enhance let-down
4. Counseling about breast preparation and diet supplementation in the context of total care of the mother and the infant
5. Use of lactation-supplementing devices

## *Wet Nursing or Cross-Nursing or Co-Feeding*

Although feeding an infant by one who is not the mother is an established means of sustaining life, it has been uncommon in Western cultures. There were no medical contraindications provided the nursing woman was in good health, was infection free, and was taking no medications. The threat of human immunodeficiency virus (HIV) infection has altered the risk. In special cases, surrogate nursing would be acceptable by individual arrangement, with HIV testing in both mother and infant. The chief obstacle had been psychologic or social. Actually, women who are trying to develop a supply of milk when their own infants cannot nurse because of prematurity or illness would be benefited by having a vigorous, normal suckling infant nurse at their breasts.

In contemporary society, the term *cross-nursing* has replaced *wet nursing* to disassociate the phenomenon from negative historical connotations.<sup>22</sup> In reviewing mothers' experiences of sharing breastfeeding or breast milk, Thorley<sup>41</sup> has offered a new term to replace *cross-nursing*: *co-feeding*. She points out that wet nursing initially was an occupation and was done for hire and did not include any reciprocity. When sisters or friends nurse each other's infants, reciprocity exists. The term *co-feeding* is felt to suggest sharing. The term *milk siblingship* is proposed to suggest the bond between children breastfed by the same woman. In cross-

nursing the mother continues to breastfeed her own child in addition to the child she takes for a feeding or two per day. The circumstances described in the report by Krantz and Kupper<sup>22</sup> usually involve babysitting arrangements, which may be daily and formal or random and informal. They interviewed three women involved in a mutual agreement for babysitting purposes. The mothers were married and well-educated. The babies were girls and 4 months old. The mothers reported no physical effects on the babies. The behavioral reactions of the babies were being disturbed and "looking puzzled" if the surrogate mother spoke. Some difficulty was noticed in let-down, and all three mothers noted a difference in the way each baby suckled.

Another purpose of cross-nursing is for maternal benefit, wherein an experienced, vigorous infant is nursed by a woman whose own baby is unable to give proper stimulus to milk production. This has been done by private arrangement and has not caused any known problems. Usually the normal newborn is younger than 2 months. Cross-nursing has also been used to stimulate lactation in adoptive nursing. In this situation, the infants are exchanged to stimulate the adoptive mother's breasts and also to show the adopted infant that milk comes from breasts and how to suckle at the breast.

Cross-nursing had been used in neonatal intensive care units by mothers to encourage their own milk production. It is usually a private arrangement between mothers who have babies to nourish. A mother of an immature infant who cannot be put to the breast sought out a friend who was actively feeding a full-term infant and borrowed the infant to stimulate her production. An infant who needs to learn how to suckle correctly after weeks of bottle feeding or no feeding may benefit from being nursed by a fully lactating woman. The best pump is always a suckling infant.

The hazards to cross-nursing are undocumented but worthy of consideration. The physical problems are the potential for infection, either of mother or of baby; interruption of milk supply for the mother's own baby; and the difference in composition of milk if babies are of different chronologic or conceptual ages. The psychologic hazards could include failure of mother to let-down, refusal of infant to nurse (which does occur when infants are introduced to the practice after 4 months of age), and negative impact on siblings and the household environment. The long-range effects are not documented.

Reasonable caution is certainly appropriate, taking care to ensure that the cross-nursing mother is healthy and well nourished without any general or local infection, not taking any medications, and not smoking. The infants should probably be close in

age to the mother's own baby and also free of infection, especially thrush. If this were a commercial venture in a public daycare setting, regulations of certification, screening for tuberculosis, syphilis, hepatitis, cytomegalovirus, herpesvirus, HIV, and other infectious agents would be in order. Documents of liability might be required with signed consent forms. Mothers' experiences of sharing breastfeeding or breast milk were reviewed in Australia from 1978 to 2008 by Thorley.<sup>41</sup> The objective of the study was to explore the mothers' experiences when they shared breastfeeding, why it was done, and what was the process. The most common reason to participate was to provide human milk for their babies, exclusively, including whenever they were separated from their infants or temporarily unable to feed the infants themselves. Most of the respondents to the survey were selective about with whom they would share. They otherwise found positive response from friends and health care professionals, although they noted a change in attitude in the 30 years. Various cultural "rules" exist for milk-sharing. In Chinese, Japanese, and Thai families, milk can only be shared for infants of the same sex. Moslem tradition is strict in its ban on marriage between children who had the same wet nurse. In some cultures breast milk is a conduit of ancestral power. Sharing is restricted to the same clan or lineage.

Perhaps as breastfeeding knowledge and understanding reach a greater number of professionals and women, such opportunities may be more common. At present, it is significant to recognize cross-nursing as a viable option, as long as appropriate infection precautions are taken. A hospital or a physician cannot be the agent of arrangement.

# *Reproductive Function During Lactation*

---

Complete and in-depth discussion of contraception during breastfeeding is provided in the Academy of Breastfeeding Medicine Protocol #13, recently revised by two of the Academy's most knowledgeable members on the subject.

## *Fertility*

---

The understanding of the underlying mechanisms of infertility and fertility return during lactation has been increasing in the last 30 years, with studies of both animal and human models. Much has been learned from comparing the lactating and nonlactating hormonal physiology and from the study of the associated brain peptides. Although we understand more today, many significant questions remain.

## **LACTATIONAL INFERTILITY**

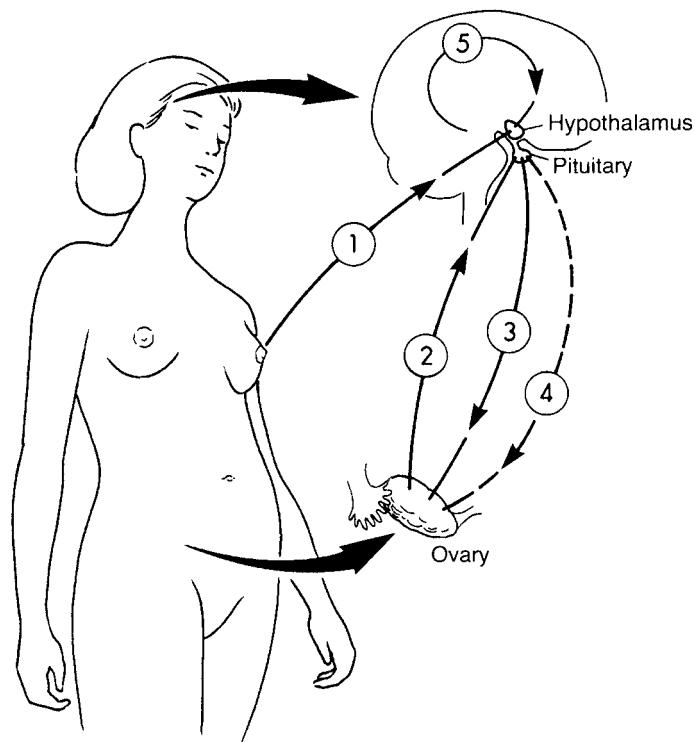

The prolonged postpartum infertility associated with lactation has been attributed to changes in the hypothalamic-pituitary-ovarian axis mediated by gonadotropin secretion. Frequent suckling at the breast causes changes in gonadotropin-releasing hormone (GnRH), which impacts anterior pituitary hormone and disorganized the pulsatility and levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), disallowing the rhythmic patterns that result in ovulation. Frequent suckling also results in high prolactin levels; however, the role of prolactin in fertility suppression is less clear.<sup>42</sup>

**Figure 20-1** illustrates the menstrual cycle and gonadotropin control. Key points include the following:

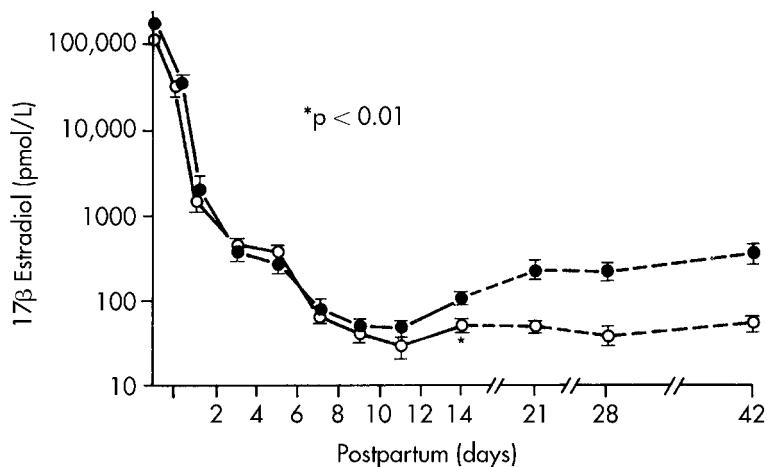

1. Follicular development is initiated by pituitary gonadotropin FSH.
2. Continued growth requires FSH and estradiol from the growing follicle in response to LH, which is released in a pulsatile fashion from the pituitary.
3. At midcycle, an increase in estradiol triggers the release of preovulatory surges of LH and FSH.
4. The follicle secretes predominantly progesterone (luteinization).
5. The oocyte is released 36 hours later.

The pulsatile release of GnRH from the hypothalamus stimulates the release of LH. In the cycling woman, estrogen increases GnRH secretion, and the combination of progesterone and estrogen decreases it.<sup>42</sup>

The postpartum period, however, is characterized hormonally by elevated levels of prolactin and low levels of gonadotropins, resulting in anovulation and amenorrhea. During breastfeeding, this state can persist for an extended period, even though prolactin levels decrease over time. As currently understood, the pulsatile secretion of GnRH is altered by the suckling stimulus, influencing ovarian activity.<sup>42</sup> Although the action of prolactin on multiple target organ sites has frequently been suggested as the cause of this ovarian quiescence, it appears that a suckling-induced alteration in hypothalamic GnRH production is the primary mechanism. Zinaman et al. found that when pulsatility is restored during lactation by administering exogenous pulsatile GnRH, LH values increase and FSH levels

**Figure 20-1.** Possible mechanisms of lactational amenorrhea: nervous impulse from nipple produces not only a rise in prolactin (1) but also changes in hypothalamic sensitivity to ovarian steroid feedback (2) and changes in gonadotropin-releasing hormone (GnRH) (3), leading to changes in pituitary release of luteinizing hormone and follicle-stimulating hormone (4). Suckling may also stimulate release of  $\beta$ -endorphin (5), thus suppressing GnRH from hypothalamus. (Redrawn from Winikoff B, Semeraro P, Zimmerman M: *Contraception during breastfeeding: a clinician's source book*, New York, 1988, Population Council.)

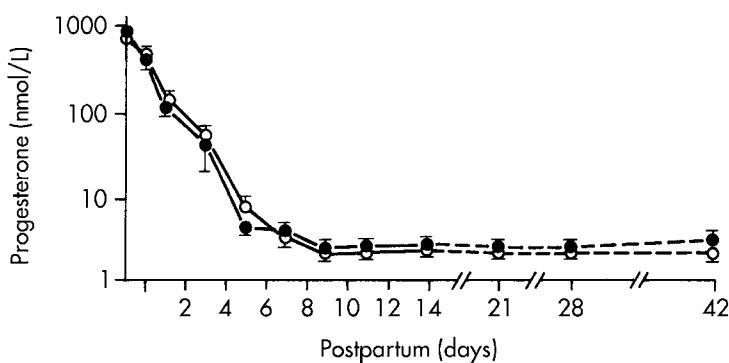

**Figure 20-2.**  $17\beta$ -Estradiol levels in postpartum period in lactating (open circles) and nonlactating (solid circles) women. Levels in lactating women vary with intensity of suckling. (From Neville MC: Regulation of mammary development and lactation. In Neville MC, Neifert MR, editors: *Lactation: physiology, nutrition, and breastfeeding*, New York, 1983, Plenum.)

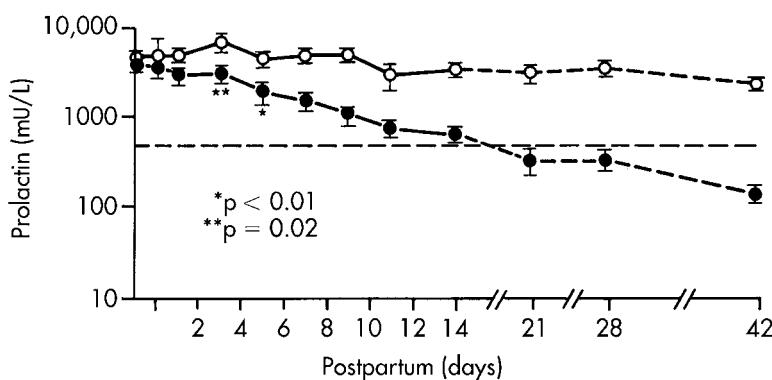

decrease while pulsatile organization of both increases, and the ovary responds accordingly.

The period of lactational amenorrhea depends on frequency and intensity of suckling (Figures 20-2 to 20-4). In these figures, open circles are lactating subjects, the solid circles are nonlactators postpartum.

Animal studies have shown that the release of FSH and LH is inhibited by intense suckling. In addition, when the nipple is stimulated while the milk ducts have been tied off there is still a suppression of estrous and menstrual cycles. Selye and McKeown<sup>63</sup> concluded that interruption of sexual cyclicity

**Figure 20-3.** Progesterone levels in postpartum period in lactating (open circles) and nonlactating (solid circles) women. (From Neville MC: Regulation of mammary development and lactation. In Neville MC, Neifert MR, editors: *Lactation: physiology, nutrition, and breastfeeding*, New York, 1983, Plenum.)

**Figure 20-4.** Prolactin levels in postpartum period in lactating (open circles) and nonlactating (solid circles) women. Levels in lactating women vary with intensity of suckling. (From Neville MC: Regulation of mammary development and lactation. In Neville MC, Neifert MR, editors: *Lactation: physiology, nutrition, and breastfeeding*, New York, 1983, Plenum.)

during lactation is a result of the suckling and not of the secretory activity of the mammary gland. This early animal work has stood the test of time. The more the suckling stimulus in frequency and duration, the more consistent is the suppression of ovulation.<sup>42</sup>

The levels of gonadotropin in all postpartum women for the first weeks of the postpartum period are decreased, which substantiates the theory of postpartum ovarian refractoriness. In the first 2 weeks postpartum, low levels of FSH are found in urine and plasma. Estrogen excretion is low with a linear increase during the first 5 to 8 weeks. In a longitudinal study of 48 women, endocrine profiles were assessed with morning blood samples from the first postpartum month until the recovery of ovulation.<sup>13,14</sup> Additional samples were drawn throughout 24 hours at the end of the third postpartum month in 10 exclusively nursing amenorrheic women. Prolactin, LH, FSH, estradiol ( $E_2$ ), progesterone, cortisol, and dehydroepiandrosterone sulfate were measured. In response to suckling, there was a smaller increase in prolactin and higher levels of  $E_2$  in women who

ovulated within 6 months postpartum compared with those who did not. Diaz et al.<sup>16,17</sup> suggest that this may explain some of the variability in duration of lactational amenorrhea. The greater prolactin response to suckling associated with longer amenorrhea may result from higher sensitivity to the breast-hypothalamus-pituitary system.<sup>16</sup>

## PROLACTIN AND DOPAMINE

There is a relationship between lactational infertility and physiologic hyperprolactinemia; however, its role in fertility suppression is not as clear.<sup>14</sup> In an extensive study of prolactin levels in lactating women, Tay et al.<sup>67</sup> measured the pattern of prolactin secretion in relation to suckling and the return of ovarian activity. Blood samples were drawn at 10-minute intervals for 24 hours at 4 and 8 weeks, when weaning was initiated and suckling reduced, at first menses, and in the follicular phase of the first menstrual cycle after weaning. Mothers fed their infants on their usual pattern, with no restrictions or alterations, in an effort to replicate natural lactation.

These data confirmed that with frequent suckling, prolactin levels do not decline significantly between feeds. When suckling became less frequent, prolactin dropped to baseline levels between feeds but surged when suckling was initiated (see Chapter 3). The natural increase in prolactin at night was evident only after weaning. Prolactin also declined greatly in association with suckling after the return of menses. This occurred at  $33.6 \pm 3.5$  weeks postpartum in this study. No relationship was seen between the duration of amenorrhea and plasma prolactin levels throughout a day, at night, or throughout lactation. The timing of the introduction of solids was strongly correlated with the duration of amenorrhea. The authors concluded that no exact link exists between release of prolactin during lactation and the duration of lactational infertility in breastfeeding women.<sup>67</sup>

However, at least one study has identified a differential response to different prolactins.

Another study explored the ability to predict duration of amenorrhea based on parameters during pregnancy. Campino et al.<sup>7</sup> followed 17 women at 34 and 38 weeks' gestation who fully breastfed for at least 6 months. During pregnancy, prolactin, estrogens (total estradiol, unconjugated estrone, unconjugated estriol), sex hormone binding globulin, dehydroepiandrosterone sulfate, progesterone, and placental lactogen, and during postpartum, prolactin, estrogens, and sex hormone binding globulin, were measured. Free estradiol in pregnancy and postpartum was calculated. They found that the 10 women who experienced long lactational amenorrhea (greater than 6 months) had a different hormonal profile during pregnancy than the seven who experienced a short duration (less than 6 months) of lactational amenorrhea. At 38 weeks' gestation, the women who experienced a long lactational amenorrhea had twice as much prolactin, approximately half the total estradiol, significantly lower sex hormone binding globulin concentration, but similar free estradiol concentration compared with those who experienced short lactational amenorrhea. They concluded that at 38 weeks' gestation, the higher ratio of prolactin/estradiol identified all women who would go on to experience a longer duration of their lactational amenorrhea, suggesting that duration of lactational amenorrhea is conditioned during pregnancy.<sup>7</sup>

The inhibition of dopamine secretion from the hypothalamus has been associated with the neural impulses from stimulation of the nipple during lactation. Normally dopamine inhibits the secretion of prolactin, and, conversely, when dopamine is inhibited, prolactin rises. Two pathways of ovulation inhibition are possible as a result of the rise in prolactin. One is a lack of responsiveness to ovarian steroids of the hypothalamic-pituitary axis of a lactating woman, leading to nonpulsatile release of

pituitary gonadotropins, FSH, and LH, which in turn results in absent or reduced ovarian activity. FSH may actually be higher at some points; LH is nonpulsatile.

The fact that there are prolactin receptors on the ovary indicates that there may be a second mechanism contributing to the infertility through the impaired ovarian response to gonadotropins<sup>5</sup> (see Figure 20-1).

## RETURN OF MENSES

The transition from amenorrhea to regular menstrual cycles is one of the most challenging times while breastfeeding and wishing to use natural family planning. The uncertainty of the onset of ovulation with the return of menses is especially difficult. The efficacy of a new postpartum transition protocol for avoiding pregnancy is reported by Bouchard et al. The use of an electronic hormonal fertility monitor (Clear Blue Easy Fertility Monitor, Swiss Precision Diagnostics, Geneva, Switzerland) identifies the fertile period. It measures changes in urinary estrone-3-glucuronide from baseline and urinary LH above a specific threshold. The device was developed to assist with conception; it has been shown to be equally effective when utilized to avoid pregnancy. The use of an online teaching and charting protocol has potential for avoiding pregnancy postpartum while lactating.

Clinically the proxy for the return of fertility is the onset of menstruation. Return of reproductive function varies depending on the length and degree of lactation. Most studies do not, in fact, report pattern of breastfeeding, that is, whether the infant is fully or exclusively breastfed or is also receiving solid foods or supplemental bottles.<sup>20</sup> By the end of the third month, only 33% of fully lactating women have had a menstrual period, whereas 91% of nonlactating women have had at least one period.<sup>13</sup>

Not all vaginal bleeds are menses; not all bleeds follow ovulation.<sup>21</sup> In 72 fully breastfeeding women studied prospectively from 42 days postpartum, vaginal bleeding was recorded daily if it occurred. Approximately half the women had some bleeding or spotting between 6 and 8 weeks postpartum. Those who experienced this bleeding eventually menstruated and ovulated earlier than those who did not, but differences were not significant. Seven women had ovarian follicular development before day 56, but neither bleeding nor follicular development was associated with ovulation in the first 8 weeks. The authors stated it was unlikely that vaginal bleeding before 8 weeks in a fully breastfeeding woman indicates a return to fertility and, therefore,<sup>58</sup> is not the return of menses.

Perez et al.<sup>55</sup> diagnosed the first postpartum ovulation by endometrial biopsy, basal body temperature, vaginal cytologic evaluation, and cervical mucus in a group of 200 women in a prospective study. The dates of first ovulation, first menses, and nursing status were analyzed. No woman demonstrated signs of ovulation before day 36, whether lactating or not. The intensity of nursing and time postpartum affected ovulation occurrence; 78% of the women ovulated before the first menses, but only 12 pregnancies occurred with first ovulation. Of the 170 women who breastfed, 24 ovulated while completely nursing, 49 while partially nursing, and 97 after weaning.

## POSSIBILITY OF CONCEPTION

A nonlactating woman has a return of her period at 25 days at the earliest, a return of ovulation at 25 to 35 days, and a 5% chance of regaining fertility before 6 weeks postpartum.

Risk of ovulation during lactation was studied by Gray et al.<sup>20</sup> in Baltimore and in Manila.<sup>18</sup> During the first 6 months postpartum, amenorrheic women had a low risk of ovulation (less than 10%) with partial breastfeeding and a 1% to 5% risk with exclusive breastfeeding with either frequent short feeds or infrequent longer feeds. This would have resulted in a pregnancy rate of 2% and 1%, respectively.

In a detailed study of 130 women in Chile, Diaz et al.<sup>17</sup> found the cumulative probability of pregnancy at the end of 6 months postpartum in women who were exclusively nursing and amenorrheic to be 1.8%. For exclusively nursing women who had a return of menses it was 27.2%, and for those partially nursing it was 40.5%.

Although many investigators continue to evaluate the impact of lactation on ovulation and menstruation, the fundamental observations remain the same<sup>68</sup> (Table 20-1). Available data on return of ovulation and menstruation can be summarized as follows<sup>60</sup>:

- I. Nursing mothers
  - A. Ovulation generally occurs before menses return and varies 14% to 75%.
  - B. The longer the first menses is delayed, the more likely the first cycle will be ovulatory.
  - C. Continued suckling and elevated prolactin levels produce inadequate luteal function in first cycles.
  - D. Exclusive breastfeeding: First bleed generally precedes ovulation return, and if an ovulation occurs it is generally inadequate for conception.
- II. Nonnursing mothers
  - A. Earliest possible menstruation is 4 weeks postpartum.

  - A. 12 weeks postpartum: 20%
  - B. 16 weeks postpartum: 40%

## MILK COMPOSITION DURING THE OVULATORY MENSTRUAL CYCLE

Acute changes in the composition of milk during the ovulatory menstrual cycle in lactating women were studied by Hartmann and Prosser<sup>23</sup> involving women during lactational amenorrhea, taking oral contraceptives, and during an ovulatory menstrual

**Figure 20-5.** Cumulative probability of pregnancy during breastfeeding. —, Nonlactating women of normal fertility having unprotected intercourse; ■, breastfeeding women having unprotected intercourse throughout 24 months of lactation; ●, breastfeeding women having unprotected intercourse only during lactational amenorrhea and adopting effective contraceptive measures at resumption of menstruation. Percentage of women in lactational amenorrhea by month postpartum ( $\nabla$ ) is also shown. (From Short RY, Lewis PR, Renfree MB, et al: Contraceptive effects of extended lactational amenorrhea: beyond the Bellagio consensus, *Lancet* 337:715, 1991.)

**Figure 20-6.** Monthly percentage probability of pregnancy during lactational amenorrhea with estimated standard errors. With cumulative percentage probability of pregnancy by months postpartum for these three groups of women, 50% of nonlactating women would be pregnant in less than 3 months, and 85% would be pregnant by 6 months. (From Short RY, Lewis PR, Renfree MB, et al: Contraceptive effects of extended lactational amenorrhea: beyond the Bellagio consensus, *Lancet* 337:715, 1991.)

cycle. Samples of milk were collected from each breast at each feed for each day for 28 days.

During the ovulatory menstrual cycle, two acute changes occurred. For the 5 to 6 days before ovulation and the 6 to 7 days after ovulation, the sodium and chloride values changed from 4.6 mM Na and 11.1 mM Cl to 10.1 and 22.0, respectively, and lactose and potassium decreased. The concentrations of lactose, Cl, K, and Na remained relatively constant during lactational amenorrhea, anovulatory menstrual cycles, and for those women taking oral contraceptives. The authors conclude that an increase in the permeability of the mammary epithelium was effected by changes related to ovulation. Perhaps the first acute change in composition is associated with the final stages of follicle maturation and the second with the regression of the corpus luteum during the ovulatory menstrual cycle (Figures 20-5 and 20-6).<sup>66</sup>

Nutritional status has virtually no effect on amenorrhea, except in the extremes. In a study of Guatemalan women, maternal energy supplements did not shorten length of lactational amenorrhea; however, supplementing their breastfed infants did shorten amenorrhea by reducing suckling. A difference exists between postpartum and nutritional amenorrhea: true nutritional amenorrhea is predictable on the basis of the height/weight ratio, lactational amenorrhea is hormonal, and when it occurs, nutrition has only a trivial role.<sup>31</sup>

## BREASTFEEDING AND BIRTH INTERVAL

Among !Kung hunter-gatherers, long intervals pass between births, which has puzzled investigators because the tribes are well nourished, have low fetal wastage, and do not employ contraceptives or prolonged abstinence. The !Kung eat only what they hunt and gather. They have no agriculture. They are lean, spare people. They have late menarche (approximately 16 years of age), first pregnancy at age 18, and early menopause at approximately 40, leaving 24 reproductive years during which they produce 4.4 children, which, with some perinatal deaths, exactly replaces their society. This compares with industrial society, where productive years begin at 11 and end at 51. Konner and Worthman<sup>35</sup> report that the !Kung have unusual temporal patterns of nursing characterized by highly frequent nursing bouts with short space between nursings. The !Kung nurse several times an hour with only 15 minutes at most between bouts, which last only 15 to 120 seconds each. Serum estradiol and progesterone levels are correspondingly low. Infants are always in the immediate proximity of their mothers until they are weaned, at approximately 3½ years, during a new sibling's gestation.

In Nigeria, the effect of duration and frequency of breastfeeding on postpartum amenorrhea is comparable in that Nigerians breastfeed for 16.5 months with a frequency of 4.5 times a day. The mean length of amenorrhea is 12.5 months. Amenorrheic mothers

who were lactating had lower levels of serum estradiol and lactic dehydrogenase. A significant association was seen between hyperprolactinemia with amenorrhea. The incidence of amenorrhea declined parallel to that of the hyperprolactinemia.

When fertility postpartum during lactation was studied in Edinburgh, suckling was the most important factor inhibiting the return to ovulation.<sup>49</sup> Suckling duration was the first factor to discriminate the mothers who experienced early ovulation. Those mothers who ovulated while breastfeeding had introduced two or more supplementary feeds per day and had reduced suckling to less than six times per day, with 60 minutes or less suckling time per day. The basal prolactin levels were less than 600 mU/L. The mothers who did not ovulate until after 40 weeks postpartum breastfed longest, suckled most intensely, maintained night feeds longest, and introduced supplementary feeds most slowly.<sup>50</sup> The prolactin levels remained substantially greater than 600 mU/L.

Another review of the effects of hormonal contraceptives on lactation by Hull<sup>43</sup> concludes that a significant number of reports indicate decrease in milk yield. The description of severe growth failure<sup>16</sup> in the nursling, even leading to "contraceptive marasmus," in Egypt and Tunisia is cause for concern.

Most large studies of birth interval and its relationship to method of feeding have been conducted in developing countries. However, Rosner and Schulman<sup>60</sup> reported on 112 Orthodox Jewish women from metropolitan New York with 266 birth experiences. The women strictly adhered to biblical and Rabbinic law that prohibits birth control. They were well-nourished, middle-class, educated women who breastfed on demand (210 infants) for a mean duration of 10.7 months, with 177 of the infants receiving formula less than once

a week. Significant positive correlations were found with duration of lactational amenorrhea, which increased as duration of breastfeeding increased. Delay in starting solids, continuation of night feedings, and postponement of other liquid feeds all were associated with prolongation of birth interval. The investigators found a longer mean duration of lactational amenorrhea (8.6 months) and mean birth interval (22 months) than other studies because of the more intensive feeding patterns<sup>60</sup> (Table 20-2).

## Contraception During Lactation

### MEDICAL ELIGIBILITY CRITERIA FOR CONTRACEPTIVE USE

WHO's Medical Eligibility Criteria for Contraceptive Use provides recommendations for policy makers to help rationalize the provision of various contraceptives in relation to the most up-to-date information available on the safety of the methods for people with certain health conditions. The document covers the following family planning methods: low-dose combined oral contraceptives (COCs), combined patch (P), combined vaginal ring (R), combined injectable contraceptives (CICs), progestin-only pills (POPs), depot medroxyprogesterone acetate (DMPA), norethindrone enanthate (NET-EN), levonorgestrel (LNG) and etonogestrel (ETG) implants, emergency contraceptive pills (ECPs), copper-bearing intrauterine devices (Cu-IUDs), levonorgestrel-releasing IUDs (LNG-IUDs), copper IUD for emergency contraception (E-IUD), barrier methods (BARR), fertility awareness-based methods (FAB), lactational amenorrhea method

**TABLE 20-2** Comparison of Studies of Breastfeeding and Its Relationship to Birth Interval When Practiced in Absence of Birth Control

Study	Mean Duration of Breastfeeding (mo)	Mean Lactational Amenorrhea (mo)	Mean Birth Interval (mo)

(LAM), coitus interruptus (CI), and female and male sterilization (STER).

The goal of this document is to provide policy- and decision-makers and the scientific community with a set of recommendations that can be used for developing or revising national guidelines on medical eligibility criteria for contraceptive use.<sup>77,78</sup>

## LACTATIONAL AMENORRHEA METHOD

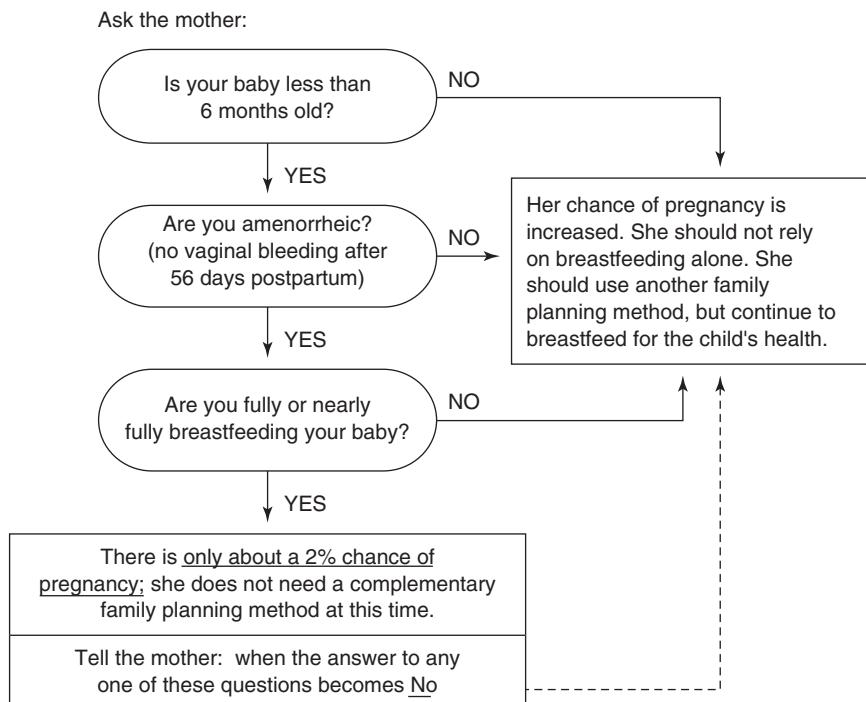

The Bellagio Consensus Conference<sup>11</sup> on breastfeeding as a family planning method established that a mother who is fully or nearly fully breastfeeding her infant and remains amenorrheic will have more than 98% protection from pregnancy in the first 6 months postpartum.<sup>9,25,30</sup> This was codified as a method of family planning the following year at a meeting at an international conference at Georgetown University.<sup>13,37</sup> The first study of the method per se found that only one woman in a study of 422 middle-class urban women in Chile became pregnant using the LAM as the only method of pregnancy avoidance in the first 6 months,<sup>13,27</sup> a protective rate of 99.5% (see Figures 20-5 and 20-6).

Menses as an indicator of ovulation has been studied with data collected not only on onset of menses but on urinary hormone assays. Among women who menstruated before 6 months postpartum, 67% of cycles were anovulatory, and the lag between anovular first menses and subsequent ovulation was 15.7 weeks.<sup>16</sup> On the other hand, after

6 months postpartum, the proportion of anovular first menses declined to 22%, and the lag to ovulation declined to 7.3 weeks. Comparing all menstrual episodes, the mean interval between first observed menses and ovulation was 8.4 weeks in the first 6 months and only 0.1 week after 6 months postpartum.

A significant distinction should be made between token breastfeeding with early solids and more rigid feeding schedules and the ad lib breastfeeding around the clock with no solids until the infant is 6 months old.<sup>6</sup> The amount and frequency of sucking are closely related to the continued amenorrhea in most women. When a totally breastfed infant sleeps through the night at an early age, requiring no suckling for 6 hours or so at night, the suppressive effect on menses diminishes. It has also been shown that if the infant uses a pacifier rather than receiving nonnutritive sucking at the breast, the suppression of ovulation is diminished.<sup>37</sup>

The degree of fertility inhibition associated with breastfeeding has decreased remarkably since the time of hunter-gatherers, cautions Diaz et al.<sup>17</sup> She points out that fertility rates vary; population and socioeconomic factors, urbanization, and nutrition influence not only breastfeeding patterns but associated ovarian quiescence. Lactational amenorrhea can provide protection against pregnancy for the first 6 months even in well-nourished women who are giving the infant some supplemental foods<sup>32-34</sup> (Figure 20-7). For women who practice

**Figure 20-7.** Use of lactational amenorrhea method for child spacing during first 6 postpartum months.

LAM, the efficacy is remarkably good (Table 20-3). Table 20-4 details the reestablishment of menses in breastfeeding women using LAM. *Bellagio and Beyond: Breastfeeding and LAM in Reproductive Health* was published as a final report in 1997 of the many years of work worldwide involving the use of LAM.<sup>13</sup> It was concluded that the efficacy of LAM is well established in prospective studies. Policy support is still needed to institute an additional method that increases the family planning choices of postpartum women.<sup>10</sup>

\*Characteristics of women: mean age (SEM; range) was 27.1 years (5.0; 18 to 39); mean parity (SEM; range) was 2.0 (1.0; 1 to 5); 23.6% of women had primary education, and only 5.4% had completed university studies.

From Perez A, Labbok MH, Queenan JT: Clinical study of the lactational amenorrhoea method for family planning, *Lancet* 339:968, 1992.

Gray et al.<sup>21</sup> studied a population of women in Baltimore in comparison to a group from Manila. Those in the Baltimore group were older, more educated, more frequently employed, and had fewer children. Women in Manila breastfed more frequently (at 10 weeks postpartum: 11.4 feeds in Manila versus 7.1 feeds in Baltimore). The mean duration of amenorrhea was 31.7 weeks versus 26.3 weeks, and mean delays before first ovulation were 38 versus 27 weeks (Manila and Baltimore, respectively). The frequency of suckling episodes was most strongly associated with ovulation in the Baltimore population, where small declines in breastfeeding were sufficient to permit the return of ovarian activity. Women in Manila, in contrast, maintained high suckling rates even when solids were introduced. More Baltimore women (49%) than Manila women (31%) ovulated before 6 months. There was no simple algorithm, however, to predict ovulation.<sup>21,69</sup>

The effects of age at introduction of complementary foods to breastfed infants on duration of lactational amenorrhea in Honduran women were reported by Dewey et al.<sup>15</sup> Introducing foods at 4 months significantly affected the likelihood of amenorrhea at 6 months but not thereafter. This effect was not seen, however, if breastfeeding frequency was maintained. The most significant determination of lactational amenorrhea was time spent breastfeeding (minutes per day), which was negatively associated with the infant's energy intake from complementary foods (Figure 20-8).

In a large prospective study of duration of lactational anovulation and amenorrhea in well-nourished Australian women—members of the Nursing Mothers' Association of Australia who

**Figure 20-8.** Average number of feeds per 24 hours by postpartum month. Lactational amenorrhea method may achieve higher efficacy than lactational amenorrhea as users of the lactational amenorrhea method would appear to practice a slightly more frequent pattern of feeding than fully lactating amenorrheic nonusers. Labbok M: Breastfeeding, birth spacing and family planning. In Hartmann PE, Hale TW, editors: *Hale and Hartmann's textbook of human lactation*, Amarillo, Tex., 2007, Hale Publishing.

breastfed for a long time—Short et al.<sup>65</sup> found that breastfeeding alone is not an effective form of contraception because all the women resumed ovulation while still breastfeeding. They compared breastfeeding women who had unprotected sex with breastfeeding women who had unprotected sex only during lactational amenorrhea and adopted other contraceptive measures after resumption of menstruation. Only 1.7% became pregnant during the first 6 months of amenorrhea, only 7% after 12 months, and 13% after 24 months.

Subsequent studies of the method show a range of high efficacies from studies in many countries. Comparisons of follicular development and hormonal profiles are important to understanding lactational amenorrhea. There is a profound dissociation between follicular growth and follicular endocrine activity, which suggests an alteration in the stimulus-response relationship at the follicular level according to Velasquez et al.<sup>72,73</sup> Serum FSH polymorphism during lactational amenorrhea was also studied by Velasquez et al. who concluded that FSH heterogeneity may be one of the critical factors contributing to incomplete follicular development and an ovulation during lactational amenorrhea.

The natural suppression of ovulation during early lactation and the concomitant amenorrhea induced by exclusive or nearly exclusive breastfeeding provide 98% or higher protection against pregnancy. Three conditions are necessary: amenorrhea, intensive breastfeeding day and night, and up to 6 months of exclusive breastfeeding postpartum. LAM can be used to time the introduction of any complementary method (barrier, etc., Figure 20-9); it is not just for users of natural family planning.<sup>37–40</sup>

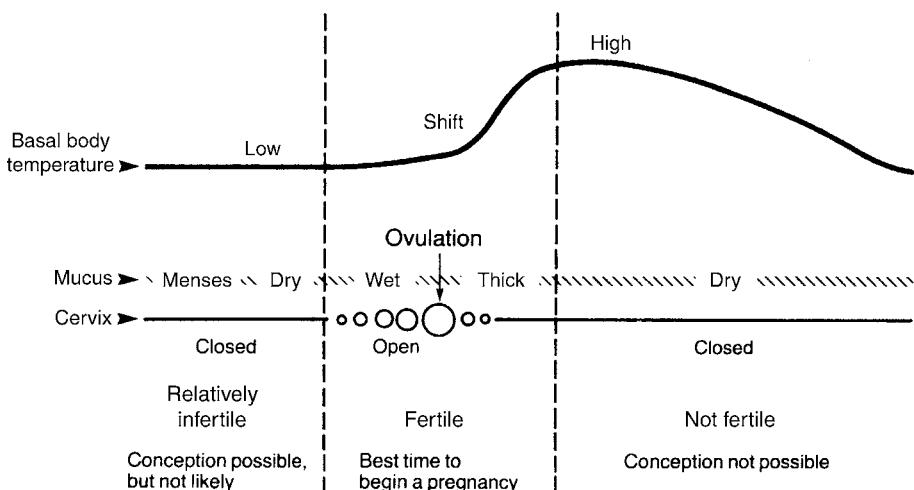

## NATURAL FAMILY PLANNING

Although lactation provides protection early in the postpartum period, a woman who is not fully breastfeeding and who is interested in avoiding conception should be informed of her options. If she does not want to use contraceptives—medications or devices—she should be instructed in the external signs of ovulation, including ovulation method, LH-releasing hormone, and home tests.

Pregnancy rates and fertility-related behavior of users of the ovulation method were studied prospectively in Kenya and Chile in two groups of breastfeeding women.<sup>38</sup> The rate of unplanned pregnancy was less than 1% in the first 6 months. The rate of unplanned pregnancies increased after menses had begun and supplementary food was added to the infants' diets. The rates were compared with the rates among nonlactating women who were also using the ovulation method to avoid pregnancy. The breastfeeding women had followed the method closely, although clients who had not used the ovulation method before the pregnancy had an increased incidence of unplanned pregnancy.

One of the difficulties of studying the use/effectiveness and continuation of natural family planning methods is that terms have always been imprecise and markers have been different between studies.<sup>48</sup> The method is effective when properly used (failure rate 3.4%) but unforgiving when use is imperfect (failure rate 84.2% in the first year).<sup>22</sup>

Unplanned pregnancy rates rise among breastfeeders after menses return compared with the rates for those who use thermal or secretion surveillance methods when not lactating.<sup>22</sup> The increased pregnancy rate was related to poor compliance and understanding of the "rules" of the method.<sup>19</sup>

**Figure 20-9.** Temperature, mucus, and cervical assessments during lactation to identify ovulation. (Courtesy National Family Planning of Rochester, New York.)

The symptothermal method of fertility awareness during lactation was studied in Canada.<sup>49</sup> A special postpartum chart was designed to record morning temperature, cervical mucus, and other signs of fertility/infertility in relation to dates and postpartum days. The intensity of breastfeeding was also recorded. There were 54 breastfeeding experiences in 47 women whose ages ranged from 20 to 39. Parity ranged from 1 to 7, with an average of 3.3. The duration of full breastfeeding averaged 3.6 months (range 3 weeks to 8 months). The duration of partial breastfeeding ranged from 2 to 28 months, with an average of 8.8 months. These mothers found that in general they could predict their fertile times with accuracy while breastfeeding. During times of weaning or change in suckling pattern, special caution was suggested, during which the mothers watched for signs of first ovulation.<sup>50</sup>

The effectiveness of periodic abstinence for lactating women shows that long periods of lactational infertility can be identified by either lack of mucus or continuous unchanging mucus flow.

Cervical mucus accepts, filters, prepares, and releases sperm for successful transport to the egg for fertilization. The advancing sperm must penetrate the mucous structure or the small interstices between the mucous macromolecules. The interstices are largest in the periovular phase of the menstrual cycle.<sup>54</sup> As ovulation resumes, irregular mucous patterns that are difficult to interpret occur and, therefore, prolonged abstinence is required. A pregnancy rate with this method was 9.1 per 100 women-years. Because two thirds of the 82 women studied were totally breastfeeding, many of the ensuing postpartum cycles may have been anovulatory or had an inadequate luteal phase, thus helping to keep the pregnancy rate low.

Studies of cervical secretions alone (mucous patterns) during lactation have indicated that the same signs in mucus are reliable during lactation.<sup>75</sup> Charting is carried out in the usual manner, and feedings are also recorded. A woman who is following her pattern postpartum should be seen every 2 weeks for guidance until her pattern is well documented. The couple should make careful observations of when (1) the infant sleeps through the night, (2) the mother reduces the number of breastfeedings, (3) the infant begins solid foods, (4) the infant begins other liquids or a bottle, and (5) illness occurs in either mother or baby. Abstinence or LAM use is advised until the situation is clear. If there has been no previous ovulation or menstruation when weaning begins, ovulation may occur quite quickly.<sup>5</sup>

**Figure 20-9** illustrates temperature, mucus, and cervical assessments during lactation.

Although contraceptive methods such as barrier methods and "the pill" have a statistically better

record in avoiding pregnancy, that is a moot point for a woman for whom these methods are not an option for religious or medical reasons.<sup>1</sup> It is, therefore, important that a clinician be as well informed about natural child spacing as possible so the best advice can be provided. Ideally, the woman has used natural family planning before the pregnancy, so she is familiar with her own patterns, but it is more urgent that she knows how to check her mucus, her cervix, and her temperature, and is not trying to learn about her fertility signs during lactation. Natural family planning programs across the United States are gaining experience with lactating women using the ovulation method and are available to assist lactating women.<sup>28</sup> Further information can be obtained from the National Office of Natural Family Planning, 8514 Bradmoor Drive, Bethesda, MD 20817-3810, (301) 897-9323, if no local office is available; <http://www.boma-usa.org> and <http://www.teenstar.org> are the websites for the Billings Ovulation Method Association in the United States.

Natural Family Planning International can be reached at [www.nfpandmore.org](http://www.nfpandmore.org) or at P.O. Box 11216, Cincinnati, OH 45211.

In a carefully designed study conducted in Chile by Perez et al.<sup>55</sup> at the Pontificia Universidad Católica de Chile Department of Obstetrics and Gynecology and by members of the faculty at Johns Hopkins University School of Hygiene and Public Health, 419 postpartum women were enrolled in the Natural Family Planning Program and were taught the method and how to record their observations. The purpose was to define cervical mucus patterns in relation to time since delivery, time of first bleed, frequency of feeding, introduction of supplements and solid foods, and time of weaning. The diaries of 110 women with detailed records were selected for critical evaluation, 49 have been reported and the preliminary observations evaluated by Barker.<sup>1</sup> Two characteristics of mucus (sensation and observation) were charted each day along with the women's breastfeeding patterns. Only seven women had used natural family planning previously. No woman menstruated before 4 months postpartum, when 10% did have first menses. By the fourth month, 50% of the women detected mucus, and not until the seventh month had 50% had first menses. Mucus was observed approximately 2 months before first menses. As women moved from total breastfeeding to partial and to complete weaning, the duration of episodes of mucus increased. Duration of mucus approached normal on weaning.

Rural women exposed to a breastfeeding education program prenatally and postpartum breastfed more and used fewer bottles than the comparison group, who had no training about lactational infertility.<sup>55</sup> However, no difference was seen in

postpartum amenorrhea. No measures of ovulation or pregnancy were made. Rural women tend to breastfeed optimally naturally. Supplementary feeding affects the return of menses and ovulation as demonstrated in a study in rural China. There was a positive correlation with the start of solid food and the return of menses and the first ovulation.<sup>76</sup> A Cochran review of lactational amenorrhea for family planning was provided by Van der Wijden et al.<sup>71</sup> who found 459 relevant studies, of which only 159 investigated the risk of pregnancy during lactation and 14 were included. The length of lactational amenorrhea among women using LAM was very different between populations studied. They could not determine if LAM made a difference beyond amenorrhea while fully breastfeeding.

## TOUCH SENSITIVITY AND OVULATION

In search of a simple method of identifying ovulation during lactation, urinary pregnanediol and estrogen and breast sensitivity were measured in six breastfeeding and six bottle feeding normal women. Two-point discrimination and touch sensitivity were measured. The mean duration of amenorrhea among breastfeeders was 24.3 weeks (range 14 to 35 weeks) and among bottle feeders 7.5 weeks (range 6 to 14 weeks). Findings, however, were not diagnostic of ovulation. Touch sensitivity tended to decrease as lactation progressed for months. The change is so gradual and difficult to detect that it has no practical value in determining ovulation.

## ORAL CONTRACEPTIVES AND LACTATION

The significant issues related to lactation and the use of oral contraceptives are the potentially adverse effects of oral contraceptives on milk production, uterine involution, and growth and development of breastfed infants.<sup>48</sup> A single case of breast enlargement in a breastfed male infant whose mother began taking norethynodrel with ethinyl estradiol 3-methyl ether (Enovid) on the third day postpartum was reported. Breast enlargement began on the third week of life. The mother had noted her milk was not as "rich" and started supplements the second week. Nursing was discontinued at about 4 weeks of age, and the breasts of the infant returned to normal in 2 to 3 weeks. The additional risks to the mother of thromboembolism, hypertension, and cancer have also been discussed extensively in the literature. These occurred with the early high-dose products.

In a study of over 900 Latina women who had developed gestational diabetes during pregnancy, they were noted to develop diabetes postpartum

if they were given a progesterone-only oral contraceptive as compared with those who received a combinations oral contraceptive or nonhormonal contraception. This is an observation that requires follow-up. A Cochrane review of combined hormonal versus nonhormonal versus progestin-only contraception in lactation was inconclusive, and it was decided that existing trials were insufficient to establish any effect of hormone contraceptive therapy on milk quantity and quality.<sup>70</sup> The WHO recommendation regarding the use of progestin-only pills states delay of onset for 4 to 6 weeks postpartum is necessary. A depot medroxyprogesterone-only contraceptive providing highly effective, long acting, reversible contraception, usual dosing every 12 weeks, was studied by Rodriguez et al.,<sup>58,59</sup> who concluded that it was not a significant risk to breastfeeding or to the baby. It was further stated that risk of pregnancy outweighed all other considerations.

## OTHER HORMONAL CONTRACEPTIVE USE

The impact of the distribution of oral contraceptives on breastfeeding and pregnancy status in rural Haiti indicated that it did not alter breastfeeding patterns in women who began the pills at 8 to 9 months postpartum. Pregnancy prevalence also decreased as a result.<sup>64</sup>

Studies of progestin-only pills beginning at 6 weeks postpartum showed that progestin-only pills do not suppress gonadotropins nor do they affect ovarian follicular development.<sup>47</sup> The contraceptive effect is believed to be mediated through local actions of the endometrium and cervix as in normally menstruating women.<sup>50</sup>

Birth control for women who are breastfeeding is still open for discussion. A Cochrane review surveyed the literature and found it grossly inadequate in spite of numerous articles published on hormonal and nonhormonal birth control utilized postpartum while breastfeeding. They found only five trials adequate for discussion but the dropout rate of participants was of concern. The authors found no major differences in infant growth or weight gain due to hormonal birth control use. They state that information is too limited to say whether women should use hormonal birth control or not. The impact on breastfeeding and the infant remains unclear.

## IMPLANTS AND INJECTIONS

The recommendation for contraceptive use during lactation is the progestin-only products (Norplant System, Depo-Provera injections and minipills, progestin once-only pills). Use of these methods has not been associated with adverse effects on

**TABLE 20-5** Effects of Contraceptive Agents on Milk Yield and Infant Development

Agent	Milk Yield	Effect on Infant
Combined estrogen/progestin	Moderate inhibitory effect Shorter breastfeeding Milk concentration unchanged Small amount of steroid in milk	Slower weight gain No long-term effects
Progestin only	No effect on volume	No effect on weight gain
Minipill (Micronor, Nor-QD)	No effect on duration unless given before 6 weeks	No reported long-term effects
Other products: Injectable DMPA, Depo-Provera and norethindrone enanthate (NET-EN, Noristerat)	Breastfeeding lasts longer? Change in milk: protein increased, fat decreased Steroid present in milk	No long-term effects
Norplant System	No effect Small amount of steroid in milk	Normal growth No long-term effects
Vaginal rings containing natural hormone progesterone	No significant differences	No effect on growth Long-term effects under study

DMPA, Depot medroxyprogesterone acetate.

Modified from Winikoff B, Semeraro P, Zimmerman M: *Contraception during breastfeeding: a clinician's source book*, New York, 1987, Population Council.

infant growth or development and may even increase the volume of milk<sup>39,62</sup> (Table 20-5).

Injectable DMPA given as a contraceptive in the immediate postpartum period was reported to be a safe and effective alternative method with no deleterious effect on the mother's milk supply or the infant's growth for women in New Delhi, India. Because loss of milk supply after the injection has been documented to occur, this study, by Singhal et al., of 100 women is significant. It is important to note, however, that the injection was not given until the milk supply was well established. Some injections were not given for 10 days. Thus the establishment of a good milk supply before the injection was important to the outcome of this study. Practitioners in lactation medicine know well that depot injections and insertion of intrauterine devices can affect milk supply in spite of claims to the contrary. The mother must be warned and allowed to make an informed decision. DMPA should not be used for at least 6 weeks if there is a history of depression.

In a study of the effects of levonorgestrel (Norplant) in breast milk on thyroid activity, Bassol et al.<sup>2</sup> compared infants of mothers with the implant and those of women assigned to intrauterine device (IUD) use. The hormones (levonorgestrel) in the breast milk significantly decreased the infants' thyroid-stimulating hormone (TSH) levels at 3 months, and the TSH levels were even lower at 6 months of age.<sup>2</sup> The higher the levonorgestrel levels, the lower the TSH levels in the infants. It is recommended that the progestin-only method not be initiated until 6 weeks postpartum on the premise that the theoretic danger to the infants from exogenous steroids has passed by this time. The practice of injecting Depo-Provera immediately after delivery can interfere with the establishment of lactation,

which is dependent upon the dramatic natural decline in progesterone postpartum.

Steroids are not bound well in plasma and not well conjugated by the liver or excreted by the immature kidneys of the neonate. Exogenous hormones may compete for receptor sites with natural ones in the liver, brain, or other tissues. As an infant's liver and kidneys mature, these issues disappear.<sup>26</sup> Medications that also contain estrogen suppress milk production.<sup>63</sup> With the many alternatives available, it should never be necessary to discontinue breastfeeding to initiate contraception.<sup>24</sup>

The growth and development of breastfed infants whose mothers received implants of Norplant containing levonorgestrel or injections of norethindrone enanthate were studied and compared with those whose mothers used IUDs.<sup>10,24</sup> The breastfeeding performance was similar. The infants were also similar in growth rate, development, and general health. Similarly, a group of mothers were given a vaginal ring that released 10 mg of "natural" progesterone every 24 hours, producing a maternal serum level of 4 ng/mL, which results in only a minimal amount in the milk and this is not absorbed by the infant gut. These infants also had normal growth and development and remained in good health.

LH-releasing hormone agonist for contraception has also been tested in nine fully breastfeeding women beginning 6 weeks postpartum. They received 300 mg LH-releasing hormone agonist (buserelin) intranasally once a day for the duration of their breastfeeding. Urinary excretion of LH, estrone, and pregnanediol was compared with that of nine control breastfeeding women. No ovulation occurred in the treated group, and seven of the nine untreated control subjects had one to six

ovulations. LH-releasing hormone has potential as a safe, acceptable method of contraception while breastfeeding, according to Fraser et al.<sup>19</sup>

Home tests to monitor fertility are available; however, women must be tested during lactation and especially during the transition period when breastfeeding frequency and feeding duration are changing. Ovarian follicular dynamics can be accurately monitored through the noninstrumented analysis of daily estrone conjugates in urine samples at home.<sup>36</sup> Readings can be affected by urine osmolarity, either high or low, giving false positive or false negative results, respectively. Controlling intake of fluids would guard against this.

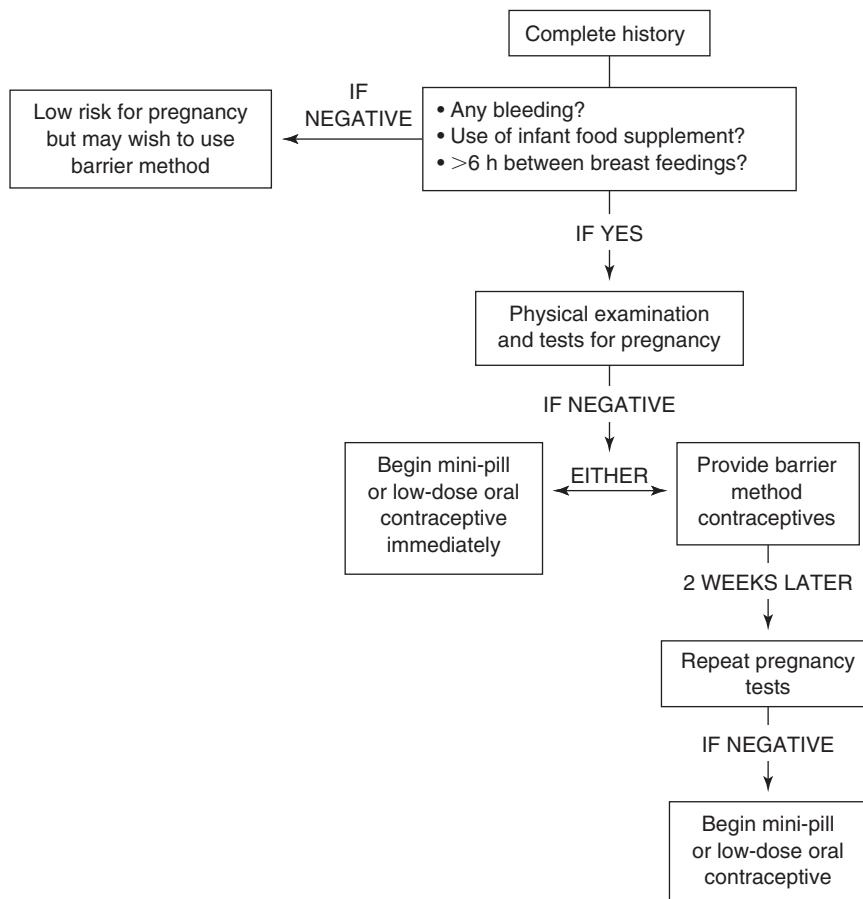

Two algorithms for initiating contraceptive treatment are shown in Figures 20-7 and 20-10.

## INTRAUTERINE DEVICES AND OTHER CONTRACEPTIVE METHODS

Various alternatives to oral contraceptives exist and have different degrees of reliability (Table 20-6). The IUDs (95% to 98% effective), cervical caps

and diaphragms (85% to 88% effective), condoms (80% to 85% effective), and vaginal suppositories, jellies, or creams (80% effective) have no known contraindication during breastfeeding because no chemicals are absorbed. The only contraceptive that is 100% effective is abstinence.

A study of 2271 postpartum women who had IUDs inserted between 1976 and 1981 and were followed for 6 to 12 months, was reported, with careful attention to details of lactation.<sup>7</sup> Data were analyzed separately for IUDs inserted immediately after birth (within 10 minutes of placental expulsion). The results of this analysis indicate that IUD insertion for breastfeeding women would be appropriate either immediately after delivery or much later (42 days or more postpartum). When inserted immediately postpartum, the delta loop and delta T were modified by adding projections of chromic sutures, which help the device remain in the uterus. The sutures biodegrade in 6 weeks, leaving a standard device in place. These authors report that breastfeeding is not a contraindication to IUD insertion, with no increased expulsion

**Figure 20-10.** Algorithm for initiating contraceptive treatment in a breastfeeding woman. (Modified from Winikoff B, Semeraro P, Zimmerman M: *Contraception during breastfeeding: a clinician's source book*, New York, 1988, Population Council; Labbok M: Breastfeeding and contraception, *N Engl J Med* 308:51, 1983.)

**TABLE 20-6** Family Planning Methods Presented by Relative Impact on Lactation

Method	Description	Efficacy	Risks to Lactation	Benefits for Lactation	Clinical/Counseling Suggestions and Special Considerations
<b>No known impact on lactation</b>					
LAM	Defined by three criteria that reflect reliable physiology for fertility delay	2/0.45	None	The required breastfeeding behaviors benefit maternal and child health and nutrition.	When any one of the criteria no longer applies, immediate transition to another method is recommended.
Abstinence/periodic abstinence/NFP methods • Complete abstinence • Calendar • Ovulation method • Symptothermal • Postovulation	Signs, symptoms, or timing of presumptive ovulation are used to identify periods of time when abstinence is necessary to avoid conception.	0 25 9 3 2	None; however, most methods may demand substantial periods of abstinence during lactation due to difficulty in assessing signs of ovulation.	None	Even experienced users of these methods will benefit from special counseling for their use during lactation because the signs and symptoms will vary and may be difficult to properly interpret during the hormonal changes that may occur during lactation.
Barrier methods: Condoms Male Female Diaphragms Cervical caps w/o spermicides alone/ sponge	Condoms: Provides barrier to prevent ejaculum from coming in contact with cervical mucus. Diaphragms/caps: Generally used with spermicide, so provide elements of both physical and chemical barriers. Spermicides: Provide chemical barrier.	15/2 21/5 16/6 32/26 29/18 32/20	Some spermicides may provide lubrication; however, some varieties may cause additional sensitivity in some individuals.	Condoms: Lubricated varieties may be useful with lactational suppression of estrogenic vaginal lubricants.	Subject to user error; some individuals have allergies to ingredients; some couples may find methods inconvenient. Few side effects. Highly effective if used consistently and correctly. The condom can provide some protection against sexually transmitted diseases. If a patient has previously used a diaphragm or cervical cap, it should be refitted at the 6-week postpartum visit.
<b>Little to no known impact on lactation</b>					
IUD Noncopper/ nonhormonal IUD Copper IUD: 7-10 yr	IUD functions as a foreign body in the uterus, provoking hormonal changes that reduce the possibility of fertilization of the egg and implantation of an embryo.	0.8/0.6 0.1/0.1	Some women may have excess lochia or contraction-associated uterine discharge.	Once inserted, no further action or intervention is needed during lactation.	An IUD should be inserted within the first 48 hours after delivery or delayed for at least 4 weeks as lactating women have strong uterine contractions. This also requires that IUD insertion be high in the uterus to decrease risk of expulsion.
Surgical sterilization Men: vasectomy Women: tubal ligation	Surgical blockage of path of gametes by bisecting, separating ends, and ligation of vas/fallopian tubes	0.15/0.10 0.5/0.5	Tubal ligation may necessitate temporary interruption in breastfeeding while surgery takes place. Milk should be expressed in advance for feeding during the procedure.	Once performed, no further intervention is needed. Both can be outpatient procedures.	Permanent decision. Reversal is expensive, requires surgical expertise, and may not be successful. Highly effective. Men: If coupled with postpartum infertility, simplifies contraception during the months necessary for healing. Male sterilization is easier and safer and may be performed in an office setting.

<b>Some reports of negative impact on lactation</b>					
Progestin-only • Pills • Injectables (e.g., DMPA 3 months; norethisterone 2 months) • Implants (e.g., Number, size, and content of implanted rods offer different lengths of protection in years) • Levonorgestrel IUD: up to 5 yr	Mechanism of action includes some disruption of lactation and modification of intrauterine milieu and readiness for implantation. Progestin-only contraception during lactation does not suppress gonadotropins nor affect growth of ovarian follicles during breastfeeding. Thus the contraceptive effect of POP is likely mediated through local actions at the endometrium and cervix in a manner similar to that of menstruating women. <sup>78</sup>	5/0.5 3/0.3 0.05/0.05 0.1/0.1	May decrease milk supply if started before milk supply is well established. Anecdotal reports of immediate negative impact even when initiated after lactation is well established. Progestin IUD typically has minimal impact, but has the potential to have the same impact as other progestin-only methods.	Some studies report increased milk production with injectables.	Common side effects include irregular bleeding (less common in predominantly breastfeeding women), weight gain, and headaches. Return to fertility with injections may be delayed beyond expected duration—of potential concern for some women. Must develop routine for taking daily pills. Implants require procedure for placement and removal.
<b>Expected to have negative impact on lactation</b>					
Combined pill • Contraceptive patch (e.g., ethinyl estradiol/norelgestromin) • Combined vaginal ring (e.g., ethinyl estradiol etonogestrel) • Combined injectables (e.g., estradiol/medroxyprogesterone)	Exogenous estrogen serves to suppress ovulation.	8/0.3 8/0.3 8/0.3 3/0.05	Significant risk of reducing milk supply. It is suggested that initiation be delayed until 6 months postpartum. Reduction of supply appears dose dependent. Injectables more difficult to stop if problems arise.	None	Several good noncontraceptive effects (e.g., reduced risk of ovarian and endometrial cancers, decreased anemia, regular menses). Not suitable for women with history of clotting problems, estrogen-dependent cancers, severe migraines, or women older than 35 who smoke.

From Labbok M: Breastfeeding, birth spacing and family planning. In Hartmann PE, Hale TW, editors: *Hale and Hartmann's textbook of human lactation*, Amarillo, Tex., 2007, Hale Publishing.

rate.<sup>24</sup> Conversely, the presence of an IUD has no adverse effect on lactation. The appropriate time for insertion should be selected to predate anticipated ovulation but guarantee patient compliance. A study showed that the use of the TCu-380A IUD in breastfeeding women resulted in fewer insertion-related complaints and lower removal rates for bleeding and pain in 12 months postpartum than in nonbreastfeeders. No intrauterine perforations were reported in either group. Copper IUDs are usually smaller, so there is little problem with the effects of let-down on the uterus.

A group of 32 women hospitalized for uterine perforation necessitating transperitoneal IUD removal and a matched control group of 497 women who had worn IUDs uneventfully were compared.<sup>24</sup> Of the women in the study, 97% were postpartum compared with 68% of the control subjects. Of the parous study group, 42% were lactating, and of the parous control subjects, 7% were lactating when the IUD was inserted. The risk of perforation was 10 times greater in the lactating than in the nonlactating women, unrelated to time of the insertion postpartum. In another group hospitalized for difficult transcervical IUD removal, the risk was 2.3 times greater for lactating women.<sup>24</sup> The authors recommend caution, not abandonment of the procedure, during lactation, because they believe the IUD is the best form of artificial contraception during lactation. The ideal candidate is a woman who wants reversible contraception to space births or limit size of the family, especially breastfeeding parous women in a monogamous relationship.<sup>10</sup>

The Technical Guidance/Competence Group of the United States Agency for International Development (USAID) and the WHO<sup>77,78</sup> recommends IUD insertion immediately postpartum as soon as the placenta is removed, whether by vaginal or cesarean delivery. They point out it must be done by a specially trained physician. From 10 minutes to 48 hours after delivery, however, the expulsion rate is high. If this window of opportunity is missed or no urgency exists, it is best to wait. Although immediate insertion is possible, a copper-T device may be safely inserted 4 or more weeks postpartum in breastfeeding women. Using the withdrawal technique minimizes the risk of perforation. Other IUDs should not be inserted until 6 weeks postpartum.

The IUD is a long acting, reversible method of contraception with expulsion rates of 5-15 per 100 woman-years of use when used as a postplacental method immediately after cesarean section. An IUD does not affect breastfeeding. These experiences are reported by Goldstuck and Steyn from South Africa.

Use of barrier and spermicidal products is an alternative contraceptive method during early lactation before hormonal methods or IUDs are introduced. These coital-dependent methods have no

effect on lactation. The lubrication provided by the spermicidally treated condoms has the advantage of contributing lubrication when the hypoestrogenic vagina is exceptionally dry in association with lactation. A spermicide is more effective with a condom but is adequate early postpartum, when relative infertility is present. A diaphragm cannot be adequately fitted for 6 to 8 weeks postpartum, so it is not recommended during this period with or without lactation.

## ABSTINENCE

Many cultures and societies place taboos on sexual intercourse for nursing mothers as an effective means of spacing children. Usually, there are no medical contraindications to sexual relationships during lactation. In a study on contraceptive use in the United States, among white women, 34% were not sexually active in the first month postpartum, 12.5% in the second month, and 4.3% during the third month. Among black women in the survey, 25% were not sexually active in the first month, 8.1% in the second, and 4.2% in the third. Contraceptive use among those sexually active was absent in 16%, 12.2%, and 13.8% in the first, second, and third postpartum months, respectively, among whites. Among blacks, no method was used by 27.3%, 22.7%, and 22.3%, in the first, second, and third postpartum months, respectively.

## *Sex and the Nursing Mother*

---

### SEXUAL AROUSAL ASSOCIATED WITH SUCKLING

If one examines normal adult women in regard to the menstrual cycle, sexual intercourse, pregnancy, childbirth, and lactation, one observes that these events are all influenced by the interaction of the same hormones—not only estrogen, progesterone, testosterone, FSH, and LH, but oxytocin and prolactin as well. The breast is known to respond during all these phases, enlarging before menstruation, during pregnancy, before orgasm, and during lactation. The nipples also respond during these phases. Furthermore, the uterus contracts during childbirth, orgasm, and lactation. Body temperature rises during ovulation, childbirth, orgasm, and lactation. As pointed out in Chapter 3, oxytocin is a critical element in the let-down reflex during lactation. Oxytocin levels also rise during orgasms and labor, and oxytocin causes the uterus to contract and the nipples to become erect. Newton and Newton<sup>52,53</sup> report other similarities in women, including sensory perception and emotional reactions, during these events.

The psychophysiologic similarities between lactation and coitus are as follows:

1. The uterus contracts.
2. The nipples become erect.
3. Breast stroking and nipple stimulation occur.
4. The emotions experienced involve skin changes (vascular dilatation and raised temperature).
5. Milk let-down (or ejection) reflex can be triggered.
6. The emotions experienced may be closely allied.
7. An accepting attitude toward sexuality may be related to an accepting attitude to breastfeeding (and vice versa).

Women also report hot flashes in association with some feeds, especially at night. This phenomenon has been studied by Marshall et al.,<sup>45</sup> who looked at oxytocin effect. Initiation of breastfeeding was accompanied by an increase in skin conductance resulting in increased skin temperature, especially of the breast. The pattern is similar to menopausal hot flashes.

Given the biologic and hormonal similarities of lactation to the other events in the sexual cycle of adult women, it is not surprising that some women experience some form of sexual gratification during suckling on certain occasions. In a study of 111 parturient women, only 24 of which breastfed, Masters and Johnson<sup>46</sup> reported that sexual arousal was experienced during suckling on some occasions. The exact incidence of this response is unknown, but it is thought to be uncommon. Nursing mothers may have an element of guilt surrounding these experiences and underreport. That guilt may lead to early weaning in some cases. For some women, the breasts are highly erogenous. The handling and manipulation of the breast necessary during lactation by both mother and infant can, in the right but unpremeditated circumstances, be stimulating. Clearly, the majority of women who enjoy breastfeeding have no feelings or responses to the stimulation of the breast that could be construed as sexual arousal, although they enjoy breastfeeding and the intimacy with their infant that it provides.

The erotic response to nursing the infant has no significance in terms of being normal or abnormal. The decline of breastfeeding because of feelings of shame, modesty, embarrassment, and distaste has been reported and interpreted as indicating that breastfeeding is viewed as a forbidden sexual activity. For such women, any sexual allusions and excitement accompanying breastfeeding are not permissible and cause shame. Such attitudes are more common in lower social groups and need to be considered in counseling mothers about breastfeeding prepartum or when premature weaning takes place. Major changes in the number of women who breastfeed may not be possible until society can accept the

breast in its relationship to nurturing the infant and as an object of less sexual ambivalence.

The sensuousness of breastfeeding has been the topic of discussion in women's magazines as more has been written about women and their bodies. For the well-educated, well-read woman who breastfeeds her infant because she intellectually arrives at the decision, such discussions are an avenue of increased knowledge. Others may still be uncomfortable about breastfeeding if it is apt to be "pleasurable." The physician may sense this discomfort in a patient prenatally by her responses to bodily change during pregnancy. Cultural attitudes are an important part of this response and are deeply ingrained in an individual by the time she reaches the age of parenting. Professionals need to be sensitive to the patient and cautious about imposing cultural change on a patient while still being alert to needs for information and openness. A woman who experiences any erogenous reaction to breastfeeding, especially with an older child who may inadvertently roll the nipple while feeding, should not be criticized, but the phenomenon should be explained and discussed openly by the physician.

## **SEXUAL ACTIVITY OF NURSING MOTHERS**

A review of the limited data available on lactating women in the study by Masters and Johnson<sup>46</sup> does indicate that in their group of 111 postpartum women, the nursing mothers were more eager than nonnursing mothers to resume sexual relations postpartum. The data were independent of the fear of pregnancy. They report that this interest was apparent 2 to 3 weeks postpartum. Individual reports through a questionnaire indicate that 30% of nursing mothers believed their sexual relationships were improved and only 2.5% believed they were worse postpartum. The individual testimonies of nursing mothers indicate they had a better feeling about themselves as well as their relationships with their husbands and family in general. In a study of sexual behavior during pregnancy and lactation, the desire returned by 4 weeks for most women, long before they thought it was safe. The longer they had been married and the more children, the sooner the interest returned and the sooner they felt it was safe. No change in interest or enjoyment occurred with weaning.

In studies of recovery after childbirth, the longer duration of breastfeeding (more than 5 months) has been associated with a longer duration of awareness of perineal damage (dyspareunia) during intercourse and a longer amenorrheic period in some women. High prolactin levels and decreased libido have also been observed in women with evidence of continued vaginal discomfort. In the clinical study

of lactational amenorrhea in 422 women in Chile, however, Perez et al.<sup>55</sup> recorded the incidence of intercourse to be one to two times a week, beginning 4 weeks postpartum.

The frequency of coitus during breastfeeding was studied at four sites: Birmingham, United Kingdom; Montreal, Canada; Sydney, Australia; and Manila, the Philippines.<sup>74</sup> The frequency was lower than reported in other studies of married women, ranging from 4 to 30 episodes a month while averaging three to five times a month. Rates were not correlated with number of children but were related to maternal age, being slightly more frequent in younger women. The resumption of coital activity in these populations was more variable, with a median of 8 weeks postpartum, with 75% resuming activities by the end of the third postpartum month. Thus "normal" encompasses a broad range.

More general observations indicate that although some women may have increased interest in sexual relations while nursing, others may experience no interest at all for 6 months or so. Whether this results from the satiation of the mother's needs for intimate relationship and stimulus through nursing, general fatigue, or fear of pregnancy is debatable.<sup>46</sup> Sexual stimuli may trigger the ejection reflex, and milk ejection may have a negative effect on some men. A practical solution to spraying milk during lovemaking is feeding the infant or expressing some milk beforehand. The total knowledge of nursing and suckling as a biologic phenomenon will help couples understand such reactions and thus avoid inappropriate psychologic responses.

The conflict in some adult men over their role in regard to the nursing mother's breasts is usually a result of guilt or upbringing. There is no need to advise against fondling the lactating breast during lovemaking, although physicians have often imposed rigid restrictions on sexual activity in the lactating woman. No scientific basis for such restriction exists, and no difference in the incidence of infection and mastitis is associated with such activity. Unusually restrictive protocols are often imposed on patients without medical indication.

It is helpful to discuss with lactating women that the hormonal effect on the vagina may be excessive dryness with an increase in dyspareunia. With the abrupt withdrawal of gonadotropins and ovarian hormones and elevation of prolactin at the time of delivery of the infant and placenta, the vaginal epithelium becomes thin and atrophic.<sup>57</sup> Normally, the vagina and ectocervix are lined with stratified squamous epithelium, which is multilayered and protective. It is also responsive to ovarian hormones. The greatest maturation and thickness occur around ovulation in response to peak estrogen secretion. During pregnancy, progesterone inhibits the maturation of the epithelial cells. The vaginal lining retains its

thickness, but cells do not fully mature because the effect of progesterone overtakes the effect of estrogen on the epithelium and cervical mucus; both hormones are abundant during pregnancy.

The lowered ovarian hormones that cause vaginal dryness and lack of cervical mucus during lactation lead to discomfort during intercourse. The dryness responds to locally applied lubricants and tends to improve over time. A sudden change may actually reflect ovulation. The breast that is being stimulated by feeding frequently may not be as sensitive during lovemaking. Usually this, too, is transient. Physicians should perhaps remind mothers that some adjustment to attend to fathers' needs may be necessary.

## SEXUAL ABUSE AND BREASTFEEDING

In most cases, sexual abuse or any type of abuse during childhood takes its toll for a lifetime. Sexual abuse during adult life, especially during a relationship that results in pregnancy, impacts a mother's ability to accept the pregnancy, endure the labor, and mother the child. The role of abuse is being recognized as significant in all phases of women's pregnancies and postpartum periods. Anthropologists have identified abuse as a significant thread in the lives of low income women living in the most inhuman conditions in the world.<sup>3,9,11,61</sup> Those studying childbirth issues and breastfeeding have noted a relationship between alleged inadequate milk and abuse as well as an inability to breastfeed. Chin and Solomonik<sup>9</sup> have analyzed the term "inadequate," not just as a description by the woman for her milk supply but as a metaphor for the lives of low income women in the United States who have been identified in numerous statistical reports as the least likely to breastfeed.<sup>9</sup> Chin and Solomonik<sup>9</sup> note that everything about their lives is inadequate: education, income, health services, and life span. Their lives are saturated with violence, lack of safety, and fear even in their own homes. Chin and Solomonik<sup>9</sup> suggest an agenda to explore the relationship between these social inadequacies and the forces that compel these women to choose the less optimal infant feeding by bottle. Childhood sexual abuse is not limited to families in poverty but has been reported in as many as 20% of children.<sup>56</sup> Sexual abuse can have short- and long-term effects that manifest in various symptoms, including health problems, behavior problems, posttraumatic stress disorder, and interpersonal difficulties. Amnesia for the original abusive events can develop until the events of childbirth and subsequently putting the newborn to the breast triggers an anguished flashback. Kendall-Tackett<sup>29</sup> described the long-term effects of sexual abuse, which she divided into five domains: emotional

distress, impaired sense of self, avoidance, interpersonal difficulties, and health problems. Avoidance is a major challenge to the physician. One mechanism of avoidance is the ability to numb one part of the body to avoid reliving the trauma inflicted. A mother may appear to be absent from her body when the baby is taken after breastfeeding. Physicians need to take careful and caring histories with any patients, but especially when a patient shows these signs and symptoms. It may be necessary to obtain a psychiatric referral if simple effort does not ameliorate the situation. As more information is brought forward, we learn of successful breastfeeding with mothers with a history of child abuse by a family member. Coles<sup>11</sup> interviewed eleven women and identified four key themes: "enhancement of the mother-baby relationship, validation of the maternal body, splitting of the breasts' dual role as maternal and sexual objects, and exposure and control when breastfeeding in public." A case report published by Beck<sup>3</sup> vividly described the original abuses, the victims' labors and deliveries, and breastfeeding that triggered panic attacks, disassociation, and flashbacks. After extensive interviewing of 18 women who were sexually abused by family members before the age of 16, Coles and Jones<sup>12</sup> reported two key themes: safety issues for survivors and their babies in clinical encounters and wishing for better and safer clinical experiences because of feelings of pain, fear, blame, helplessness, and guilt in the health care environment. The authors suggest important steps to make the health care experience more tolerable for these women who fear the intimacy of this care. Many of these suggestions are appropriate for all patients.

Severe physical violence between intimate partners during pregnancy is a major risk factor for early cessation of exclusive breastfeeding. This correlation has been made in many cultures around the world. Using a health services survey, the Conflict Tactics Scale, Moraes et al. investigated premature cessation of breastfeeding in Brazil. They concluded that severe physical violence during pregnancy was an important risk factor for early cessation of exclusive breastfeeding. They suggest that health care workers who deal with lactating women need to be trained beyond the biologic aspects of lactation to include the maternal, psychologic dimensions. Similar findings were reported from multiple African countries (Ghana, Kenya, Liberia, Malawi, Nigeria, Tanzania, Zambia, and Zimbabwe) by Misch and Yount. Partner violence was associated with early breastfeeding cessation. Screening for intimate partner violence victimization both prenatally and postpartum may mitigate the potential intergenerational effects of violence the authors recommend. Sexual assault has a pervasive negative effect on a new mother's sleep quality and risk of depression report

Kendall-Tackett et al., who studied over 6000 mothers with young infants using an online survey. Although assault history had negative effects, the effects were less severe for those mothers who breastfed than those who bottle fed or mixed fed. Abuse of any kind has long-term effects. Breastfeeding appears to trigger repressed memories of the events and becomes difficult for some women. Clearly, the process is not completely understood. A physician, initially during pregnancy and then postpartum, plays an essential role in helping a patient cope. The issue may go unidentified until a pediatrician enters the picture. As well as screening for depression, a pediatrician should be alert to a possible history of abuse, while carrying out care of the infant.

## *Nursing During Pregnancy and Tandem Nursing*

---

Pregnancy can and does occur while a woman is lactating. When it does occur, it produces a number of questions. There is no need to wean the first infant from the breast, which is often ordered by a physician. It is possible to lactate throughout pregnancy and then to have two infants at the breast postpartum. This is now sufficiently common to be called *tandem nursing*.

The amount of nourishment provided the first infant at the breast depends on age and other supplements. When an infant at the breast is only a few months old when pregnancy occurs, there is some rationale to continue breastfeeding for the benefit of the infant until it is time to wean to solids and other liquids at 6 months of age or so. This child will be about a year old when the new infant arrives and, if still at the breast, may have demands in excess of the mother's ability to provide. Concern has been expressed that the older infant will take much of the nourishment needed by the new infant. In some societies, it is believed that a suckling infant will "take the spirit" from the newly conceived fetus; thus weaning is mandated once pregnancy is confirmed in these communities.

The milk produced immediately postpartum by the mother who never stopped nursing appears to be colostrum. The kangaroo has been observed to have a teat with mature milk for the older offspring and a teat for the new offspring who requires significantly different nourishment. Such a provision does not exist for humans. Mothers who want to maintain both infants at the breast have shown that it can be done without any apparent effect on the nourishment of the new infant. Counseling of such a mother should take into account the mother's resources to receive adequate

rest, nourishment, and psychologic support to withstand the added demand, physically and mentally, on her.

If the first child will be older than 1 year of age when the new infant arrives, the need for physical nourishment is minimal, and continuation at the breast is more for the security and psychologic benefits. This is referred to as comfort nursing and may continue for several years (see [Chapter 10](#)). Abrupt weaning should be avoided, and consideration should be given to the impact of separation when the mother is confined during the birth of the new infant. This is an argument for 12-hour hospitalization for delivery for women who request it. The first few days of colostrum are most vital for the new infant, and the supply is not infinite; therefore, priorities need to be set concerning the older child. The new baby should be nursed first. Some older infants reject the colostrum.

The growth rate of children weaned during a subsequent pregnancy was compared with that of children weaned at the same age from nonpregnant mothers in a longitudinal study in Bhutan by Bohler and Bergstrom,<sup>4</sup> who followed 113 children closely for the first 3 years of life. The period of overlap for lactation and pregnancy was 5 months (median), increasing by 1 week for each month reduction in birth interval. When a child stopped breastfeeding during the mother's subsequent pregnancy, the growth rate was reduced during the last months before termination of breastfeeding compared with children weaned at the same age from nonpregnant mothers and with children who continued to breastfeed.

In a study of 503 La Leche League members, Newton and Theotokatos<sup>53</sup> reviewed breastfeeding during pregnancy practices and found that 69% of breastfeeding children weaned spontaneously when the mother became pregnant. Many of the children may have been at an age to wean even without an intercurrent pregnancy.

Moscone and Moore<sup>51</sup> conducted a questionnaire survey of 57 women who were concurrently pregnant and breastfeeding. The main reasons given for continuing breastfeeding after conception involved the emotional needs of the breastfeeding child; 43% of the children continued to breastfeed throughout pregnancy and after birth of the sibling. The main reason for mother-initiated weaning was breast and nipple pain. When the child weaned during the pregnancy, it occurred during the second trimester and seemed to be associated with diminished milk production. Three pregnancies terminated in spontaneous abortions (a rate higher than in the general population of 5%). The ages of the children at onset of pregnancy varied from 4 to 42 months. The feeding pattern was one to eight times a day for less than 5 minutes to more than

30 minutes. A descriptive study of 2617 women in a prenatal clinic in Egypt revealed that 95% had previously breastfed and 25.3% conceived while breastfeeding; 4.4% conceived in the first 6 months, 15.1% while still amenorrheic, and 28.1% while exclusively breastfeeding. Only 4 pregnancies (1.5%) occurred when all the prerequisites for the LAM method were present. In Egypt, especially in rural areas, infants are breastfed for at least 2 years. Pregnancy while breastfeeding is common in Egypt.<sup>64</sup>

## *Impact of Nursing During Pregnancy*

Among rural Guatemalan women who were part of a nutrition supplementation trial, 253 of the 504 pregnant women had another pregnancy overlap while breastfeeding (50.2%); 41.4% of mothers with concurrent pregnancy and lactation continued to breastfeed into the second trimester and 3.2% into the third trimester. These "overlap" mothers received more supplements. The authors stated that overlap resulted in short recuperative periods (less than 6 months) requiring increased supplement intake and reduced maternal fat stores. The energetic stresses and short recovery time did not significantly affect fetal growth. It appeared the mother buffers the energy stress, protecting fetal growth.<sup>44</sup>

Significant decreases in bone mineral density do occur during breastfeeding when calcium demands are the greatest.<sup>41</sup> These changes are reversible and do not persist after a subsequent pregnancy according to Prentice et al.,<sup>56</sup> who studied calcium utilization and reproduction related osteoporosis extensively. They indicate that extended periods of breastfeeding and closely spaced pregnancies are unlikely to have a lasting effect on bone mineral status and osteoporosis when a mother is healthy and well nourished. Although short birth intervals and breastfeeding during pregnancy further deplete fat stores in a malnourished mother, healthy, well-nourished women fare well and replenish their stores during a subsequent pregnancy.<sup>43,44</sup>

## **INFANT HEALTH**

Although pregnancy during lactation can cause flavor and volume changes that lead to early weaning, the milk still provides immunologic benefits. This is clearly demonstrated by Bohler and Bergstrom<sup>4</sup> among women in Bhutan in which abrupt weaning caused diarrhea, stunted growth, illness, and even death. Research in India showed that overlapping breastfeeding and pregnancy in a malnourished mother produced growth retardation in the older

child. Healthy infants in the United States derive significant nutritional and immunologic benefit in the second year and beyond, however. The risk to a nursing depends on a child's age, other diet, and the amount of human milk available.

## FETAL HEALTH

The nutritional status of a mother is key to adequate fetal growth. Varying results of fetal growth patterns are reported related to a mother's nutritional status before pregnancy. A significant issue is viability of the pregnancy. Breastfeeding stimulus triggers oxytocin release and concern focuses on the potential for initiating uterine contractions and fetal loss. Studies of oxytocin sensitivities in pregnancy and the state of oxytocin receptors during early pregnancy are graphically illustrated in [Figure 3-19](#). The uterus is insensitive until close to 40 weeks in most women. It is well documented that nipple stimulation can be as effective as intravenous Pitocin for inducing labor at term.

## Risk of Fetal Loss or Preterm Labor

Retrospective studies of fetal loss and preterm loss suggest that breast stimulus could be the source in some women. The Miscarriage Clinic in London states that once a pregnancy is clinically detectable, breastfeeding should pose no added risk of pregnancy loss, and there is no reason to link breastfeeding and miscarriage. Most obstetricians, however, caution against sex during pregnancy in a woman with a history of fetal loss or premature birth. Breast stimulus is equally proscribed in such circumstances. The stimulus is not exactly equal. In addition, the nursing will be nursing several times per day every day. Twin pregnancies and other multiples are considered high risk and weaning is usually recommended if the mother is nursing.

The decision to continue nursing when a new pregnancy is normal with no factors for a high-risk pregnancy should rest with the comfort level of the mother and child. The breast pain can be improved by wearing a supportive bra and repositioning during breastfeeding. The decrease in volume of milk is usually not remediable, but milk usually returns toward the end of pregnancy and is completely regenerated at delivery.<sup>49</sup>

In a study of 68 Peruvian women who breastfed during pregnancy and 65 who had not breastfed during the pregnancy, Marquis et al.<sup>44</sup> reported that on day 2 postpartum women who breastfed had higher concentrations of lactose and lysozyme but lower lactoferrin than women who did not breastfeed. At 1 month, immunoglobulin A was lower among women who breastfed. The infants of the women who breastfed were five times as likely to have respiratory symptoms ( $p < 0.05$ ) in these early weeks.<sup>44</sup>

Women who were 2 months pregnant and weaning their infants showed a progressive loss of secretory activity by the mammary gland, seemingly due to an inhibition of milk secretion that overrides the stimulus provided by the infants. These results were compared to milk of women weaning without pregnancy.<sup>52,53</sup>

Many of the changes in child-rearing practices in recent years have increased the freedom and response to human needs. Carried to extremes, instant gratification becomes a right rather than a privilege. Sometimes a mother may need help in seeing that she need not feel guilty if she decides to wean the older child. If it is only an occasional feeding or suckling experience for added security, especially when security is threatened by the arrival of a new infant, it may be tolerable in terms of endurance for the mother, and she may agree willingly. When, however, continuing nursing becomes a strain or is painful or stressful, she should feel free to stop. When a mother feels real resentment toward the older child who is nursing, it is time to wean gently but firmly. If such a situation can be anticipated, it is probably easier for an older child to be weaned before delivery of the new infant.

Sore nipples are the most stressful symptom during pregnancy and may be the first sign of the new pregnancy as the hormonal milieu changes. There is no specific treatment, although having the toddler repositioned at the breast may ease the discomfort. If the toddler is old enough to understand, asking him or her to nurse more gently or "more softly" may help. The soreness may last for the first trimester or for the entire pregnancy until the new baby is born.

## DECISION: SORTING OUT PERSONAL FEELINGS

Little is in the medical literature about nursing during pregnancy and tandem nursing. A mother must make up her own mind if there are no medical contraindications. Much depends on the age of a child, the nursing pattern, and the nutritional and emotional needs of the child. Medical indications to wean during pregnancy are uterine bleeding, signs of preterm labor, or failure to gain enough weight during pregnancy.

Tandem nursing for some women is too much "touching," especially when the infant and the toddler are a year or more apart in age. Nursing twins or triplets presents a similar situation for some mothers.

As with any such decisions to wean, it is best for a physician to work this out in frank discussion with a mother (and father, if available) so that any misgivings, resentment, or feeling of failure can be dealt with openly. Many patients automatically suspect the physician of being antagonistic to

breastfeeding if the physician suggests weaning. Even when the reason is purely but urgently medical, discussion should be open and include options and alternatives and their risks. Weaning is part of a baby's growing up, but it is sometimes part of a mother's moving on as well.

While tandem nursing requires ordinary hygiene, it is usually not necessary to limit each child to one breast because any infections or colds have spread before the first symptom. There are a few precautions. If one child has thrush, assigning one breast may keep it under control. If the older child develops a herpetic lesion or cold sore, he or she must not nurse. The newborn could acquire a potentially fatal herpes infection.

The dilemma of tandem nursing and weaning an older child has been dealt with in other societies with various manipulations, such as painting the breast with pepper or bitter herbs to make it taste terrible. The mother may leave the child with other caregivers. The provision of love and affection during this difficult adaptation for the child is what makes the difference between a traumatic occasion and a step toward growing up. Equally important is the provision of some opportunity for a mother to express her concerns and doubts during the process to her physician, who should be neither judgmental nor unduly rigid in the medical care plan.

## Reading for Parents

One book recommended for parents is *Adventures in Tandem Nursing (Breastfeeding During Pregnancy and Beyond)* by Hillary Flower, La Leche League International, Schaumburg, Ill., 2003.

## CHAPTER 21

# *The Collection and Storage of Human Milk and Human Milk Banking*

---

Breast milk expression has become a very common practice. Although it is associated with maternal employment, it is also associated with the desire to make it possible for someone else to feed the infant. Pumping to donate the milk has been an uncommon reason, as has been pumping for a hospitalized infant. The prevalence of breast milk expression was determined by reviewing the data from the 2005 to 2007 Infant Feeding Practices Study II by the Center for Food Safety and Applied Nutrition, of the Food and Drug Administration (FDA), and the Centers for Disease Control and Prevention (CDC).<sup>37</sup> Of mothers whose infants were younger than 4½ months, 85% had expressed milk at some time since birth, 43% having done so occasionally and 25% on a regular schedule. The number was higher among first-time mothers and slowly declined as the infant became older ([Figures 21-1](#) and [21-2](#)).

The human milk bank has entered another era. The interest in providing human milk for infants with special needs, especially premature infants, has increased, but the concerns regarding donor milk have also escalated. Regulatory bodies have decreed that donor milk must be pasteurized. Milk banks have recognized the need for donors to be carefully screened and women at high risk for certain infections eliminated from the donor pool.

When there are risks associated with using even a mother's own milk for a given baby, the risk/benefit ratio is determined. Because of the effects of heating, cooling, freezing, and storing milk, some of the most valued and precious qualities

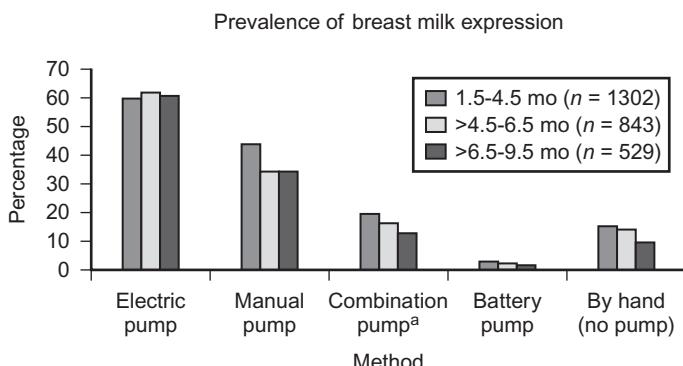

are diminished or destroyed; feeding the milk fresh or at least fresh frozen and not heated preserves most of the constituents. The value of the milk produced by women who deliver prematurely has been discussed in [Chapter 15](#).

### *Historical Perspective*

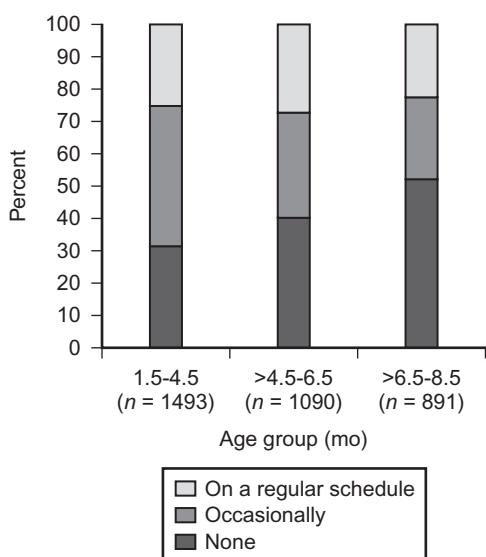

---

When "wet nursing" was the immediate alternative feeding to replace a mother's own milk, and no safe ways were available to store milk of any species, no human milk banks existed.<sup>7</sup> As pasteurization became available and formulas based on milk from other species increased in popularity, the pool of human milk diminished. "Wet nurses" were increasingly difficult to locate, and often were not safe sources because of wet-nurse lifestyle, risk for infections, and poor nutrition. It had already been clearly demonstrated in the early twentieth century that infants who did not receive their mother's milk had six times the risk for dying in the first year of life (see [Chapter 1](#)).

The impetus behind milk banks at the turn of the twentieth century was actually the medical profession's desire to remove the control of infant feeding from wet nurses and separate the product (human milk) from the producer. Pediatricians, anxious to improve the prognosis for infants deprived of their own mother's milk for medical and social reasons, developed a means of storing human milk for general use for sick infants. The first milk bank was

**Figure 21-1.** Percentage of breastfeeding mothers who had successfully expressed milk, according to method of milk expression and infant age group. The 1.5- to 4.5-month sample is based on breastfeeding mothers who responded about methods used to successfully express milk since their infant was born; the >4.5- to 6.5-month sample is based on mothers who responded in the previous 3 months; and the >6.5- to 9.5-month sample is based on mothers reporting about methods used in the previous 2 months. Samples are smaller than the total of those who had successfully expressed milk during a given period (1315, 845, and 653, respectively, for the successive age groups) as a result of question nonresponse. Respondents could mark all answers that applied; therefore percentages in each age group do not sum to 100%. <sup>a</sup>Combination pumps were defined as both electric and battery operated.

**Figure 21-2.** Breastfeeding mothers' prevalence of breast milk expression in the previous 2 weeks, according to infant age-group.

opened in Vienna in 1900. The first one in the United States was established 10 years later at the Massachusetts Infant Asylum, where wet nurses had been the only sources of human milk.<sup>29</sup> In 1919 the first human milk bank was founded in Germany in Magdeburg by Dr. Marie-Elise Kayser. In 1934, she wrote guidelines that were used throughout Europe for the creation and operation of milk banks.<sup>67</sup>

Early attempts at providing donor milk depended on casual screening of donors for tuberculosis, syphilis, and various acute contagious diseases.<sup>47</sup>

There was little research investigating human milk, but the dairy industry was rigorous in its attempt to store and market bovine and other mammalian milks. This technology was applied on a small scale, but other human milk banks appeared after Denny and Talbot created the one in Boston. The American Academy of Pediatrics (AAP) established its first formal guidelines for human milk banks in 1943.<sup>10,11</sup> Similar guidelines were provided in other countries. After World War II, milk banks were mandated on both sides of the Berlin Wall. In 1959 the Federal Republic of Germany (West Germany) had 24 milk banks, and the German Democratic Republic had 62.<sup>66</sup> The numbers gradually decreased.

As technology advanced in newborn care and in infant nutrition, science replaced nature. The interest in human milk faded, and with it the call for banked human milk, in the 1960s and into the 1970s. Experience in Rochester with short-gut syndrome and malabsorption syndromes, however, resulted in the development of a registry of lactating women, who donated fresh milk when needed. A milk bank was developed with donors providing frozen milk on a regular basis. By 1975, five large commercial milk banks were operating in Britain. Milk banks also sprang up across the United States. The system thrived with the establishment in 1985 of the Human Milk Banking Association of North America (HMBANA). The association not only facilitated communications among banks, but also began to investigate processes, develop uniform policies, and most importantly, provide professional and public education.<sup>76</sup>

The threat of human immunodeficiency virus (HIV) and hepatitis, the return of tuberculosis,

and drug abuse have cast a long shadow on milk banks in the United States. This resulted in the closure of all but seven milk banks in North America and five in the United States in the nineties (see Appendix H). In Europe, milk banking has been key in the nourishment of premature and other high-risk infants. The Sorrento Maternity Hospital has supplied 50,000 L of milk from 10,000 donors in 40 years and provided 700 L a year both locally and across Britain in the nineties.<sup>3</sup> In 1994 the remaining 18 milk banks in unified Germany supplied about 15,000 L.

Many developing countries, especially in Central and South America, are establishing milk banks as part of national efforts to promote breastfeeding.<sup>62</sup> Studies done in nurseries in Guatemala have shown a marked decrease in mortality and morbidity rates by providing every infant with human milk, especially colostrum.<sup>12</sup> The United Nations Children's Fund (UNICEF) has encouraged and supported such efforts.<sup>82</sup>

The First International Congress on Human Milk Banking: A Vision of the Future was held in Brazil in 2000, sponsored by the Brazilian Association of Milk Banks. There are 154 milk banks in Brazil. Representatives from South America, France, United Kingdom, North America, and the Caribbean attended. All of the milk banks processed the milk. Some screened the serum of donors, but not all. None paid donors but some did provide pumps.<sup>75</sup> Regulations vary by locale. A resurgence of milk banks in the United States has occurred in the last 10 years, stimulated in part by the recognition of the value of human milk for premature and especially very-low-birth-weight infants by neonatologists. Another stimulus was the establishment of a for-profit milk bank in California, approved and licensed by the State of California. This milk bank, supported by venture capitalists, studied the safest ways to process milk. The milk bank was able to measure the caloric value of the milk and provide milk of 20, 22, 24, and 28 cal/oz. Its most important contribution has been the development of a supplement consisting only of human milk to be used to enhance the protein, calcium, and caloric content of a feeding of mother's milk for a premature or other compromised infant who requires extra calories, protein, and minerals.

## *Storing Human Milk*

It is often necessary to store milk for infants, especially in the hospital. The storage of human milk involves two types of milk: mother's milk and donor milk. The distinction becomes important in how the milk is stored and prepared for an infant. It is also important because many states have developed

codes for donor milk but fortunately have not regulated mother's milk as yet. Certain guidelines are appropriate for each milk. Indications for use of such milk were alluded to in other chapters but are briefly summarized here.

## **MOTHER'S MILK FOR A HEALTHY INFANT**

The conditions under which a mother collects and stores milk while at work are not always ideal. At home, at work, or at school, milk should be collected with clean equipment, stored in sterile containers (dishwasher cleaned and dishwasher dried suffices), and handled with just-washed hands. The limits of temperature and time are an important consideration in the storage of milk.

To assess microbial growth and stability of milk protein and lipid at varying temperatures and for varying lengths of time, Hamosh et al.<sup>30</sup> collected samples from 16 healthy women with healthy babies who were exclusively breastfed. Sampling was done early in lactation (1 month postpartum) and late in lactation (5 to 6 months postpartum). The milk pH decreased from  $7.02 \pm 0.20$  to  $5.16 \pm 0.26$  after 24 hours of storage at  $38^\circ\text{C}$  ( $100^\circ\text{F}$ ), and significant differences in pH occurred at all temperatures at 24 hours or longer. Proteolysis was minimal at  $15^\circ\text{C}$  ( $59^\circ\text{F}$ ) and  $25^\circ\text{C}$  ( $77^\circ\text{F}$ ), but became apparent at  $38^\circ\text{C}$  ( $100^\circ\text{F}$ ) at 24 hours. Lipolysis was marked in the first 24 hours at all temperatures compared with freshly expressed milk. Bacterial growth or normal flora was minimal at  $15^\circ\text{C}$  at 24 hours, low at  $25^\circ\text{C}$  at 8 hours, and higher at  $38^\circ\text{C}$  by 4 hours.

The authors concluded that storage of human milk is safe at  $15^\circ\text{C}$  for 24 hours and  $25^\circ\text{C}$  (room temperature) for 4 hours and should not be stored at  $38^\circ\text{C}$ . Proteins appear to maintain their structure and function in short-term storage. The marked lipolysis appears to slow bacterial growth at the same time.<sup>30</sup>

## **PASTEURIZING BREAST MILK AT HOME**

Many women face the dilemma of discarding milk pumped when they had a *Candida* infection of the breast before it was diagnosed. Freezing does not destroy *Candida*. It has been suggested that milk could be "pasteurized" at home, for use at home by the mother's own infant. Below are the steps for home pasteurization for one's own infant, not a milk bank:

Pour all milk into a large saucepan, and place over medium heat on the stove.  
Using a candy thermometer, gradually bring the milk to a temperature of  $145^\circ\text{F}$  ( $62.5^\circ\text{C}$ ).

Watch closely, and stir often, keeping milk at this temperature for 30 minutes.

Milk can then be poured into appropriate storage containers.

Label each container with the baby's name and the date and time of pasteurization.

Freeze the pasteurized milk in dishwasher-clean containers until ready for use.

Do not boil the milk (boiling occurs at 212°F or 100°C).

If performed correctly, this process will decrease nutritional and immunologic components by about 30%, but will destroy all microorganisms.

See Protocol 8 in Appendix P for more information. This milk should not be shared, but used only for the mother's baby.

## MOTHER'S MILK FOR A SICK INFANT

The following situations are common scenarios for the use of mother's own milk.

1. A mother plans to breastfeed the infant ultimately but needs to provide pumped milk until the infant can be put to the breast.
2. An infant requires the special nutritional benefits of human milk (as with those infants who are recovering from intestinal surgery), but cannot nurse at the breast.
3. An infant weighs 1500 g or less and has difficulty digesting and absorbing other milks and is usually fed by nasogastric tube.

## MILK SHARING

Milk sharing has become a popular source of human milk, and the various methods have generated much discussion in various media. Serious analysis of the activity has shown that it is not safe. A carefully executed study of milk samples purchased on the Internet showed high contamination with bacteria and, in some cases, pathogenic bacteria. The authors also reported poor collection, storage, and shipping practices. This study did not measure toxins, pharmaceuticals, or medications, which are also a risk in shared milk for the sick or premature infants. Caloric content and protein levels were not measured. Clearly, Internet sharing or selling milk by unscreened donors is not recommended. Small community-based nonprofit milk sharing systems where the donors are screened provide safety. They do not guarantee the caloric content, and it is known that the caloric content can be as low as 15 cal/oz. Neonatal intensive care units (NICUs) who need milk for high-risk infants should only accept milk from certified sources.

## DONOR MILK FROM A MILK BANK

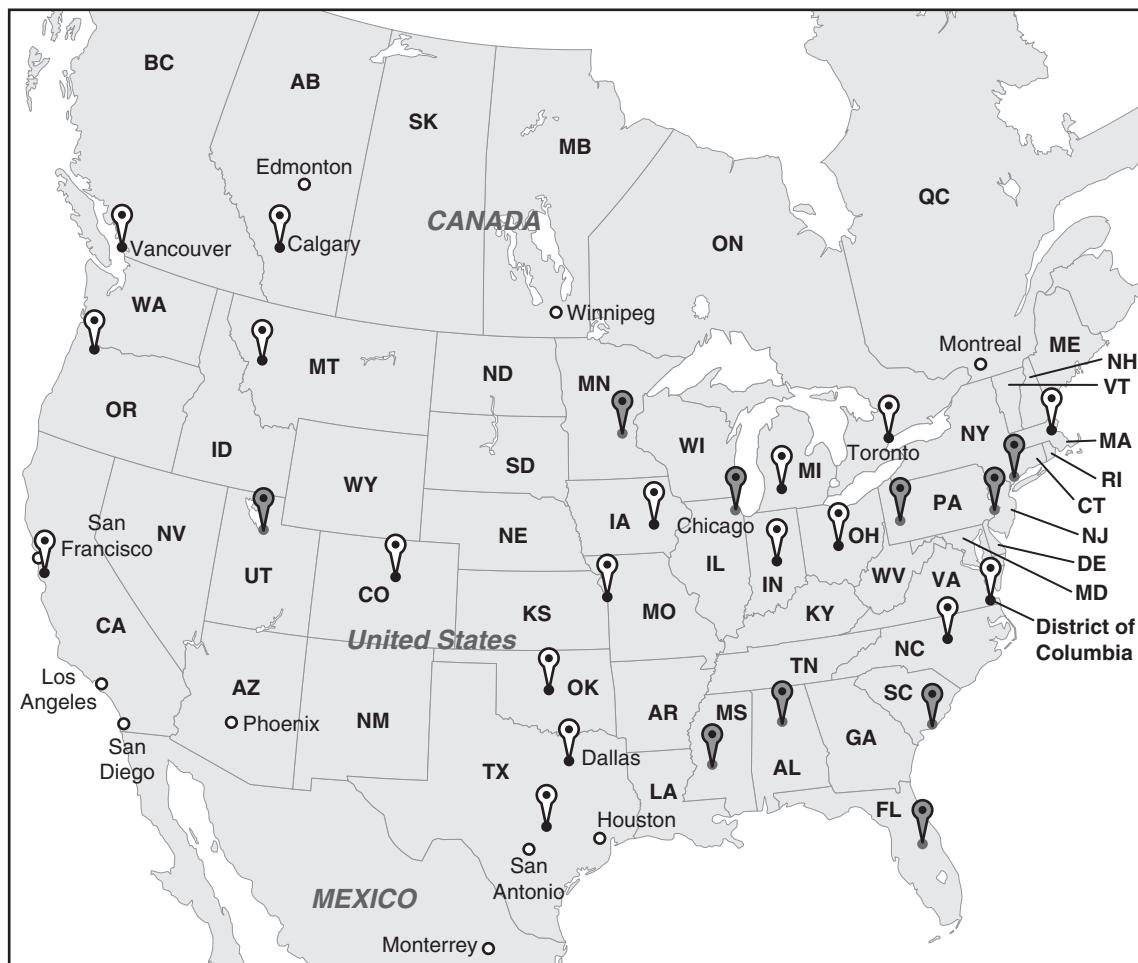

The following scenarios are common reasons for obtaining donor milk from a bank.

1. An infant is at risk for infection or necrotizing enterocolitis. Fresh colostrum is held to be especially protective and may be collected from low-risk, carefully screened mothers, who are not breastfeeding their own infants.
2. An infant has a gastrointestinal anomaly or other reasons for intestinal tract surgery, especially short-gut syndrome.
3. A physician thinks an infant would benefit from the nourishment in human milk because of prematurity, especially if the infant weighs less than 1500 g.
4. A mother is temporarily unable to nourish her own breastfed infant completely. It may be that the mother's supply is inadequate when she first puts the infant to the breast after weeks of pumping, or when the mother has been ill or hospitalized. Usually these infants are already at home.
5. Donor milk is an excellent transition from parenteral nutrition when mother's milk is not available. It allows earlier weaning from parenteral solution—earlier than when formula is known to be tolerated.
6. Metabolic disorders, especially amino acid disorders, respond well because of the physiologic profile of human milk (decreased casein, tyrosine, and phenylalanine). In addition, human milk is protective against infection, which may be a serious complication of these disorders.
7. An older infant or child has unique feeding difficulties, usually characterized by an inability to tolerate any oral nourishment except human milk (e.g., a child dying of HIV infection).

## STRUCTURE OF A MILK BANK

Most informal and casual milk banks operating in conjunction with a NICU have disappeared.<sup>61</sup> NICUs may provide a deep freeze for storage of a mother's own milk for use by her infant. They store it for feeding of the infant and do not process it at all except to culture random samples for contamination. Most do not permit "donating" milk to other infants except by private arrangements between the two mothers with a physician's approval. No feeding is given to an infant in the hospital without a physician's order. Smaller public milk banks have phased out since state legislation or local medical practice standards have mandated strict surveillance of samples and pasteurization.

A few large, well-established banks operate in the United States and around the world (Figure 21-3). A network of these milk banks meets and shares information through the HMBANA in

**Figure 21-3.** HMBANA milk bank locations in the United States and Canada. White markers represent established milk banks; gray markers represent banks in development. (Data from [www.hmbana.org/locations](http://www.hmbana.org/locations) (Accessed 26.05.15).)

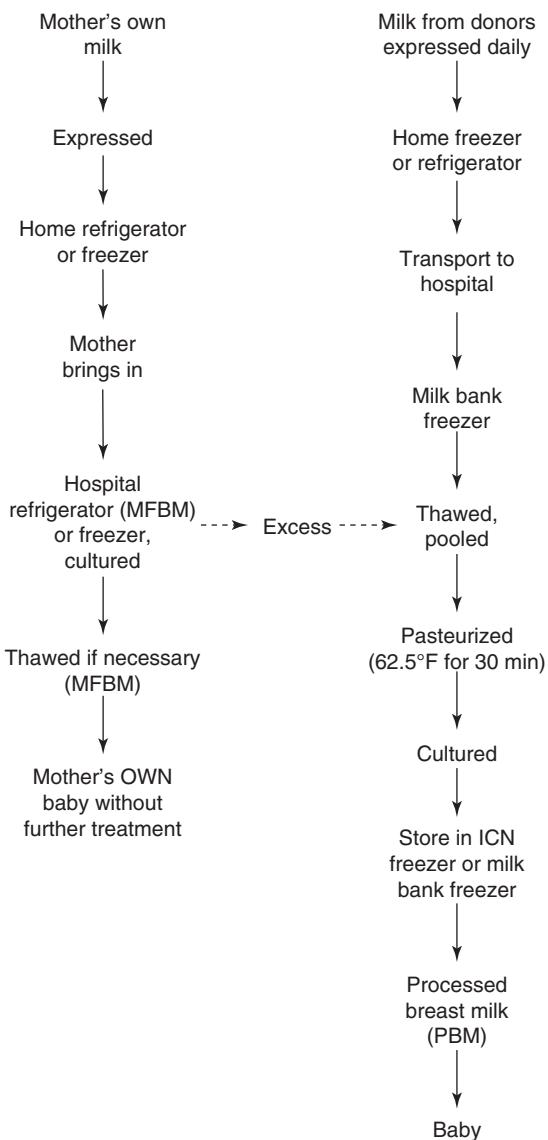

North America.<sup>2,76</sup> Copies of the association's guidelines for milk storage are available for a fee. HMBANA works closely with the FDA concerning FDA regulations for human tissues and fluids. Appendix H provides the guidelines (Figure 21-4).

The Mother's Milk Bank of the Institute for Medical Research in San Jose, California, was established in 1974. It has a full-time coordinator and a medical director, provides milk for hundreds of infants, and contributes to the fund of knowledge on human milk. Because the milk is provided to patients only by physician's prescription, it is reimbursable by health insurance carriers of California. Mother's Milk Bank has developed procedures and policies regarding milk collection, storage, and processing. This was first described in detail by Asquith et al.<sup>2</sup> and documented with an extensive bibliography.

The State of New York passed an amendment to the public health law in 1980, in which it was declared policy that any and all infants requiring

human breast milk be assured access to sufficient quantities of wholesome human breast milk, donated by concerned lactating mothers on a continued and systematic basis. New York State has regulations, which have the force of law, governing human milk banks. They address construction, medical direction, donor qualifications, milk collection and storage, maintenance of records, and milk distribution. They are available on the Internet in Part 52, Subpart 52-9, of Title 10 (Health) of the New York Code of Rules and Regulations, which can be accessed from the New York State Department of Health's Public website at [http://www.health.ny.gov/regulations/nycrr/title\\_10](http://www.health.ny.gov/regulations/nycrr/title_10) (accessed 30 April 2015).

Neonatologists caution that the cavalier feeding of unsterile unsupplemented breast milk to premature infants may produce iatrogenic problems. Mothers who pump and save milk for their own infants should follow the instructions/guidelines for storing mother's own milk (see Appendix J, Protocol #8).

**Figure 21-4.** Flow chart of process for the mother at home pumping for her hospitalized infant (*left*). The right column outlines the steps a donor takes when collecting milk for the bank. The mother described on the *left* can become a donor if she has an abundance of milk and is screened to be a donor. *MFBM*, Mother's frozen breast milk.

## QUALIFICATIONS OF DONORS

A mother who is willing to donate milk should be healthy and fulfill the following qualifications (Box 21-1):

1. Normal pregnancy and delivery
2. Serologically negative for syphilis, hepatitis B surface antigen, cytomegalovirus (CMV), and HIV
3. No infection, acute or chronic (i.e., not at high risk)

### BOX 21-1. Donor Screening Procedures

1. Donors answer questions on a verbal health history screening form. Primary health care providers for the prospective donor and her infant are asked for verification of health.
2. Donors are tested serologically for:
  - a. HIV-1 and HIV-2
  - b. HTLV-I and HTLV-II
  - c. Hepatitis B
  - d. Hepatitis C
  - e. Syphilis
3. Repeat donors are treated as new donors with each pregnancy.
4. Milk banks will cover the cost of the serologic screening if the tests are done by the milk bank.

#### Reasons for excluding a donor

- Receipt of a blood transfusion or blood products within last 12 months
- Receipt of an organ or tissue transplant within last 12 months
- Regular use of more than 2 oz of hard liquor or its equivalent in a 24-hour period
- Regular use of over-the-counter medications or systemic prescriptions (replacement hormones and some birth control hormones acceptable)
- Use of megadose vitamins or pharmacologically active herbal preparations
- Total vegetarians (vegans) who do not supplement their diet with vitamins
- Use of illegal drugs
- Use of tobacco products
- Silicone breast implants
- History of hepatitis, systemic disorders of any kind, or chronic infections (e.g., HIV, HTLV, TB)

4. Not taking medications, smoking, or using excessive alcohol
5. Capable of carrying out sterile technique
6. If donating for other infants, own child is healthy and without jaundice

When a directive from the Department of Health and Social Security in Great Britain mandated HIV testing for donors to milk banks, it was observed that the list of 19 established milk banks dwindled to six.<sup>3</sup> The Sorrento Maternity Hospital, however, in accordance with the directive of the Department of Health and Social Security, screened all donors for HIV antibodies. Only four mothers of 470 potential donors have refused to be tested, contrary to fears that the ruling would discourage donating.<sup>3</sup>

The donor should not be taking medications regularly, including certain oral contraceptives and any nonprescription medications, such as

aspirin or acetaminophen. Her infant should be well and should not have had neonatal jaundice. If the mother is donating only for her own infant, the state of the infant's health does not prevent her from donating. Any time the donor becomes ill, however, she should discard milk from the previous 24-hour period and not save milk until the illness is ended if the milk is to be donated.<sup>40</sup>

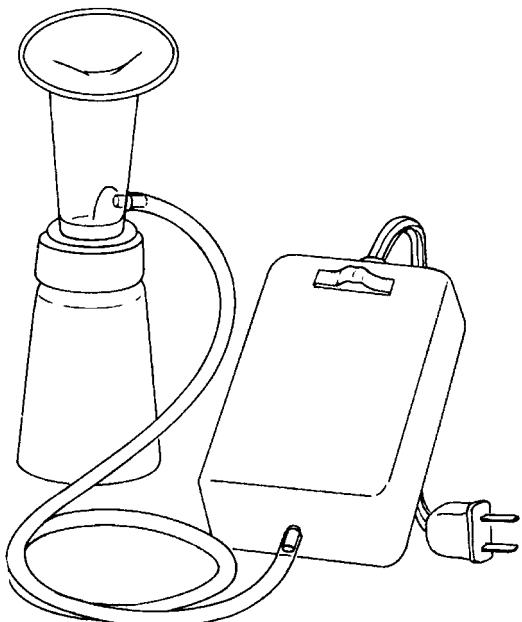

Discarding milk during maternal illness is the most difficult regulation to which a mother must adhere. The desire to contribute may overshadow the mother's understanding of the risk it poses for an infant who is not her own receiving such milk.

The one limiting factor in donating milk is that the woman must be lactating. Becoming a professional donor of milk today is highly unlikely. The amount of protein has been noted to be lower after 6 months of lactation in some women; thus after 6 months or, at most, 8 months postpartum it is advisable to evaluate a given mother's contributions to confirm that protein and caloric content is sufficient. There is always the theoretical risk for a donor mixing her collections with cow milk. Milk can be tested for bovine protein. Prolacta Bioscience and Medolac, for-profit milk banks, can screen for a mother's DNA. These two milk banks screen all donations to confirm a match to the certified donor's DNA.

## TECHNIQUE FOR COLLECTION

Whether collecting for a mother's own infant or for other uses, it is of prime importance to maintain cleanliness and minimize bacteria in the process of collection. The mother should be instructed in washing her hands and her breasts before handling the equipment or pumping.

The two major ways of collecting are letting the milk drip while the infant nurses on the other side, and pumping or manually expressing the milk.<sup>26,28,70</sup> Drip milk is acceptable for one's own infant when it is used as an occasional tide-over feeding in the mother's temporary absence; however, it is not appropriate for donor milk. Dripped milk has been found to have lower caloric value, lower fat, and a much higher incidence of contamination. Pumped milk has a higher fat content than dripped or manually expressed milk, and in most individuals the volume is also greater. Any equipment used, such as hand pumps, tubing, and collecting bottles, should be sterile. When an electric pump is used, the parts that come in contact with the milk should be sterile or disposable (Figure 21-5). Many hospitals own electric pumps, or one may be rented from a local medical equipment rental company. Some women can pump large volumes of fat-rich milk manually, and for them, manual expression would be acceptable.

**Figure 21-5.** Purse-sized electric pump. This type of breast pump is serviceable for women who are fully lactating.

The hospital or the bank should provide a program of education for the donors. Milk samples should be cultured initially to ensure proper technique and the absence of significant contamination. Then samples should be sent for culture on a random basis. Studies have shown that milk collected at home has a higher contamination rate than that collected while the same donor is hospitalized, or with equipment maintained by the hospital. Collection at the hospital also avoids the transportation problem.

Many hospitals use the 4-oz sterile water-nursing bottles packaged by formula companies for collections by discarding the water at the time of collection and then filling them with milk. This can be costly if the hospital is paying for feeding supplies. Other programs suggest the use of 50-mL plastic centrifuge tubes, which are pre-sterilized and have tight-fitting tops. These tubes have the advantage of more appropriate volume and easy measurability and sterility. Ideally the hospital or milk bank provides a uniform container. Soft plastic bags are not recommended; however, pump companies sell bags that are safe. If a woman wants to donate a large amount of previously collected and frozen milk that suddenly becomes available (the infant weans or dies), then this milk is a valuable resource. It can be handled separately with culturing and pasteurization, if the milk bank has a protocol for accepting such milk.<sup>1-3</sup>

The efficacy of various methods of removing milk from the breast has been evaluated. Electric

pumping was clearly more effective in raising the maternal prolactin levels and increasing the volume of milk when compared with hand pumping and manual expression.<sup>86</sup> The study did not compare various brands of pumps but types of pumps. A hospital may own a breast pump that is 10 or 20 years old, however, which may not have safety features that are built into current models. Problems of contamination are a significant issue because old models may not protect against milk backing up into the motor or tubing, normally thought to be free of milk, and of potential contamination. Care must be taken to check each machine and follow directions for its proper use. Old vacuum extraction pumps should be discarded.

The use of most of the modern electric pumps with their disposable tubing and collecting vessels makes mechanical pumping the most efficient and cleanest of the methods. In addition, the milking action of an electric pump produces more physiologic stimulus to the breast. Most electric pumps provide attachments for pumping both breasts simultaneously. With double pumping, overall production may be increased, and time for pumping may be cut in half.

Bank milk collected by manual expression is less likely to be contaminated than that collected by hand pumps, even when pumps are boiled or placed in an electric dishwasher.<sup>77</sup> The rubber bulb of the hand pump, resembling a bicycle horn, retains milk and bacteria and should not be used. "Nesty cups," which are placed inside the brassiere to collect milk drippings between feedings, have been associated with the greatest contamination and are not recommended. Some women develop mastitis using small hand pumps.<sup>21</sup>

Donowitz et al.<sup>14</sup> reported contaminated breast milk as the source of *Klebsiella bacteremia* in a NICU. Unpasteurized human milk from a single donor fed through nasogastric and nasoduodenal tubes to sick newborns was found to be contaminated from the safety overflow bottle and tubing of the electric breast pump maintained in the NICU. This part of the tubing and equipment should be sterilized or disposed of between collections, according to the manufacturer's instructions. Strict attention to sterilization of equipment is imperative. Older electric pumps that do not have a built-in mechanism to prevent milk from getting into the permanent "works" should be discarded. Only pumps with disposable or cleanable parts and a safety valve should be used.

The bacteriologic benefit to discarding the first 5 to 10 mL of milk pumped from the breast remains disputed.<sup>8</sup> Some banks require that their donors follow instructions for discarding the first 5 to 10 mL of milk expressed at each pumping and each breast. When a donor is collecting for

long-term storage, this may be appropriate. When a mother is collecting for her own baby and her volume is meager, discarding 10 mL may be counterproductive. This is particularly important initially, when early colostrum and milk are less in total volume but high in value to the infant. At home, later, when production is abundant and technique may be less stringent, discarding 2 to 3 mL might be appropriate. This will allow a clean collection without washing the breast before pumping, which is associated with sore nipples in some women.

## COLLECTION AND STORAGE CONTAINERS

Colostrum was reported by Goldblum et al.<sup>28</sup> to impart greater stability to its components than did mature milk. None of the cellular or humoral immunologic factors investigated were diminished when colostrum was stored at 4°C (39°F) for 24 hours in any of the containers (Table 21-1).

The effect of the container on the stability of the constituents of milk was investigated by Garza et al.<sup>25</sup> Pyrex and polypropylene containers were found not to interact with water-soluble and fat-soluble nutrients such as vitamin A, zinc, iron, copper, sodium, and protein nitrogen. Polyethylene bags were found to spill easily, to be harder for mothers to fill without contamination, and to be difficult to handle in the nursery. The containers also leaked and punctured easily, resulting in 60% lower secretory immunoglobulin A (IgA) levels because of adherence to the material. It appears that rigid polypropylene plastic containers may have a significant advantage in maintaining the stability of all constituents in human milk collections and may be easier and safer to handle.

Paxson and Cress<sup>57</sup> have reported a significant difference in the survival of leukocytes when milk is collected and stored in plastic containers rather than glass, because the cells apparently stick to the glass. The phagocytosis of these cells, however, is not affected by the container. The researchers further demonstrated that varying the osmolarity or protein concentration does not alter the number or the phagocytosis of the cells. Because they believe the main reason for feeding preterm infants human milk is for the protection against infection, they suggest nasogastric feedings instead of nasojunal feeding (to maintain pH in the acid range; in the small bowel, the pH is 6.5 to 8). The milk is collected in sterile plastic containers and maintained in the refrigerator until it is fed to the infant, avoiding heating, freezing, and alkaline solutions (see Table 21-1).

**TABLE 21-1** Effect of Container Type on Milk Constituents

Constituent	Pyrex	Polypropylene	Polyethylene Bags	Polyethylene (Rigid)
Colostrum	Constituents stable	when refrigerated	24 hours	in all containers
<b>Mature milk</b>				
Cells	Stick to glass	Maintain phagocytosis	Stable	Stable
Fat-soluble vitamins	No effect	No effect	—	—
Micronutrients	No effect	No effect	—	—
Secretory IgA	—	—	Lower	Stable
Difficult to handle	—	—	Very Spill easily	—
Recommend for donor milk	Highly	No	No	Yes

## STORAGE AND TESTING OF MILK SAMPLES

Fresh, refrigerated, unsterilized mother's milk can be used for 48 hours following collection. If the milk is to be used fresh chilled, it should be refrigerated at home and brought in promptly for use within 48 hours. If it is to be frozen, this should be done immediately at  $-18^{\circ}\text{C}$  ( $0^{\circ}\text{F}$ ) (standard home freezer) or in the top of a refrigerator freezer. The milk stored in the latter should be deep frozen within 24 hours if it is to be stored any length of time. The milk kept at  $-18^{\circ}\text{C}$  can be kept for 6 months. Freezing and thawing, which can occur in a freezer that is part of a refrigerator, significantly alters the energy content and predisposes the milk to separation of the fat layer. Therefore, milk stored in the freezer compartment of a refrigerator freezer with separate doors should be placed well back in the freezer (not in door) and stored for only 1 month. In the hospital or at a bank, all samples should be labeled with name of donor, date, and time of collection. Milk is stored in the freezer in such a way that the oldest milk is used first, and all milk of a single donor is kept together and used only for the infant of that mother.

When a hospitalized mother is contributing fresh milk to her own infant, it is usually not cultured. Pumping is usually done with the help of the nursing staff. Colostrum seems to be more resistant to contamination.<sup>13</sup> Once a mother has been discharged home and she is producing mature milk, however, random sample culturing of her milk samples every week or two is a mechanism for checking milk-expression technique.<sup>17</sup> NICUs have found that random testing improves technique in general.

Because using the fresh milk from the mother to feed a premature infant is becoming commonplace, it is important to be aware of the bacteria cultured from fresh samples during refrigeration.<sup>5</sup> Samples pumped by hand pump and manually expressed were cultured at zero time and after 48 and 120 hours of refrigeration by Sosa and Barness.<sup>66</sup> Although 8 of 41 samples had no growth, the others had the same

**TABLE 21-2** Positive Bacterial Cultures From 41 Breastfeeding Mothers

Bacterial Groups*	No. (%) of Cultures	
	Skin and Nipple	Milk
<i>Staphylococcus epidermidis</i>	77 (94)	29 (71)
<i>Streptococcus</i>	17 (21)	6 (15)
<i>Propionibacterium</i>	10 (12)	5 (12)
<i>Staphylococcus aureus</i>	4 (5)	—
<i>Pseudomonas aeruginosa</i>	2 (2)	—
<i>Klebsiella pneumoniae</i>	1 (1)	2 (5)

\*Two or more organisms were identified in several skin, nipple, and milk cultures.

**TABLE 21-3** Positive Rate of Breast Milk Cultures Over Time

Cultures	Time of Refrigeration (h)		
	0	48	120
Positive	33	27	11
Negative	8	14	30
Total	41	41	41

bacteria on skin and nipple as appeared in the milk (Table 21-2). Concentration was low and decreased over time (Table 21-3), which is attributed to the bacterial inhibitory factors present in milk. This suggests that refrigeration of carefully collected breast milk is a safe method for more than 48 hours. Guidelines for collection and use of mother's own milk appear in Appendix P, Protocol #8.

## STANDARDS FOR RAW DONOR MILK

Labeling donor milk immediately on arrival at the bank is mandatory. Bar coding is the most accurate method and is done by Prolacta and Medolac.

Hospitals have also adopted the methodology. Centralized breast milk handling and barcode scanning improved safety and reduced breast milk administration errors at Orange County Childrens hospital. Errors were reduced to zero.<sup>69</sup>

The FDA and the CDC do not recommend use of donor milk without heat treatment.<sup>76</sup> Rare children, however, require fresh donor milk and cannot tolerate the heat-treated product. For these infants, the guidelines should be carefully followed. These special donors must be meticulously screened and monitored for high-risk behaviors. Parents of the infant recipient should sign an informed consent form.

All raw donor milk should be screened microbiologically before use. No generally accepted microbiologic criteria exist for such milk, except that no potential pathogens should be present.<sup>9</sup> Such pathogens include *Staphylococcus aureus*,  $\beta$ -hemolytic streptococci, *Pseudomonas* species, *Proteus* species, and *Streptococcus faecalis*. Some milk that cannot be fed raw can be pasteurized.<sup>77</sup>

Other guidelines for raw donor milk include the following<sup>73</sup>:

1. Each pool of milk shall have a sterile sample taken for bacteriologic screening.
2. Only milk from a specially certified donor with less than  $10^4$  colony-forming units per milliliter (CFU/mL) of normal skin flora (e.g., coagulase negative staphylococcus, diphtheroids, *Staphylococcus epidermidis*, or *Streptococcus viridans*) will be acceptable to dispense raw. The presence of any pathogen is unacceptable.

## STANDARDS FOR PASTEURIZATION OF DONOR MILK

Milk suitable for pasteurization should meet the following minimum standards<sup>74</sup>:

1. A total aerobic count that does not exceed  $1 \times 10^6$  CFU/mL.
2. *S. aureus* that does not exceed  $1 \times 10^3$  CFU/mL; risk for feeding heat-treated enterotoxins when *S. aureus* exceeds  $1 \times 10^6$  CFU/mL.
3. Presence of organisms defined as being of fecal origin does not exceed  $1 \times 10^4$  CFU/mL.
4. Presence of organisms not part of normal flora does not exceed  $1 \times 10^7$  CFU/mL.
5. Presence of no unusual organisms such as *Pseudomonas aeruginosa*, spore-bearing aerobes, or spore-bearing anaerobes.

## HEAT TREATMENT

When human milk was pasteurized at  $73^\circ\text{C}$  ( $163^\circ\text{F}$ ) for 30 minutes, minimal immunoglobulins A and G (IgA, IgG), lactoferrin, lysozyme, and C3

complement remained. When the temperature was kept at  $62.5^\circ\text{C}$  ( $144.5^\circ\text{F}$ ) for 30 minutes, there was a loss of 23.7% of the lysozyme, 56.8% of the lactoferrin, and 34% of the IgG, but no loss of IgA, according to work done by Evans et al.<sup>19</sup> Similar studies of heat treatments of graded severity were carried out by Ford et al.<sup>20</sup> The findings were similar. Pasteurization at  $62^\circ\text{C}$  for 30 minutes (Holder method) reduced IgA by 20% and destroyed IgM and lactoferrin. Lysozyme was stable at  $62.5^\circ\text{C}$  but destroyed at  $100^\circ\text{C}$ , as was lactoperoxidase and the ability to bind folic acid against bacterial uptake.<sup>53</sup> Growth of *Escherichia coli* increased when introduced into heated milk. Vitamin B<sub>12</sub>-binding capacity declined progressively with increasing temperature of the heat treatment.<sup>22</sup>

The effects of the Holder method on antiinfective agents were reviewed by Orloff et al.,<sup>55</sup> who concluded that high temperatures destroyed much of the bacteriostatic effect of human milk, thus decreasing the benefit to infants. These data raise the question of whether any heat treatment might not increase the risk for enteric infection in infants.

The alterations of the lymphocyte and antibody content after processing were of concern. Significant changes with heat, including a decrease in total lymphocyte count and in specific antibody titer to *E. coli*, are noted.

Welsh and May<sup>81</sup> discuss antiinfective properties of breast milk and provide two tables to demonstrate the stability of the antibacterial and antiviral properties of human milk.

Low-temperature short-time pasteurization of human milk was reported by Wills et al.<sup>84</sup> using the Oxford human milk pasteurizer. Heating at  $56.0^\circ\text{C}$  for 15 minutes destroyed more than 99% of the inoculated organisms, which included *E. coli*, *S. aureus*, and group B  $\beta$ -hemolytic streptococci. The remaining activity of antimicrobial proteins after different time/temperature treatments is shown in Tables 21-4 and 21-5.

Bacteriologic screening of donor human milk before and after Holder pasteurization was done at the Mother's Milk Bank at Austin, Texas. 810 samples from 219 certified donors were used to create 303 pools of pasteurized donor milk. Forty-four pools of preterm donor milk were also studied. After Holder pasteurization, 93% of the pooled milk samples had no growth on routine cultures. All donor milk with any detectable bacterial growth after pasteurization was discarded. Holder pasteurization was considered by the authors to be an effective means to remove detectable bacteria from samples. Viruses and enveloped bacteria could not be detected by culture.

High-temperature short-time (HTST) pasteurization is a method used in the commercial dairy industry. It is used for large volumes as well as lesser

volumes in professional human milk banks. It requires establishing 72°C (87°F) for 15 seconds, which involves greater technical skill than the Holder method. The investigators report that HTST is effective in the elimination of bacteria as well as important pathogenic viruses. A time of 16 seconds is recommended rather than the original 15 seconds. Subsequently, they have demonstrated that HTST preserves the nutrients in human milk.

HTST treatment (72°F or 87°C up to 16 seconds) of human milk inoculated with endogenous bacteria and CMV rendered the milk bacteria free in 5 seconds and CMV-free in 15 seconds.<sup>27</sup> Folic acid and vitamins B<sub>1</sub>, B<sub>2</sub>, B<sub>6</sub>, and C were

not affected. Bile salt-stimulated lipase was inactivated by these conditions. Lactoferrin and IgA and secretory IgA antibody activity were stable at 72°C (162°F) for 15 seconds. Lysozyme concentration and enzymatic activity were increased, suggesting that lysozyme may be sequestered in the milk.

The HTST technique was thoroughly studied by Terpstra et al.<sup>73</sup> to determine its effect on the bioburden of human milk. HTST was effective in eliminating all bacteria and lipid-enveloped viruses, as well as at least one nonlipid envelope virus from spiked samples. Furthermore, HTST preserved IgA and other proteins important to immune defences. The authors suggest HTST is the method of choice for milk banks<sup>73</sup> (Tables 21-6 and 21-7).

The effect of temperature on transforming growth factor (TGF)-α and TGF-β<sub>2</sub> of human milk concentrations during pasteurization (at temperatures commonly used by donor milk banks) slightly decreased TGF-α concentrations, but not milk TGF-β<sub>2</sub>. There was little difference when temperature was increased to 71°C.<sup>48</sup>

## PASTEURIZATION BY HOLDER METHOD

Recommended pasteurization of human milk for banks, according to HMBANA guidelines, follows these steps.<sup>76,78</sup>

1. All containers shall be tightly closed with new caps to prevent contamination of milk during heat treatment.
2. Heat processing.
  - a. Aliquots of milk shall be processed by completely submerging the containers in a well-agitated or shaking water bath pre-heated to a minimum of 63°C.
  - b. A control bottle, containing the same amount of milk or water as the most filled container of milk in the batch, shall be fitted with a calibrated thermometer to register milk temperature during heat processing. The control bottle should follow the same process as the rest of the batch at all times.
  - c. The thermometer shall be positioned such that approximately 25% of the milk volume is below the measuring point of the thermometer.
  - d. The monitored aliquot shall be placed into the water bath after all other aliquots and shall be positioned centrally among the treated aliquots.
  - e. After the temperature of the monitored control bottle has reached a minimum of 62.5°C, the heat treatment shall continue for 30 minutes. Milk shall not reach a core temperature higher than 63°C.

## VIRUSES IN HUMAN MILK

The dilemma of CMV is a significant one because the virus does pass into the milk. In a study of postpartum women, CMV was recovered from the genital tract in 10%, from the urine in 7%, from the saliva in 2%, and from the breast milk in 30%.

CMV does persist after storage at 4 and -20°C (39 and -4°F) in some specimens.<sup>68</sup> It is destroyed at 62.5°C after 30 minutes.<sup>15</sup> Donor milk should be accepted only from CMV-negative mothers. Mothers who are seropositive may be permitted

to provide for their own infants because they continue to provide the antibody protection as well.

Hepatitis virus also passes into milk, and donors should therefore be screened and be seronegative. The question of having seropositive women feed their own infants is discussed in Chapter 17.

The acquired immunodeficiency syndrome (AIDS) virus has been identified in human milk.<sup>77,85</sup>

Most banks require that donors be HIV negative, but because seropositivity may take months to develop, some mechanism for excluding high-risk donors should be in place. On the other hand, some think that donors should not be screened. Holding all milk samples for several months may not be practical, and pasteurizing all milk may decrease the value of the nutrient. Some AIDS experts are concerned that the threat may seriously alter the future of milk banks.<sup>43</sup> It has been demonstrated that heat treatment kills the virus when milk is inoculated experimentally.<sup>16</sup> HTST has been shown to eliminate these viruses.

The virus associated with HIV and human T-cell leukemia virus (HTLV) were incubated at temperatures from 37 to 60°C, and the virus titer was determined over time by a microculture infectivity assay. It required 32 minutes at 60°C to reduce the virus titer.<sup>46</sup> Using the HMBANA standard of 62.5°C for 30 minutes totally destroyed the viruses. No virus could be recovered after the process, even with repeated subculturing. Human milk contains one or more components that inactivate HIV-1, but that are not toxic for the cells in which the virus replicates.<sup>55</sup> These components are under study and are probably lipids (Table 21-8).

### Lyophilization and Freezing

The impact of lyophilization was similar to that of heating, showing a decrease in total lymphocyte count and in immunoglobulin concentration and a specific antibody titer to *E. coli*. (Lyophilization is the creation of a stable preparation of a biologic substance by rapid freezing and dehydration of the frozen product under high-vacuum freeze drying.) This technique is being utilized to store the human milk fortifier produced by Prolacta Biologics (Monrovia, California).

Freezing specimens up to 4 weeks showed no change in IgA or *E. coli* antibody titer, although the lymphocyte count was decreased. The technique involved freezing to -23°C (-9°F) and thawing at 1, 2, 3, and 4 weeks. Although cells were present after freezing, they showed no viability when tested with the trypan blue stain exclusion method.

The storage of human milk at 4°C (39°F) for 48 hours caused a decrease in the concentration of milk macrophages and neutrophils, but not of the lymphocytes, which also maintained their activity, according to Pittard and Bill.<sup>58</sup> The loss of cells may be desirable if the graft-versus-host reaction in a premature infant, who is possibly immunodeficient, is of concern.

Evans et al.<sup>19</sup> reported their results with 3-month storage at -20°C and with freeze drying and reconstitution (lyophilization). They found no significant change in lactoferrin, lysozyme, IgA, IgG, and C3 after 3-month freezing, but a small loss of IgG after lyophilization (Table 21-9).

### Exposure to Environmental Conditions

Concern always exists when milk has been left out of the refrigerator or thawed and not used, and it has resulted in discarding many ounces of valuable milk. Rechtman et al.<sup>60</sup> tested three scenarios in the laboratory and the effect on the bioburden and nutritional content. Microbial analysis showed that breast milk that had been frozen at -20°C and then thawed did not develop a microbial load approaching 10<sup>4</sup> CFU/mL, which is the acceptable limit for raw unpasteurized milk. Similar results were found when the milk was stored at 23°C (room temperature) for 8 hours, or had undergone repeated freeze-thaw cycles (see Table 21-4 and Figure 21-6). The authors<sup>60</sup> point out that human milk is robust. Milk left unrefrigerated for less than 8 hours, or in a refrigerator for a day, maintains its nutrient value. Analysis of vitamin content and free fatty acids showed only slight changes. Unpasteurized milk that has been accidentally thawed and left in the refrigerator remains safe and can be refrozen. Fresh milk can be safely added to frozen milk by the mother at home.

**Figure 21-6.** Bacterial growth at 3.5 hours.

## NUTRITIONAL CONSEQUENCES

Initially, the focus in processing human milk was the effect on its unique antiinfective properties,<sup>28,33</sup> but attention has been given to the nutritional consequences as well.<sup>63</sup> Storage for 24 hours did not affect vitamin A, zinc, iron, copper, sodium, or protein nitrogen concentrations at  $37^{\circ}\text{C}$ .<sup>71,83</sup> Ascorbic acid levels decreased greatly when stored at 37 and  $4^{\circ}\text{C}$  at 24 and 48 hours. (They remained stable for 4 hours.) Other investigators have found that ascorbic acid levels drop 40% with heating.<sup>25,71</sup>

Levels of unsaturated fatty acids apparently are also affected by heating and cold storage, but the data need clarification.<sup>51</sup> It is anticipated that heating or freezing and thawing are capable of damaging membranes surrounding milk fat globules.<sup>65</sup> The fat globule could then undergo fragmentation and allow greater access of milk lipases to triglycerides. The percentages of polyunsaturated fatty

acids, linoleic (C18:2) and linolenate (C18:3), decreased after both heating and freezing, but monounsaturated and saturated fatty acids were unaffected.<sup>79</sup> When milk is stored at  $-11^{\circ}\text{C}$  for 48 hours, release of fatty acids progresses over time with an increase in the proportion of free C18:2, C20:4, and other long-chain polyenic acids. No measurable lipolysis occurred when milk was stored at  $-70^{\circ}\text{C}$ . The higher the temperature and the longer the time, the greater is the accumulation of free fatty acids.<sup>39</sup> Other investigators have confirmed this, concluding that the lipoprotein lipase and bile salt-stimulated lipase remain fully active at  $-20^{\circ}\text{C}$ , but not  $-70^{\circ}\text{C}$ , with or without the presence of serum. Berkow et al.<sup>6</sup> therefore recommend that milk be stored at  $-70^{\circ}\text{C}$ . Other enzymes were not affected by freezing and storing except lactoperoxidase, which lost activity (Tables 21-10 and 21-11).

Freezing at -80°C significantly decreases the energy content of human milk both from fat and carbohydrate. Thus -80°C is not recommended for long-term storage.<sup>42</sup>

Because the nourishment of low-birth-weight (LBW) infants has been the purpose of many milk banks, the ability of preterm infants to utilize treated bank milk is relative. Pasteurization at 62.5°C for 30 minutes was reported not to influence nitrogen absorption or retention in LBW infants.<sup>63</sup> When raw, pasteurized, and boiled human milks were fed to very LBW (VLBW) (less than 1.3 kg) preterm infants in three separate consecutive weeks, fat absorption was reduced by one third in the heat-treated group. There was a reduction in the amount of nitrogen retained in the heat-treated group, as well, although the absorption was unaffected. The absorption and retention of calcium, phosphorus, and sodium were unaffected by heating or freezing. The mean weight gain was one third greater when the infants were fed raw human milk.<sup>83</sup>

Pasteurization decreased vitamin B<sub>12</sub> by approximately 50% and folate-binding capacity by 10%<sup>48</sup> (see Table 21-11). Sterilization (100°C for

20 minutes), on the other hand, had similar effects on vitamin B<sub>12</sub> binding and completely inactivated folate binding.<sup>53</sup> Vitamins A, D, E, B<sub>2</sub>, and B<sub>6</sub>, choline, niacin, and pantothenic acid were barely affected by pasteurization, whereas thiamine was reduced up to 25%, biotin up to 10%, and vitamin C up to 35%.<sup>80</sup>

Refrigeration at 4 to 6°C for 72 hours allows little bacterial growth and causes no change in nutrients or infection-protective properties. Freezing does have some effect on both, and the milk can be kept for months, whereas heating has significant effect, and the milk still requires freezing for storage. Quick freezing and frozen storage do not significantly affect levels of biotin, niacin, folic acid, vitamin E, and the fat-soluble vitamins. Photooxidation and absorption by the container or tubing are always a consideration. Vitamin C is reduced by both these processes.<sup>23</sup>

The effect of heating and freezing on the various constituents of human milk has been studied by a number of investigators. Their data should be considered before deciding how to store milk for special purposes, such as sick or premature infants.<sup>64</sup>

## ANALYSIS

Routine analysis of the nutrient value of milk samples has been considered not practical, so gross screening by creamatocrit has been done by some banks and nurseries. A method of infrared analysis using a Milko-Scan 104 Infrared Analyzer (A/S Foss Electric, Hillerod, Denmark) has been described by Michaelsen et al.<sup>50</sup> It is simpler and more rapid than previous methods. These investigators in Denmark found a linear correlation between infrared results and the standard reference methods of Kjeldahl for nitrogen (protein), Roese Gottlieb for fat, and bomb calorimetry for energy. These techniques were used on all incoming milk, and on the outgoing pooled milk in banks in Denmark.

All the milk from the same mother was thawed, pooled, and stirred vigorously on arrival at the bank. A 10-mL sample was taken and stored at -5°C until analysis. Samples were collected every 2 weeks and were analyzed up to 2 to 3 weeks after expression. For the 2554 collections of milk contributed by 224 women, the mean protein content was 9 g/L and the fat was 39 g/L. The greater the body mass index of the mother, the greater was the protein and fat content.

The authors suggest that by selecting the milk with the highest protein content (12 g/L), a high-protein milk can be created with a higher energy content (725 kcal/L) for use in VLBW infants. Furthermore, they recommend pooling milk from up to five mothers to decrease the variability in nutrient levels.<sup>50</sup>

The product available from Prolacta Bioscience is labeled by both caloric content and protein content. Neo20 contains 20 cal/oz and 1.2 g of protein per 100 mL. Prolact20 also contains 20 cal/oz and 1.2 g protein/100 mL, as well as essential minerals. Prolacta Bioscience has also produced a human milk fortifier (Prolact + H<sup>2</sup>MF) that contains only human milk. Nutritional constituents are provided on the label. This allows fortification of mother's milk or donor milk to meet the growth needs of VLBW infants using a human milk product. Ross Laboratory and Mead Johnson products called human milk fortifier (a misnomer) are made solely of bovine products.

At the Hvidovre Milk Bank in Copenhagen, monitoring of the macronutrients in donor milk is part of the bank's quality assurance standards. Donors are discontinued if their milk protein content becomes less than 8 g/L. Their milk was viewed as adequate for their own baby but not for high-risk infants, especially premature infants.

## CREAMATOCRIT

Testing milk for protein, fat, and carbohydrate has not been done by most banks. However, Lucas et al.<sup>44</sup> have suggested a quick method of analysis. It involves standard hematocrit microtubes and a centrifuge. The percentage of cream, or "creamatocrit," is read from the capillary tube. Fat and energy content have a linear relationship, as follows:

$$\text{Fat (g/L)} = \frac{\text{Creamatocrit [\%]} - 0.59}{0.146}$$

$$\text{kcal/L} = 290 + (66.8 \times \text{Creamatocrit [\%]})$$

Accuracy is within 10%.

The Research Institute for Health Sciences provides the following formula for calculating the fat and energy content of milk, using the measurement of the creamatocrit (%):<sup>59</sup>

$$\text{Fat (g/L)} = (6.24 \times \text{Creamatocrit [\%]}) - 3.08$$

$$[r = 0.98, 95\% \text{ confidence limit} = \pm 4.39 \text{ g/L}]$$

$$\text{kcal/dL} = (5.57 \times \text{Creamatocrit [\%]}) + 45.13$$

$$[r = 0.92, 95\% \text{ confidence limit} = \pm 12.61 \text{ kcal/dL}]$$

Studies done comparing energy value calculated by creamatocrit with energy value from percentage of carbon, as measured by Manchester bomb calorimeter using pooled pasteurized milk samples, were somewhat inaccurate compared with data obtained by creamatocrit on fresh or fresh-frozen samples.<sup>65</sup>

The methodology was validated with further analysis by Lemons et al.,<sup>41</sup> who repeated the studies and confirmed actual measurements of total fat and caloric content. Because the protein and lactose

content remains relatively constant over time, the variation in fat content is the primary constituent affecting caloric value of the milk. Neither freezing for up to 2 months, nor pasteurization, affected the creamatocrit. There was no evidence of fat globule degradation during storage that affected the test.

Special cautions while performing this simple test should include the following:

- Use a representative, well-mixed sample.
- Complete a sample of pumping from at least one breast; do not take just a spot sample.
- Use a well-mixed 24-hour sample.
- Use a tube at least three fourths filled, seal one end.
- Centrifuge for 15 minutes in standard table-top centrifuge.

A new technology, the Creamatocrit Plus, has been reported by Meier et al.<sup>49</sup> The device is a special centrifuge that spins and calculates the creamatocrit. It automatically calculates the fat and calorie content. This device has been in use in research and in NICUs. Its accuracy was compared with the standard laboratory centrifuge with a hematocrit reader, and the standard laboratory centrifuge with digital calipers, utilizing 36 milk specimens from 12 women. The results varied less than 1% from each other. Laboratory measurements for lipids and calories were confirmatory.<sup>49</sup> NICUs that use mother's milk can easily check the content of a mother's milk with this device. Human milk fortifier derived solely from human milk (Prolact + H<sup>2</sup>MF) and HM-derived cream (Prolact CR™) were combined with mother's milk and fed via feeding tube to premature infants in continuous enteral feedings. This mixture avoided the loss of fat and micronutrients and resulted in the benefits of bioactive elements from mother's milk and increased fat delivery. It improved infant weight gain.<sup>72</sup>

## ULTRASONIC HOMOGENIZATION

Pooling specimens of human milk may not result in a milk of uniform fat content after storage. The separation of fat during processing, storage, and administration by continuous nasogastric infusion, whether by gravity flow or continuous mechanical pump, results in significant loss of fat and variation in the milk received (47.4% of fat with slow infusion and 16.8% with fast infusion).

Homogenization by ultrasonic treatment was studied by Martinez et al.,<sup>45</sup> who found that changes in fat concentration during infusion and loss of fat during administration, caused by the fat sticking to the container and tubes, were eliminated. Furthermore, the fat-soluble vitamins are preserved. Because 31% of iron, 15% of copper, 12% of zinc, 10% of calcium, and 2% of magnesium

sulfate are in the fat fraction of both human and cow milk, preserving the fat is essential to maximizing nutrient intake from human milk, especially in compromised infants. Tube feedings have been noted to reduce vitamins B<sub>2</sub>, B<sub>6</sub>, A, and C in human milk.

Ultrasonic homogenization was accomplished in this study by subjecting the milk to treatment in a Tekmar Sonic Disruptor TSD-P 250 (Tekmar Co., Cincinnati, Ohio). The homogenization time (2, 4, or 8 minutes) is a function of the volume of milk and intensity of vibration. The procedure should be done with milk in an ice bath. It has not been tested to determine the amount of lipase, if any, that survives pasteurization and would be capable of digesting the fat after homogenizing.

## MICROWAVE EFFECTS

Milk should be thawed in the refrigerator, and each bottle should be used completely within 24 hours. Defrosting in the microwave oven may lead to separation of layers, and microwaves decrease vitamin C content. The greatest danger of microwaving is that the milk heats and the container does not, so an infant could be burned or the milk significantly overheated.

The effects of microwave radiation on human milk have been much debated. The only nutritional effect identified has been the lowering of the vitamin C level. Lysozyme activity, total IgA, and specific IgA to *E. coli* serotypes 01, 04, and 06 were tested in 22 freshly frozen milk samples before and after heating for 30 seconds at low-power and high-power settings of the microwave oven.<sup>59</sup> Additional samples were tested at low (20 to 25°C), medium (60 to 70°C), and high (98°C or higher) microwave powers, before the addition of *E. coli*

suspension. Microwaving at high temperatures (72 to 98°C) greatly decreased all the tested anti-infective factors (Table 21-12). *E. coli* growth at 98°C or higher was 18 times that of untreated thawed human milk. Low temperatures did not affect total IgA or specific IgA to *E. coli* serotypes 01 and 04 or specific IgA to *E. coli* serotype 06. At only 20 to 25°C, the growth of *E. coli* was five times that of the untreated thawed milk.<sup>59</sup>

In the experimental laboratories, the microwaves are carefully controlled. In the home, they vary tremendously. Ovesen et al.<sup>56</sup> admitted that the temperature had to stay under 60°C (140°F). Above that, antibodies were decreased and at 77°C (170°F), they were totally destroyed. Vitamins B<sub>1</sub> and E were apparently stable, but they did not test for vitamin C. It is very clear that IgA, secretory IgA, and lysozyme were affected by microwaving at 14 to 25°C (i.e., lower temperatures). Time is important because even at 30% power the temperature will increase over time.

Microwaving clearly interferes with the antiinfective properties of human milk—the higher the temperature, the greater the effect (Table 21-13)—and is not appropriate for heating human milk.

## SPECIALTY MILKS

New technologies offer the potential for providing specialty milks. Simple homogenization would preserve the fat, as noted. However, because of the presence of active enzymes, once the fat membrane is ruptured by homogenization, the milk should be used promptly to prevent excessive fat breakdown. Lyophilization, or freeze drying, is an opportunity to concentrate the nutrients without increasing the volume. Adding a freeze-dried aliquot to liquid human milk is preferable to using the commercial

**TABLE 21-12** Impact of Microwaving on Antiinfective Factors in Human Milk\*

bovine-based products. Such a human milk product is available from Prolacta. In Denmark, infrared analysis of milk donations is used to provide high-protein or high-fat pools of milk. In Canada and the United States, some banks identify donors with dairy-free diets for specific infants with bovine protein allergies.<sup>1–3</sup> Gluten free milk from mothers on gluten free diets is available. Fat free milk can be prepared from a mother's own milk by NICU staff for an infant with chylothorax that does not need pasteurization. It is described in Chapter 14.

## CONTAMINATION WITH COW MILK

Donor milk is at risk for being contaminated with cow milk by the donor. The California Mother's Milk Bank checks its contributions with a simple test directed at precipitating the casein. It mixes 1 mL of donor milk with 1 mL of 8 N sulfuric acid and 8 mL of water, and lets it sit at room temperature for 5 hours. If cow milk is present, it will precipitate.<sup>54</sup> Human milk makes a floccular curd. A quicker, more accurate method is to check the DNA of the sample to match the donor. This is done by both Medolac and Prolacta.

## SOUR MILK FOLLOWING STORAGE

For decades, women have reported to the Lactation Study Center that their fresh-frozen breast milk smells sour, and even rancid. When thawed, it is rejected by their infant. Although a slightly soapy odor had sometimes been noted, it had never been reported to be harmful or to be rejected by the infant. This soapy smell has been attributed to a change in the lipid structure associated with the freeze-thaw effects of the self-defrost cycle in the freezer-refrigerator.

The cases reported to the Center, however, have suggested true lipid breakdown is associated with the rancid smell. The speculation first suggested in

the first edition in 1979 was that some women have more lipase activity than others, as noted in the study of lipase and hyperbilirubinemia. Some mothers reported that their milk began to smell as soon as it cooled, whether refrigerated or frozen. Others have noted that their stockpile of milk, meticulously stored in anticipation of returning to work, was rancid and rejected by their infants when thawed months later. When these mothers heated their milk to a scald (not boiling) immediately after collection and then quickly cooled and froze it, the effect was not apparent, and their infants accepted the heat-treated milk. That process, it was speculated, inactivated the lipase and halted the process of fat digestion. On the other hand, scalding rancid milk will not improve the flavor or smell. Scalding does not work for all mothers. A few mothers have noted improvement when they lowered the pressure and speed of the pump. This is also noted in the bovine literature.

In the over 4 decades since the first thoughts about sour milk were published, many women have experienced the devastation of discovering they had stored quarts and quarts of sour milk. Some women found scalding helped prevent souring. But no studies were done predominately because no investigator could accumulate enough samples to study lipase levels. This problem was solved thanks to the wise thinking of the Medolac Bank leadership. Medolac had received thousands of donor milk samples and, in the screening process, identified some that were sour. They separated the sour milk samples out, kept them frozen, and shared them with the Lactation Study Center at the University of Rochester. Analysis of lipase activity, fatty acids, and pH were done. The samples had already been cultured at Medolac, and no samples had excessive growth, or any species except skin flora. Cultures were unremarkable.

Lipase levels were compared with levels in known normal milk samples. Lipase in the sour milk was half that of the normal samples, not increased. Lactic acid was increased and lactate was low or unmeasurable, similar to the normal samples. This was reported by the Academy of Breastfeeding Medicine meetings in Los Angeles, California, in October, 2015. Further studies are underway at the Lactation Study Center. The cause of the souring or human milk is still unconfirmed.

## FINANCIAL ASPECTS OF BANKING

Established milk banks have various financial structures.<sup>3</sup> Charges can include fees for equipment rental and for processing milk. Certainly a hospital should recover costs of collecting and processing. Precedent for this has been set in the United States. Because some states have passed legislation mandating the availability of human milk for all babies

who need it, reimbursement and funds must be available for its proper handling.

All banks have a minimal charge that partially covers the costs of processing, such as labor, equipment, and supplies. The largest cost is shipping it frozen overnight. As with blood banks, the recipient is not charged for the milk itself. Third-party payers do reimburse for this, and Women, Infants, and Children (WIC) programs also provide this reimbursement in more and more states.

The recommendations from the State of New York suggest that the monitoring of standards of a hospital-based bank be absorbed into existing hospital surveillance. New York State has not approved a bank in the state, however one should be approved by the end of 2015. Freestanding banks would be monitored by the state and local health departments. Economic analysis indicates that the primary costs would be administrative overhead costs. Also acknowledged are staff costs, minimal equipment costs, and laboratory costs, as well as costs to the state health department to administer the system. Much consideration is being given to limiting banks to hospital settings, where health professionals and equipment are readily available, and quality control is part of the system.

The average processing fee charged by milk banks in the United States begins over \$4.00 per ounce, although it does not totally cover costs.<sup>3</sup> No infant is refused access for lack of funds, and milk banks cover their costs by various methods, including donations, subsidies, and grants. With proper physician orders and paperwork, most third-party payers cover the cost of banked human milk. The cost of milk from Prolacta Bioscience is higher, but it only covers costs of operation and preparation. They provide information about the milk (calories, protein, fat, etc.). Prolacta makes a supplement to add to mother's milk that contains additional protein and fat from human milk. The supplement made by formula companies is made from bovine milk. The bovine-based supplement made by formula companies carries a significant charge.

Costs of necrotizing enterocolitis (NEC) and the cost-effectiveness of exclusively human milk-based products in feeding extremely premature infants were determined by Ganapathy et al.<sup>24</sup> NEC is costly in terms of medical needs and increased length of stay in the hospital. When costs were calculated for infants receiving bovine supplement, compared to the cost of caring for infants who do not get NEC, there was a huge saving. The cost of patients without NEC averaged \$74,000, and with NEC \$236,000. The cost of bovine supplement was \$1.30 per packet. The cost of human milk supplement was \$6.25 per mL. The calculated saving per infant given human milk was over \$8000. Cost ignores the benefit of avoiding the lifelong burden of NEC.

While banks in North America, HMBANA, and parts of Europe have been not-for-profit and do not pay the donors for their milk, historically that has not always been true. For hundreds of years, when the need for human milk was a life-or-death matter, donors (called wet nurses) were given room and board for themselves and their infant, or some other "pay." British royalty always hired women to take care of the offspring. When the child was young enough to be breastfed, one attendant would be labeled the dry nurse; the breastfeeding nurse was the wet nurse. They were employees. Recently, the Mother's Milk Cooperative was organized in Michigan, the state best known for cooperatives organized for various purposes by official legal documentaries and co-op lawyers. Co-ops are owned by the members. The Mother's Milk Co-op is owned by the donors, and the donors make the decisions. Donors receive pay for their milk, which they can keep or turn into the co-op pool. Most mothers are able to earn enough money so they can stay home with their infants instead of going back to work.

The science of milk banking has been advanced in recent years. Prolacta was designed in California and funded by venture capitalists who wanted to improve the science behind this priceless commodity, human milk. Prolacta has developed the best pasteurization program that preserves the most nutrients and antiinfective properties. They have designed a human milk supplement made entirely of human milk. The calories and nutrients of all their products are on the label. The milk costs more than HMBANA, but it is sterile and quality controlled.

Medolac, a newer company, has developed a product of human milk that is made entirely of human milk, is sterile, shelf stable for over a year, and does not need to be frozen or refrigerated. The constituents are on the label. It is cheaper than frozen products and has been approved by the FDA. Medolac pays the Mother's Milk Co-op for the milk it purchases.

Minimum requirements for human milk prepared for fragile premature infants include that it must be sterile and have standard calories and nutrients.

## Breast-Pumping Equipment

Breast pumps have assumed an undeserved prominence in breastfeeding management in the last decade. Stimulated by the need to return to work for some women, but also by promotion by lactation professionals, the rise has persisted. Sadly, lactation professionals may also sell or rent this equipment that they recommend as necessary, thus setting up an egregious conflict of interest. Not all women need a pump. For thousands of years,

women breastfed successfully without a pump. For everyday problems like engorgement or a plugged duct, a mother can use her hands. Every mother should be trained in how to manually express her breasts before she leaves the hospital. Even before a pump is applied, the breast should be massaged and milk gently expressed. This approach reduces trauma and enhances the let-down reflex. Breast pumps are medical devices. They have multiple roles, including relieving engorgement, stimulating and increasing milk production, collecting milk for a sick infant who cannot nurse, or providing donor milk to a milk bank. The FDA regulates breast pumps. It monitors the performance of medical devices by several pathways, including mandatory reporting programs and a passive surveillance system that receives reports on adverse events and product problems. FDA databases list FDA-cleared breast pumps, characterize adverse breast pump events, and identify any FDA-initiated or manufacturer pump recalls. The medical device reporting regulation requires reporting of significant medical device-related adverse events by manufacturers, importers, and users. Examples of a significant event are device-related deaths, serious injury, and malfunction. All reports are entered into the Manufacturer and User Facility Device Experience database, which dates back to 1991. Two medical device epidemiologists at the FDA have reported on the events listed in FDA databases, along with an independent epidemiologist from the University of Michigan and a nurse consultant at the FDA, who reviews postmarked adverse events. The FDA recorded 37 reports between 1992 and 2003; 81% were for electric or battery-powered pumps. Tables 21-14 and 21-15 record the pump type and adverse events. Most reports were for device malfunction, which means failure of the device to meet specifications. Table 21-16 is a brief summary of five incidents reported to the FDA. The patient problems were predominantly pain, soreness, discomfort, and tissue damage from the electric pump. The most common problems for the manual pump were tissue damage and infection. The authors point out the importance of reporting such events to the FDA so that the problems can be corrected. The FDA toll free number is 1-888-463-6332. The website for Med-Watch is <http://www.fda.gov/Safety/MedWatch> (Accessed 30 April 2015).

As noted earlier, several types of breast-pumping devices have provoked questions concerning the sterility of milk collected. Additional issues need to be considered, including efficiency, ease of use, potential for breast trauma, availability, and cost. A good pump should be capable of completely emptying the breast and of stimulating production. It should be clean and easy to keep clean, contamination free, easy to use, and atraumatic.

## HAND PUMPS

The "bicycle horn" pump has been marketed in drugstores for years without instructions for use or cleaning. At the museum at the Corning Glass Works in Corning, New York, a glass and rubber hand pump made by Davol (circa 1830) is on display next to glass baby bottles and pewter nipples. The current model is the same, except the glass has

**TABLE 21-16** Examples of Medical Device Reports Submitted to the United States Food and Drug Administration and Retrieved from the Manufacturer and User Facility Device Experience Database

Case	Event Reported
1	This was reported for a manual breast pump by a consumer in January 2003. The pump was applied to the engorged breast to relieve pain and pressure. The suction created on the nipple tissue was so great that it pulled a clot to the surface. The action tore approximately one fourth of the nipple off, resulting in bleeding and leaving the breast susceptible to infection. The infection was treated with antibiotics; however, the nipple did not heal for 7 weeks and made successful breastfeeding nearly impossible.
2	This was reported for a manual breast pump by a health professional in January 1999. In late September 1998, in the NICU, a set of premature twins became ill. The organism, <i>Pseudomonas aeruginosa</i> , was isolated as the cause of their illness. Because this organism is easily spread and is life threatening to infants in a NICU, swift action was taken. These infants were placed in isolation, and more than 50 items in the NICU were cultured as the possible source of this organism. All these cultures were negative. The mother of the twins was aware of the seriousness of the situation and the actions we were taking to find the source. She reported that the tubing from her breast pump system always seemed to have liquid in it. She wondered if this could be the source. Immediately, the company (breast pump manufacturer) gave her another kit and sent her complete kit to the laboratory to be tested. The tubing, breast shield, and valve from the kit, in addition to her pumped breast milk, all grew <i>P. aeruginosa</i> . After another course of antibiotics and discontinuation of the previously pumped breast milk, the infection abated. In response to this incident, a committee composed of a neonatologist, infection control director, lactation consultant, and manager met to develop a strategy to prevent any further incidents. This group recommended that the manufacturer make changes to their breast pump system.
3	This was reported by a consumer for an electric breast pump in December 2000. The unit got stuck on the breast, and the suction release did not work.
4	This was reported for an electric breast pump in April 1999. When using this single-breast electric pump, the reporter experienced extreme pain. The suction was so much that even on the lowest setting, it hurt badly. The pump did not get enough milk, resulting in engorgement.
5	This was reported by a lactation consultant for an electric pump in October 1997. The mother had been using the breast pump for 24 to 48 hours when she began experiencing skin breakdown on her nipples. The breakdown resulted in wounds with bleeding, pain, two cracks on her right nipple, and four cracks on her left nipple. The wounds had since scabbed over. The mother sought medical advice from the lactation consultant who advised her to switch to a different barrier on her nipples. The lactation consultant claims this particular breast pump has a history of causing tissue damage. The device squeezes and pulls on the nipples, which leads to tissue damage.

NICU, Neonatal intensive care unit.

been replaced by plastic. The dangers of this pump are many. They can be summarized by saying the milk is contaminated, a spray of milk can go directly into the bulb, the pump requires constant emptying, and it can be quite traumatic to the nipple, areola, and breast and predispose women to mastitis.<sup>21</sup>

Modifications of the bicycle horn pump insert a removable collecting bottle in place of the well. The modification permits feeding the infant directly from the collecting vessel by placing a nipple on it. Milk does not wash back over the breast, and pumping is not interrupted for emptying. The bulb still may harbor bacteria because it is difficult to clean. The limitations of the effect of creating a simple vacuum and applying a simple, rigid, sharp-edged flange against the breast are still present. This pump is satisfactory for temporary use, but it takes time to become proficient in its use, and it may never create enough pressure to be effective. Another model (Nurture) with a special flexible silicone funnel overcomes some of these problems. The cylindrical pump is comprised of two all-plastic cylindrical tubes that fit inside one another to create a vacuum. A rigid flange at the top of the inner tube accommodates the nipple and areola. The flange also has a gasket for tight fit at the other end. The outer tube collects the milk and is adapted for use as a feeding unit when an artificial nipple is attached on top. The mother creates the vacuum by pulling the outer tube, and creates rhythm by alternately pushing the outer tube in and out (Figure 21-7). It is simple, easy to clean, and the milk is usable directly from the collecting cylinder with a nipple attached. This pump is excellent in the hands of an experienced, dexterous mother. The product

has several manufacturers, and models differ slightly. Some have a choice of flanges. The only precaution is that 220 mm Hg of negative pressure can be produced if the cylinder is drawn at least three quarters of the way out when empty or when there is fluid (pumped milk) in the cylinder. The pressure desired can be achieved by pulling out the cylinder only a fraction. Most cylinder pumps are marked by the manufacturer to indicate degree of a cycle.

## ELECTRIC MECHANICAL PUMPS

Battery-operated pumps are available, but they have all the disadvantages of most battery-operated devices. In most cases, they are not sufficiently powerful to stimulate the breast adequately. They are ineffective for women whose infants are not feeding at the breast, such as premature infants or those hospitalized in NICUs. These small hand pumps work for some fully lactating women and for those who have no trouble with volume but need a pump that fits in their purse for use while at work or school.

Small, purse-size electric pumps may be effective for the fully lactating woman (see Figure 21-5). They have an advantage over a manually powered hand pump, in that the electric power frees one hand for the mother to stroke the breast and encourage let-down. If flow is going well, the hand is free to perform other tasks, such as read, hold a telephone, or write, not an insignificant advantage for a busy, working, breastfeeding woman. Most small electric models have a small hole in the flange base that must be closed with a finger to develop the suction, as in many hospital suctioning devices. This also gives the mother control over the pressure. By rhythmically opening and closing the hole with the finger, the operator can simulate a milking action that is effective in extracting milk. The manufacturers, unfortunately, do not always point this out.

Hand-held mechanical devices may not be enough for a woman trying to build up a supply when the infant cannot stimulate the breast directly. A new mother may become discouraged at the low volume of her production and discontinue the process. Part of the management of a sick infant is to be sure that the mother's milk production is also progressing. Most hospitals provide a lactation consultant for lactating women with babies in the NICU, or have trained the unit's nursing staff to provide assistance. NICUs in the United States should provide a room with electric pumps for the mothers of infants in the NICU to learn how to pump their milk and breastfeed their infants. This is a key resource for any NICU because appropriate nourishment is key for the survival of infants in NICUs. Newly designed NICU's

Figure 21-7. Cylindric pump in use.

should have pumping resources beside the infant's isolette or warmer.

Full-size electric pumps are the most efficient, because the motor applies the mechanical effort. The mother can concentrate on applying the cup to her breast, massaging the breast, and relaxing so that adequate let-down can take place. All electric pumps are not equal, and some guidance is needed to be sure that the mother understands the principles involved. Nursery staff should be familiar with the equipment. The pumps are no challenge to skilled nurses in the NICU, who are adept at handling much more complicated electronic equipment.

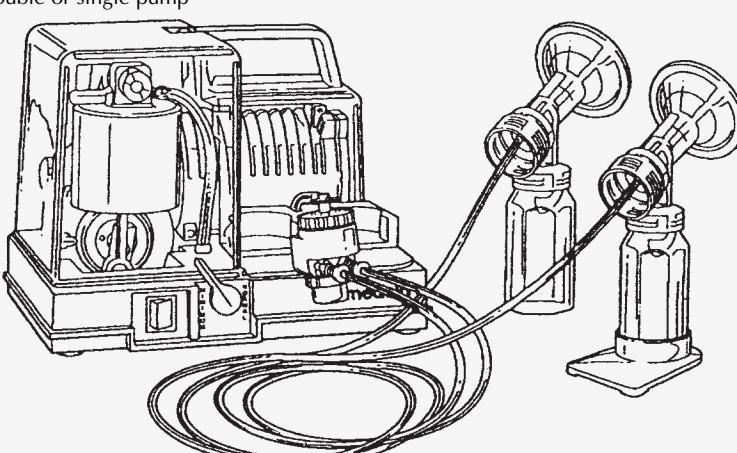

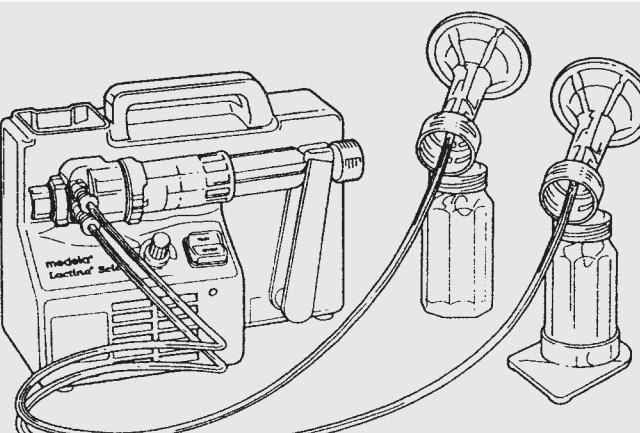

A pump that cycles pressure instead of maintaining constant negative pressure will be less likely to cause petechiae or internal trauma to the breast.

The ultimate effect of pressure also depends on the length of time the pressure is applied. Tissue cannot withstand sustained high pressure. Pressure sustained for 2 seconds or at a rate of 30 pumps per minute is considered maximum time or minimum rate.<sup>18</sup> Negative pressures should have a governing mechanism to avoid excessive pressures. Mean sucking pressures of most normal full-term infants range from  $-50$  to  $-155$  mm Hg/in $^2$ , with a maximum of  $-220$  mm Hg/in $^2$ . Manufacturers recommend about 200 mm Hg/in $^2$  to initiate flow in most women.

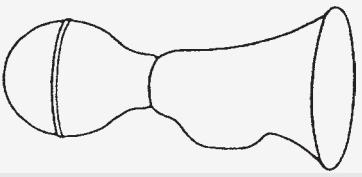

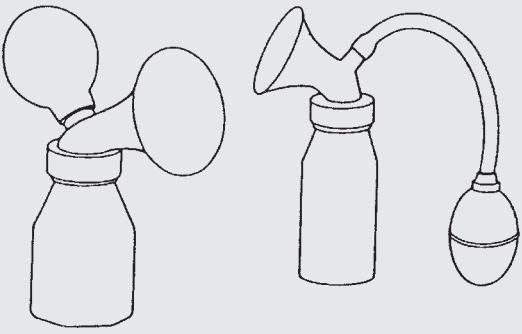

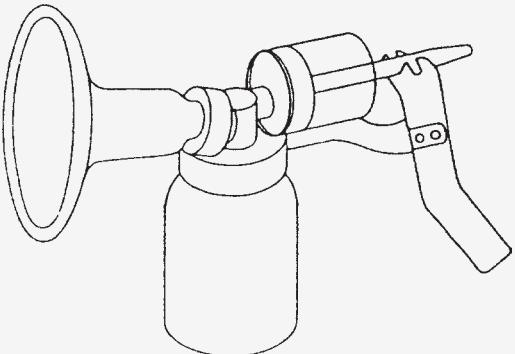

A careful study by Johnson<sup>35</sup> of more than 1000 patients at the University of Texas, using a variety of pumps, has confirmed some facts about pumps. The amount of negative pressure possible and the control mechanisms were recorded (Tables 21-17 to 21-19).

**TABLE 21-17** Electric Pumping Devices

Mechanical Pump	Advantages	Disadvantages
<b>Medela</b>  Classic electric breast pump Heavy duty for hospital use (available to rent)	Comfortable Automatic cycling Adjustable vacuum Double or single pump	
<b>Lactina Select electric breast pump</b>  Light, portable, economical		

**TABLE 21-18** Hand Pumping Devices

Hand Pump	Advantages	Disadvantages
Bicycle horn	Inexpensive Portable	 Difficult to clean Bulb retains bacteria Works as vacuum No instructions Can cause trauma Not appropriate for donor milk Milk washes back over nipple Requires constant emptying Not recommended
Evenflo	Inexpensive	 Difficult to clean Bulb harbors bacteria even when boiled
White River	Pliable flange Can feed baby from collecting container Works well for less experienced mother with good let-down No milk contacts mechanism	

An increasing number of pumps on the market have similar designs, but each has its special nuances. A standard electric pump capable of cycling pressures to 220 mm Hg (2.5 to 8.5 psi/Hg) is usually required to stimulate production *de novo* (that is, when an infant is unavailable to suckle directly, such as a small premature infant on a ventilator in the NICU). Breast pumps have been identified repeatedly for years as the source of infection.<sup>52</sup> Improvement in design, with a safety trap between the collecting vessel and the machine to prevent milk getting into the mechanism, is important. In addition, all equipment that

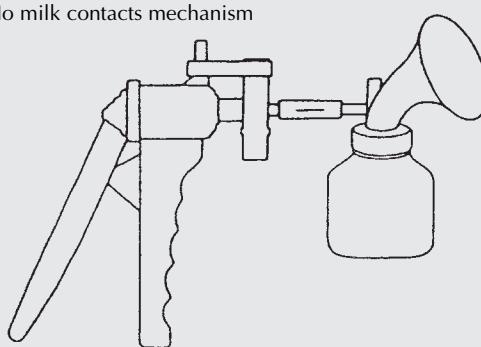

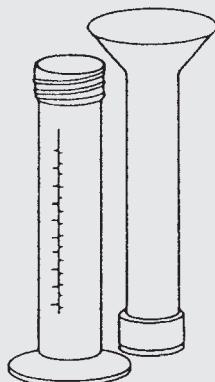

comes in contact with milk or the breast should be sterilizable or disposable. The well-designed electric pump properly used is the best system for stimulating lactation and increasing volume for hospitalized infants.

In the hospital, as with all special equipment, it is advisable to select the best equipment to fill the needs of that hospital, and then purchase more of the same model so that staff can learn how to use one model properly and can instruct the patient.

Similarly, the equipment should be checked on a routine basis, cleaned, and bacteriologically tested.

**TABLE 21-19** Hand Pumping Devices

Hand Pump	Advantages	Disadvantages
<b>Cylindric</b> Two all-plastic cylindric tubes fit inside one another to create vacuum; inner tube has flange at top and rubber or nylon gasket	Less expensive than electric Portable Can feed baby from collecting container Easily cleaned and sterilized	Requires some dexterity Works as vacuum with some rhythm Rigid flange Can achieve >220 mm Hg of pressure Must follow instructions
<b>Lloyd</b> Glass flange attached to collecting jar; trigger handle mechanism creates vacuum; has vacuum relief switch	Less expensive than electric Portable Can be cleaned No milk contacts mechanism	Handle difficult to squeeze Hand becomes cramped Awkward Large breast and nipple may hit flange Transfer of milk to feeding unit necessary

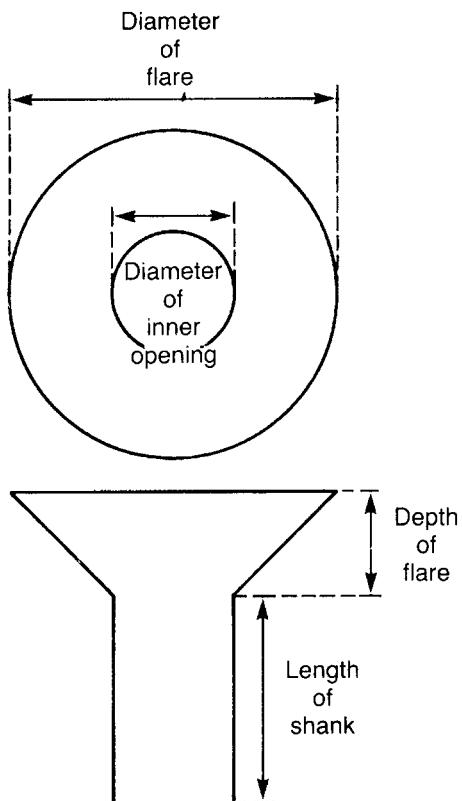

Accessory equipment (disposable) can be resterilized for the same patient but not for a second patient.

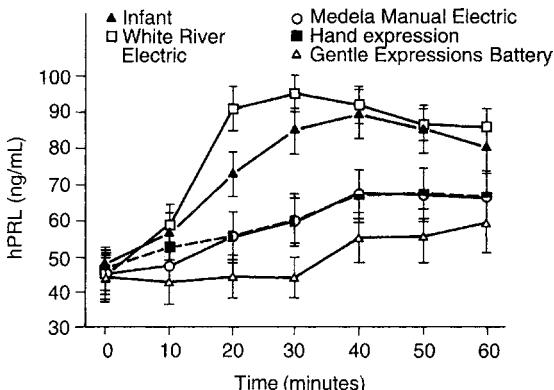

Although attention is usually given to the pressure mechanisms, the cup or flange that is applied to the breast is equally important. The diameter and depth of the flare are fixed for the hand pumps, but a choice is offered for the standard electric pumps (Figure 21-8). The nipple should have room to be drawn out, and the flange should be adequate to transmit pressure or milking action to the collecting ampullae under the areola. The hand pumps are too small, however, bigger is not always better. A mother may find that the smaller model of the two offered may be more physiologically suited to her anatomy. This feature does not correlate directly with overall size of the breast. The ideal range is 68- to 82-mm outer diameter and 35- to 40-mm

depth of flare (see Figure 21-8).<sup>33</sup> Silicone funnels adapt well to all sizes and shapes because of their flexibility. Study of type of pump, hand and electric, shows the difference in effect on prolactin production and milk volumes obtained. See Figures 21-9, 21-10, and 21-11 and Table 21-20.

The WIC branch of the Hawaii Department of Health studied whether an electric or a manual pump would increase breastfeeding duration for those women returning to work or school.<sup>32</sup> Of 246 women, 76.8% of women who used the manual pump (76 of 107) and 72.3% of those using the electric pump (94 of 139) breastfed for 6 months. The manual pump only pumped one breast at a time, so pumping took longer. The groups were matched for age, parity, ethnicity, and socioeconomic status. Contrary to most studies, the women with some college education breastfed for a shorter

Method	Mean Net AUC	SEM
Infant	224.7	75.4
White River Electric	174.1	41.3
Medela Manual	218.5	157.5
Hand expression	140.5	66.5
Gentle Expressions Battery	186.7	67.6

\*Levels of plasma oxytocin with breast stimulation calculated as mean net area under the curves (AUC) for each of the five methods for the 60-minute sampling session. No significant differences were noted.

From Zinaman M, Hughes V, Queenan JT, et al: Acute prolactin, oxytocin responses and milk yield to infant suckling and artificial methods of expression in lactating women, *Pediatrics* 89:437, 1992.

school were randomly assigned to use a novel (Embrace, Playtex, Westport, Conn) or a standard (pump-in-style, Medela, Baar, Switzerland) electric pump. Milk extraction was greater with the standard pump; 24-hour production did not differ. However, women were equally likely to select either of the two pumps.<sup>34</sup>

The universal availability of a double collecting system, so both breasts are "pumped" simultaneously, greatly enhances production and saves time.

Tables 21-21 and 21-22 provide data on expression and pump methods and logistic model factors.

To test the effect on milk ejection, an electric pump was programmed to cycle 45 to 125 times per minute with vacuums between 45 and 273 mm

Hg by the research laboratories of Hartman. The time it took for milk to be ejected was determined by ultrasound of the opposite breast measuring the dilation of lactiferous ducts. Ejection occurred between  $136 \pm 12$  and  $104 \pm 10$  seconds. This compares with ejection time when the infant suckles at  $56 \pm 4$  seconds. The vacuum affected the volume of milk, but not the time of ejection.<sup>38</sup>

When this same research group investigated means of assessing milk injection and breast milk flow, they measured milk flow rates while the mother pumped milk with an electric pump at different settings. They determined the milk duct diameter by ultrasound in the other breast simultaneously. They reported a direct relationship

**TABLE 21-21** Expression and Pumping Methods

Type	Action	Equipment	Availability
Hand expression	Hand action stimulates milk ejection reflex and compresses milk ducts	None	Universal
Hot jar (base cooled with cold cloth)	Cooling creates a vacuum so that the milk flows from breast (higher pressure) to the jar (lower pressure); suction pressure may be difficult to control	Suitable glass jar, hot water, cold water, cloth	Widespread
Manual pump: Compressing a bulb, pulling on two connected cylinders, or squeezing and releasing a handle	Negative pressure created by hand; arm action of the pump causes milk to flow from breast to pump; suction pressure may be difficult to control; some brands designed to reduce arm/hand fatigue; some work on a "draw and hold" principle rather than an even in-out action	Pump Cleaning supplies Most pumps have at least 3 parts One-handed pumps available and 2 pumps can be used for double pumping	Depends on market demand/distribution
Battery pump: Power provided by battery, manner of creating pressure may vary	Negative pressure at pump causes milk to flow from breast to pump; adjustable suction pressure and cycling time in some brands; some work on a "draw and hold" principle rather than even in-out action	Pump Batteries: New batteries may be needed after 2-4 hours use; some have AC adapters available Cleaning supplies Most pumps have at least 4 parts Most are hand-held so weight of pump plus milk may be a concern	Depends on market demand/distribution
Small pump: Electric, diaphragm	Negative pressure created by pump action of the pump causes milk to flow from breast to pump; adjustable suction pressure and cycling time in some brands	Pump Electricity supply Cleaning supplies Most pumps have many parts Two collection sets can be used for double pumping for most brands	Depends on market demand/distribution

*Continued*

**TABLE 21-21** Expression and Pumping Methods—cont'd

Type	Action	Equipment	Availability
Large electric: Piston pump, rotary vane pump, diaphragm pump; power may be provided by car battery or by foot treadle	Negative pressure created by action of the pump causes milk to flow from breast to pump; suction pressure may be difficult to control; some brands designed to reduce arm/hand fatigue; some work on a "draw and hold" principle rather than an even in-out action	Electricity supply or other power source Cleaning supplies Most pumps have 10 or more parts Two collection sets can be used	Depends on market demand/distribution; larger pumps generally purchased by hospitals or rental companies for loan to mothers

Note: Some brands of pump have a flexible breast cup that compresses the breast, and some have a choice of sizes of breast cup. Multiuser pumps require high-quality cleaning procedures and frequent servicing.

There is no one type of pump that is suitable for all mothers and all circumstances. To obtain quantities of milk by any method requires an effective milk ejection reflex.

Analysis was limited to those with complete data on the relevant questions.

\*Indicates statistical significance at the  $p<0.05$  level.

<sup>†</sup>Includes mothers with no other children and mothers with other children whom they did not breastfeed.

<sup>‡</sup>Hand expression was not a response option on the question that asked about the type of pump device used most often.

From Labiner-Wolfe J, Fein SB, Shealy KR, et al: Prevalence of breast milk expression and associated factors, *Pediatrics* 122: S63-S68, 2008.

between increases in duct diameter and increases in milk flow rates.<sup>59</sup>

Breast pump efficiency was studied by Hartmann et al.,<sup>31</sup> utilizing a procedure for objective determination of breast pump efficiency by measuring milk removal from one breast in a 5-minute period in 30 women using an electric breast pump (vacuum pattern of Medela Classic). They compared these data with breastfeeding characteristics. They determined each woman's breastfeeding characteristics by collecting milk samples before and after each feed from each breast, by either manual breast pump (Medela AG) or hand expression, by test weighing the infant, measuring degree of fullness, and direct measurement of breast volume, techniques standardized in their laboratory. The authors concluded that pump efficiency can be measured if maternal characteristics, and the amount of milk in the breast available to be expressed, are known. The proportion of available milk expressed varied greatly between mothers.

Investigators in this same laboratory looked at the impact of vacuum on volume of milk expressed. They looked at 23 mothers (two were expressing milk only and not feeding the infant), who expressed their milk for 15 minutes. The pumps were set at their own maximum comfort levels and then at lesser vacuum levels. The mother's maximum comfort level produced more milk than at lesser pressures. Milk flow was greatest at the onset, and cream level was highest at the end of the 15 minutes at maximum comfort level.<sup>36</sup> Milk output from the right and left breasts was compared in mothers who were exclusively pumping and had not fed their infants at the breast.<sup>18</sup> It was reported that differences between right and left breasts are common, with the right often more productive. The difference was not related to handedness, but was consistent through the day and over time.

Methods of milk expression for lactating women were reviewed for the Cochrane Collaboration by Becker et al.<sup>4</sup> They found 12 studies that met criteria, of which six could be utilized, involving 397 mothers. Compared with hand expression, a study found that a greater volume of milk could be collected utilizing an electric pump. Providing a relaxing tape to be played while pumping resulted in a greater volume of milk. Pumping both breasts simultaneously took less time, but no difference in total volume was found in this study. There was no difference in milk contamination, breastfeeding at hospital discharge, fat content of milk, or serum prolactin by method of pumping. No data were reported on maternal satisfaction, adverse effects, or economic advantages.<sup>4</sup>

A complete assessment of all the pumps readily available on the market and details about other equipment for breastfeeding are provided by the U.S. Food and Drug Administration website:

<http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures> (Accessed 30 April 2015). The information is extensive, including renting or buying, where to get, how to assemble, how to use and how to clean various pumps.

Information can also be found at company websites. In order to obtain unbiased information, one should seek online sources that are familiar with all the brands and are not also marketing a particular brand.

## CHAPTER 22

# Breastfeeding Support Groups and Community Resources

---

Certain changes in cultural aspects of Western civilization have contributed to the widespread use of artificial feedings for human infants as well as to the changing structure of the family. Urbanization has been associated not only with industrialization but also with the separation of generations. This has produced the nuclear family. Nuclear families are smaller, mobile, isolated families often stranded in a large urban population. In a nuclear family, a young couple and their new infant are totally without personal human resources. That is, no one cares enough to give individual support to the family. They have no one to turn to and from whom to receive advice, encouragement, and support.

### *Historical Perspective*

---

*Rites of passage* were described by the French author Van Gennep<sup>28</sup> as the ceremonies and rituals that mark special changes in people's lives. The list includes marriage, motherhood, birth, death, circumcision, graduation, ordination, and retirement. In our present culture, support exists for most of these events except birth and motherhood. The most critical rite of passage in a woman's life, Raphael<sup>22</sup> points out, is when she becomes a mother. Raphael further distinguishes this period of transition with the term *matrescence*, "to emphasize the mother and to focus on her new life-style." Traditional cultures herald a mother giving birth, whereas our culture announces the birth of an infant. The former highlights the mother, the latter the infant. Matrescence is a time of coddling. In preindustrial societies, a mother is coddled for some time after birth, having only the responsibility of the infant's

care while the mother's needs are met by doulas. Mothering the mother should be part of the postpartum support for a new mother.

A number of other forces added momentum to the bottle feeding trend that began in the 1920s, when manufacturers finally were able to mass produce an inexpensive container and rubber nipple with which to feed infants inexpensively. Pediatrics was a new specialty to guard the health of children. The focus was on measuring and calculating. Physicians seemed more secure when they could prescribe a measure of nutrition. The rise in the female labor force has also been credited with having an impact on the method of feeding infants, who were no longer taken everywhere with the mothers to be nursed but instead were left behind to be bottle fed. The technology of the infant food industry was a continuing influence on the nutritional thinking of both medical and lay groups.

Breastfeeding was never totally abandoned. Always groups of women prepared themselves for childbirth and read and researched feeding and nutrition and chose to breastfeed. In the mid-1940s, Dr. Edith Jackson began the Rooming-In Project at Yale University in New Haven, Connecticut. Families in New Haven who sought "childbirth without fear" and an opportunity to room-in with their infants usually chose to breastfeed. In the rooming-in unit, breastfeeding was often "contagious" because one mother successfully nursing would encourage others to try. Hospital stays averaged 5 to 7 days, during which time a mother-infant couple was cared for as a pair. More than 70% of the patients left this hospital breastfeeding. The national average at that time (1945 to 1955) was less than 25%.

Students and staff who were exposed to the philosophy of this unit went to many parts of the country, taking with them tremendous commitment to prepared childbirth and nurturing through breastfeeding. The classic article on the management of breastfeeding by Barnes et al.<sup>2</sup> was published as a result of counseling hundreds of nursing mothers. The students of Jackson inoculated many hundreds of hospitals and communities with a zeal for breastfeeding.

## *Development of Mother Support Groups*

The need remained for nuclear families to have access to support and conversation about healthy infants, mothering, and breastfeeding. The La Leche League, developed by a group of seven mothers to meet these needs, was established in Franklin Park, Illinois, in 1957. The original intent was to provide other nursing mothers with information, encouragement, and moral support. Thousands of local chapters and a network of 32,000 state and regional coordinators synchronized their activities with the headquarters in Schaumburg, Illinois. La Leche League International's (LLL) 4000 groups were in 66 countries, including the United States, Canada, parts of Europe, New Zealand, Africa, and other parts of the world.<sup>14</sup>

An excellent publication, *The Womanly Art of Breastfeeding*,<sup>14</sup> was prepared by the original group of mothers involved in the La Leche League. The League celebrated its fiftieth anniversary in Chicago in 2007 and published the eighth edition of this publication. La Leche League continues to provide information and updated publications about common questions that arise during lactation. Local groups offer classes to prepare mothers to breastfeed. They help with suggestions about the nitty-gritty details of preparation, nutrition, clothing, and mothering in general. They also provide every mother with a telephone counselor. To be qualified to serve as a counselor to another mother, a member must demonstrate knowledge and expertise in breastfeeding as well as an understanding of how to counsel and render support. "Telephone mothers" do not give medical advice and are instructed to tell a troubled mother to call her own physician for such advice. Interested local physicians provide medical expertise for the group when a medical opinion is appropriate. The league provides support for mothers to reduce the time the physician needs to spend counseling on the non-medical aspects of lactation. Most information needed by new mothers is not medical.

In the decades that this support system has been in place, no good substitute for this mother-to-mother program has evolved because a woman needs a true doula.

Similar programs have been developed in more than 70 other countries. A well-established and respected program in Norway is Ammehjelpen International Group; in Australia, the Nursing Mothers' Association of Australia; and in the United Kingdom, the National Childbirth Trust.

The group dynamics are important and feelings of normalcy are reinforced. The information and experience were shown to be important, but the support from the group had far greater influence on success in breastfeeding. Meara reports similar observations on league activities in a nonsupportive culture.

The Breastfeeding Association of South Africa is a nongovernmental, nonprofit, voluntary organization founded in 1978 by South Africans for the express needs of South African women. Their special problems and solutions are well described by Bergh.<sup>4</sup> Support groups for all life's events, especially those covering health, have become a common feature (more than 150 parent support groups exist). In the field of perinatal care, groups are available for infertile couples; couples who are expecting; those who have experienced pregnancy loss, loss of a premature infant, or loss of a term baby; those who had a cesarean delivery; and so on. Physicians should be aware of the groups that function in their communities and the policies and philosophies they embrace.

The International Childbirth Education Association also provides resources for a new family in many countries. Its program makes preparation and training available for couples during pregnancy and afterward as parents. Its scope embraces the entire childbirth concept, of which breastfeeding is part.

Adolescents need special support to improve the outcome of their pregnancies, to encourage them to breastfeed, and to establish the special relationship with, and commitment to, their infants. A study done in the Breastfeeding Educated and Supported Teen Club in Melbourne, Florida, looked at the impact of specific breastfeeding education provided by a lactation consultant in group classes. Teens were randomly assigned to the program or as a control; ethnicity and age were not significant factors. Of the 43 adolescents in the education group, 28 (65%) initiated breastfeeding, but of the 48 control subjects without education, only 7 (14.6%) initiated breastfeeding ( $p < 0.001$ ). The authors concluded that targeted education makes a difference in adolescents.<sup>29</sup>

When a similar study was performed involving low-income women, a community-based program

studied a hospital, home visit, and telephone support system provided by a community health nurse and a peer counselor for 6 months. After random assignment, those receiving intervention breastfed longer. The infants had fewer sick visits and use of medicines than the group with "standard care." The cost of the program per mother was \$301, which was offset by the savings on the cost of formula and health care.<sup>21</sup>

In another study, adult women without a personal breastfeeding support system at home were randomized to receive support or not. The support group received support in the hospital and at home from a practicing midwife in the community. She visited in the hospital daily and was available by pager continually. After discharge, she telephoned within 72 hours and then weekly for 4 weeks. At home, the participants had access to the midwife by phone and pager. One home visit was made the first week and then as necessary. In the supported group, 26 of 26 were still breastfeeding at 1 month, but only 17 of 25 (68%) in the unsupported group were breastfeeding, proving that intensive professional support works. The costs of the program were not provided.<sup>19</sup>

Active support outreach clearly affects the duration of breastfeeding and ultimately saves health care dollars. Such programs can be included in private practice.

## *Community Resources*

Most hospitals provide training in preparation for childbirth. Part of the program is about the new infant and how to plan for neonatal care. These programs often serve as the initial stimulus to consider breastfeeding. Many such programs are given by hospital-based lactation consultants.

When a large health maintenance organization looked at 5213 new mothers enrolled in a commercial managed care plan by telephone survey at 4 to 6 months postpartum, 75% had breastfed for some time. Of these, 75% breastfed for more than 6 weeks. Breastfeeding for more than 6 weeks was associated with level of education, employment status (part-time, 84%), and adequacy of postpartum information. Health plans and employers should consider promoting breastfeeding, concluded the authors.<sup>8</sup>

Because hospitals have become competitive and are marketing their services, many are developing birthing centers and are trying to capture the attention of the childbearing public with special services. These services often include classes on child rearing, including breastfeeding. Physicians should investigate the programs and printed materials distributed by the hospitals where their

patients deliver. Many pediatricians are coping with the flood of patient information from conflicting sources by printing up an office manual (desktop printers make this quite feasible). This is especially helpful if the patients give birth at more than one hospital or more than one lay advocacy group is active in the community. Hospital procedures and policies can influence the success or failure of breastfeeding mothers.<sup>26</sup> Pediatricians should be aware of the policies at the hospital(s) with which they are associated.

In a few short decades, we have gone from a paucity of support groups and resource literature to an overwhelming flood. Health care books and childbearing and family-rearing advice books are cascading off the presses, written by everyone from qualified experts to poorly informed freelance writers. Some are written by health care professionals who have personal experience in childbearing. Pediatricians should be familiar with a few good references for parents and provide a list for patients in the practice.

The Young Women's Christian Association (YWCA) in most communities may also provide preparation for childbirth. Its classes usually provide programming that appeals to young and unwed women, a group in need of services rarely provided by other sources.

The Visiting Nurses Association and the public health nurses on the staff of the local county health department are special resources particularly skilled at counseling new mothers with their infants. They can provide valuable information to the physician who is working with an infant who fails to thrive at the breast by witnessing the breastfeeding scene at home. As discharge from the hospital occurs earlier and earlier, pediatricians should consider employing nurse practitioners who are prepared to make house calls immediately after birth.

Many other organizations, local and national in scope, have the perinatal period and the family as their focus. Many of these are also interested in promoting breastfeeding as part of their overall goals.

The World Health Organization (WHO) and United Nations International Children's Education Fund (UNICEF) have joined an international effort to create a supportive atmosphere in hospitals around the world by developing the Baby Friendly Hospital Initiative (BFHI) (see Chapter 1). Both WHO and UNICEF provide international support for breastfeeding, especially in developing countries. The ten steps toward becoming a Baby Friendly Hospital are listed in Box 1-2 in Chapter 1.

The BFHI was designed originally to rid hospitals of their dependence on artificial infant formulas and to encourage the support of breastfeeding in these facilities. It is designed to create a supportive atmosphere with trained and knowledgeable staff.

The ten steps describe the essentials of the program. In 2009, the BFHI materials were revised by WHO. The program was expanded to integrate BFHI with the Global Strategy for Infant and Young Child Feeding. This revision included the expectation that staff be trained to provide support and education for mothers who were not breastfeeding. The 2009 update also included a review of labor and delivery practices. Step 4 has been extensively revised to promote skin-to-skin and the process of the infant finding the breast and latching on, immediately after delivery. BFHI expects that every infant will spend up to an hour accomplishing the first feeding while skin-to-skin with the mother.

Worldwide achievement of Baby Friendly Hospitals accreditation has been extensive. In the United States progress has been slow. The provision of millions of dollars in grant money has allowed many hospitals to train their staff and rebuild their programs to meet the 10 steps and achieve accreditation.

## GOVERNMENT ORGANIZATIONS

The United States government has taken an active interest in the promotion of breastfeeding as well. In the goals for national health prepared by a multidisciplinary task force in 1978, it is stated that by 1990, 75% of infants leaving the hospital shall be breastfed and at 6 months of age at least 35% will still be breastfeeding.<sup>20</sup> The rates in 1990 fell well short of the goals, and they were thus restated to be achieved by the year 2000, extending to 50% the number to still be breastfeeding at 5 to 6 months. The goals for 2010 included 75% breastfeeding at hospital discharge, 50% at 6 months, and at least 25% breastfeeding at 1 year. A midcourse correction indicated that 60% exclusive breastfeeding should continue for at least 3 months and exclusivity should continue for 6 months for 25%.<sup>20</sup> National statistics continue to fall short of predictions although the gap is shrinking.

The U.S. Office of the Surgeon General conducted a national workshop on breastfeeding and human lactation in Rochester, New York, in June 1984 to develop recommendations for national policy. A publication from the workshop was available from the U.S. Government Printing Office in Washington, District of Columbia. A follow-up workshop was held in Washington, District of Columbia in 1985, gathering the representatives of the major official national organizations for obstetrics, pediatrics, and family physicians, including the credentialing organizations for physicians, nurses, nurse midwives, and dietitians. The organizations responded to a request for each to approve a model statement in support of breastfeeding. This was accomplished by January 1987.

The organizations prepared a review of curriculum within their disciplines to ensure adequate education, training, and accreditation regarding human lactation and breastfeeding for their members. Although improvements have been made and certifying examinations have incorporated questions about breastfeeding and human lactation, curriculum development in most institutions has lagged behind. Available curricula to solve this problem have been developed by the AAP/ACOG and Wellstart.

Although C. Everett Koop, U.S. Surgeon General in the 1980s, maintained his commitment to breastfeeding, later Surgeons General did not. Twenty-five years to the day later, June 9, 2009, the Academy of Breastfeeding Medicine convened the first summit on breastfeeding in Washington, District of Columbia. Dr. Koop opened the meeting with a televised message, the same message he concluded with in 1984. The summit was directed at a different audience, not at breastfeeding zealots and supporters but the United States government and its many agencies and the health care and insurance industries. The purpose was to educate the participants on the value of breastfeeding and the necessity to support breastfeeding, including reimbursement for services provided to patients in hospitals and at home. Progress has been made. The Centers for Disease Control and Prevention (CDC), the Office of Women's Health, and the Surgeon General took action and have participated in collecting data, and changing programs. The sitting Surgeon General issued the first "call to action" charge.

The Office of Women's Health and others invested time, talent, and resources in the issues of maternal employment. Annual summits were convened, continuing to involve the government agencies, the health care industry, and insurance providers.

Six summits have been convened and the seventh will have been held in June 2015, sponsored and executed by the Academy of Breastfeeding Medicine. Most significant has been the generous grant support from the WW Kellogg Foundation from the very first summit. Not only did Kellogg fund the summits but the foundation has dedicated its grant resources to breastfeeding issues across the country. Kellogg now supports over 100 programs large and small. Nothing has done more to facilitate the progress of breastfeeding than the commitment of the Kellogg Foundation. The credit for this contact goes to the brilliant grant writing by ABM and the overwhelming support of Mary Ann Liebert Publishers, Inc.

During these 6 years of summits, much progress has occurred among minority groups who have formed their own organizations such as Mocha

Mothers and Black Mother's Breastfeeding Association. The Women, Infants, and Children (WIC) program has changed its policy to encourage breastfeeding and support breastfeeding mothers. Employers are supporting their lactating employees one company at a time.

Issues of rural health have begun to include those surrounding birth and the infant's welfare. Programs are being developed to increase breastfeeding among rural women. Although the incidence of breastfeeding has increased among well-educated, self-motivated, middle-class Americans, the number of impoverished, less well-educated women who breastfeed remains small. Progress is being made, community by community, by dedicated health care workers, dietitians, and WIC staff. Health professionals often serve as a catalyst in developing such programs but should always be ready to serve as knowledgeable, supportive consultants to the efforts of others.<sup>11</sup>

The U.S. Department of Agriculture's Supplemental Nutrition Program for Women, Infants, and Children (WIC) nutrition services provides supplemental nutrition and counseling to more than 50% of U.S. families with young children. There are large differences in rates of breastfeeding among the different racial groups in WIC. A study of services in North Carolina confirmed the racial/ethnic disparities in breastfeeding rates.<sup>9</sup>

The differences in availability of support services were also associated with racial/ethnic composition of the catchment area. These observations of disparity among services at WIC were also reported in an analysis of data from the Early Childhood Longitudinal Study-Birth Cohort. Breastfeeding duration was a result of cultural trends, not WIC programming. Multiple studies have done analysis outcomes at WIC sites. When the barriers to reaching the national goals for breastfeeding among the WIC population were counted, they were (1) lack of support in and outside the hospital; (2) returning to work; (3) practical issues; (4) WIC related issues; and (5) social, cultural barriers.<sup>12</sup> Issues included young age, non-Hispanic ethnicity, obesity, and depression.

Solutions that worked for local WIC programs have been peer counselors, breast pump programs, and discontinuing free formula at the hospital and by the WIC program. The major obstacle to WIC program success is budgetary. Nationally, WIC spends 25 times more money on formula than on breastfeeding initiatives.<sup>3</sup> The new food packages, however, implemented in the fall of 2009, have improved breastfeeding outcomes in Los Angeles County where exclusive breastfeeding rates at 3 and 6 months have doubled.<sup>13</sup>

The U.S. Department of Agriculture's breastfeeding program, through the WIC's Nutrition

Program, has launched a major effort to increase breastfeeding initiation and duration throughout the 50 states. The program, Best Start, included social marketing research, a media campaign, a staff support kit, a breastfeeding resource guide, a training conference, and continuing education and technical assistance. WIC has been made a permanent national health and nutrition program, and breastfeeding has been written into the legislation (see Chapter 1). The program even mandates that every WIC agency must have accommodations for employees who are breastfeeding their infants to pump and store their milk.<sup>25</sup>

## BEST START: THE CONCEPT OF SOCIAL MARKETING

Using the concept of social marketing, Bryant et al.<sup>5</sup> designed an approach to promoting breastfeeding that utilized the counseling strategies, educational materials, policies, and community-based activities that formed the Best Start Program. Social marketing "combines the principles of commercial marketing with health education to promote a socially beneficial idea, practice or product."<sup>4</sup> Typically a well-articulated program involves a combination of mass media, print materials, personal counseling, and community-based activities and services.

From these findings, a multifaceted breastfeeding promotion campaign was designed for new mothers, family members, health professionals, and the community at large. The Best Start Program proved to be extremely successful and has been replicated by others successfully.

Utilizing strategies developed in social marketing and segmentation modeling for health communication,<sup>17</sup> Best Start developed a multimedia program, Loving Support Makes Breastfeeding Work. This program was the substance of the WIC National Breastfeeding Promotion Project launched in April 1997.<sup>1,5</sup> Best Start has turned the program over to WIC for its continuation.

## THE UNITED STATES BREASTFEEDING COMMITTEE

In order to fulfill a mandate of the Innocenti Declaration signed in 1990 in Italy by representatives of 90 countries, including Audrey Nora, MD, Assistant Surgeon General of the United States, a group of interested breastfeeding supporters and advocates met in Florida in January 1996. The declaration states that each member country should have a national breastfeeding committee, and many countries have complied.

This small group of breastfeeding advocates met to discuss the need for coordination of

breastfeeding activities in the United States. After conducting an intensive needs assessment, the National Alliance for Breastfeeding Advocacy (NABA) was formed to address needs not being met by organizations, government agencies, or individuals, and convened the first National Breastfeeding Leadership Roundtable to determine if another organization was needed to move breastfeeding forward in this country.<sup>30</sup> Working on the international model, the formation of this committee, if successful, would satisfy one of the four operational targets set forth by the 1990 Innocenti Declaration. This was to establish a multisectoral, national breastfeeding committee composed of representatives from relevant government departments, nongovernmental organizations, and health professional associations in every country.

It was agreed at that meeting of 19 breastfeeding leaders to do four things: (1) to support ongoing breastfeeding projects in the United States; (2) to develop a strategic plan for breastfeeding in the United States; (3) to reorganize the National Breastfeeding Leadership Roundtable into the U.S. Breastfeeding Committee (USBC); and finally, (4) to incorporate the organization of the USBC and its leadership. The organization continued to meet twice a year and in January 1998 voted to declare itself, with the encouragement of Assistant Surgeon General Audrey Nora, MD, the USBC.

The USBC is a collaborative partnership of organizations. The mission of the committee is to protect, promote, and support breastfeeding in the United States. The USBC exists to assure the rightful place of breastfeeding in society. Major organizations that are members include but are not limited to the American College of Obstetricians and Gynecologists (ACOG), the American Academy of Pediatrics (AAP), the American Academy of Family Practice (AAFP), the LLLI, the International Lactation Consultant Association (ILCA), and Wellstart and the NABA. The National Institutes of Health (NIH), Maternal and Child Health Bureau of the Health Resources Division of the U.S. Department of Health and Human Services, Women's Health, the Food and Drug Administration (FDA), and the CDC also participated. After more than 10 years of developing its organizational skill and attracting more than 30 organizational members, it has assumed a vital role in national breastfeeding activity. It has organized coalitions in all states, has hosted coalition meetings to train state representatives, and provided a forum for sharing strategies among the members. USBC is an organization of organizations, not individuals. An important effort has been to create federal legislation to support breastfeeding women. The problems of employment for working mothers have been a major thrust that has resulted in cooperation of the summits in the development of the national program, the

**Business Case for Breastfeeding.** Because of the interdisciplinary nature of its membership as a forceful network, USBC has been developed to promote, protect, and support breastfeeding. The USBC's website is <http://www.usbreastfeeding.org>.

## WELLSTART INTERNATIONAL

A program to extend the scope of global breastfeeding promotion was launched by Wellstart International in a cooperative agreement with the U.S. Agency for International Development (AID). Wellstart International, a private, nonprofit organization headquartered in San Diego, grew out of clinical and teaching experiences at the University of California, San Diego Medical Center in the late 1970s.<sup>18</sup> In 1983, in response to a clear need to improve the breastfeeding knowledge of health professionals, a Lactation Management Education program was initiated with funding from AID. Almost 400 participants of the Lactation Management Education program now form a network of Wellstart Associates in 28 countries.

In late 1991, Wellstart joined in a cooperative agreement with AID to expand and diversify its global breastfeeding promotion activities.<sup>18</sup> The Expanded Promotion of Breastfeeding can work in any country at the request of the local AID mission. Wellstart continues to provide educational information for the training of physicians, nurses, and dietitians. Wellstart was active in global events as well.<sup>31</sup> These activities include the development of the "ten steps" for hospital care of the mother-baby dyad and the Innocenti Declarations of 1990 and 2005, the formation of the World Alliance for Breastfeeding Advocates, and the initiation of World Breastfeeding Week and the BFHI; Wellstart also and they served as one of the initial organizers of the USBC.

Other lactation centers were created in health care facilities. The purpose of these programs was to provide consultation services for mothers as well as education, training, and information for health care workers. Efforts have been made to change hospital policy regarding breastfeeding to increase the success rate. An impressive program was initiated in the Philippines. It has not only increased the incidence of breastfeeding but also lowered the morbidity rate from sepsis, diarrhea, and malnutrition. Breastfeeding programs now exist in many large cities in the United States and around the world.

## BREASTFEEDING AND HUMAN LACTATION STUDY CENTER

The Lactation Study Center of the University of Rochester School of Medicine and Dentistry in New York encourages and promotes human lactation and breastfeeding through physician education and

support. The goal is to provide information that will help practitioners encourage and support breastfeeding for all patients. Information is available to the health care professional by telephone. Originally federally funded and established at the request of the Office of the Surgeon General in 1984, the center now depends on private grants and donations from users. The drug information line operates Monday through Friday from 9 AM to 4 PM EST. Physician consultation is available by call back.

## *Lactation Consultants*

---

For years, many medical and nursing professionals have served as lactation consultants ready to respond to any colleague's request for knowledge and expertise. With the great national movement to embrace breastfeeding, however, a new type of lactation consultant has evolved from the vast pool of women who have served in local mother-to-mother programs to help others breastfeed. The health care professional needs to ensure that the lactation resources available in the community are truly of professional quality and background and that the individuals have obtained proper certification and licensure. Counseling on any topic is a special skill requiring more than personal experience with the situation.

The International Board of Lactation Consultant Examiners (IBLCE) was developed as a separate organization by the LLLI to credential individuals who want to counsel about breastfeeding.<sup>13</sup> Those who successfully complete the IBLCE certification process, which includes a written examination, are entitled to use the designation IBCLC (International Board Certified Lactation Consultant) after their names. The IBLCE has defined lactation consultants as "allied health care providers who possess the necessary skills, knowledge, and attitudes to facilitate breastfeeding." These lactation consultants perform as employees in some situations and as independent contractors in states where the medical practice act allows such activity. A lactation consultant should have professional liability insurance coverage and a license to practice in the health field in the state. Nurses, midwives, nurse practitioners, and dietitians are usual candidates. Some physicians have taken the examination.

The International Lactation Consultants Association stated, "A lactation consultant is a health care professional whose scope of practice is focused upon providing education and management to prevent and solve breastfeeding problems and to encourage a social environment that effectively supports the breastfeeding mother/infant dyad." The International Lactation Consultants Association has published Standards of Practice for Lactation Consultants, which are available in print and at the website ILCA.com.

## **LACTATION SPECIALIST AS MEMBER OF HEALTH CARE TEAM**

Modern medicine has developed a team approach to the management of many patient populations, such as elderly or handicapped persons.<sup>16</sup> A team approach also is used in the management of many categories of diseases, such as cancer and diabetes. A health care team provides medical service for the family during the perinatal period. This team includes an obstetrician and a pediatrician or a family physician; nurse midwives; nurses working in prenatal care, obstetrics, neonatal care, and public health; social workers; dietitians; and when a problem develops, perinatologists, neonatologists, and the skilled team from the perinatal center. These team members are well-educated and extensively trained professionals. Together they have lowered the morbidity and mortality rates of childbirth. The long-range prognosis for the intact survival of infants has been significantly improved.

Thus medical progress has occurred concomitantly with the isolation of the nuclear family. The result is a medically successful birth to a family poorly prepared emotionally and socially to cope. The family is inadequately prepared to take over when the mother and infant are discharged from the hospital and instantly placed on their own without a transitional period of adjustment with close support and supervision.

Lactation specialists become an important addition to the health care team, replacing the traditional family support system. Specialists not only must know their role as counselors interacting with the family, but also must understand how they interact with other members of the health care team. The professional team members are beginning to understand the importance of lactation specialists and how to work most effectively with them. Some physicians, however, provide a nurse practitioner, whose role is to fill that gap between medical care and family support. The nurse practitioner is usually skilled in well-baby care, especially breastfeeding, and in the era of early postpartum discharge home, may make house calls within 48 hours of arrival home.<sup>24</sup>

Lactation consultants quickly earn the respect of health care teams when they communicate openly with them, support mothers in a positive manner, and encourage a relationship of mutual trust and respect between the mothers and the teams.<sup>16</sup>

## *Peer Counseling*

---

Peer counseling is part of a system developed by health care providers and health educators to change personal health behavior.<sup>27</sup> It is an adaptation of a cultural technique that has been used for

generations wherein the family provided a personal advocate or ombudsman to help the individual carry out good health practices. In lay midwifery, for example, members of the group attend women throughout pregnancy, delivery, and the postpartum period. The important point is that the peer counselor is a member of the same sociocultural group as the recipient, is selected for leadership qualities and experience, and is trained in special issues.

Public health programs have used peer counselors to encourage women to seek prenatal care or well-child care for their children. Other programs have provided peer counselors for individuals with hypertension, diabetes, or other chronic diseases to help the patient access health care and carry out instructions for treatment. This concept has been applied to the WIC program.<sup>27</sup> A model program was developed in south Georgia in the mid-1980s by Wanda Grogan, PhD, and was effective in encouraging women to carry out health care advice, to keep appointments for health care, and appropriately to breastfeed their infants.<sup>28</sup> This system has been expanded to many parts of the country.

The most successful programs involve the peer counselor in all health issues so that the relationship between counselor and client continues. These peer programs are integrated with efforts to improve health habits in general and especially those associated with childbearing. The best programs train community counselors to support women through pregnancy, delivery, and early child rearing, of which breastfeeding is a part. This type of program encourages the development of a relationship that lasts several years.

Because the lowest incidence and duration of breastfeeding are among low-income women and among black mothers, a peer-support program among these clients has the highest probability of success.<sup>23</sup> Using the same model for training candidates that has been developed for other health projects has facilitated initiating the program. The local WIC program or health department is ideal for undertaking a peer-support program because the permanent, full-time staff are knowledgeable about nutrition and lactation and can provide continuity when peer counselors leave the program and new ones need training. This stability is essential to developing some consistency and permanency for the system. The WIC program supports women from early pregnancy through postpartum and early infancy periods.

Because a peer counselor is an individual from the social or cultural community who is selected because of good health behaviors and an innate ability to help others and gain respect, a peer counselor for breastfeeding is a respected member

of the community or neighborhood, is of the same or similar ethnic background and of similar educational and economic level, and has breastfed one or more children. The tremendous success of the La Leche League was based on peer counseling among well-educated, white, middle-class American women.

Some physician practices have employed (yes, peer counselors should be trained and paid) peer counselors successfully to take some of the roles of health care professionals who lack the time to relate on an even plane with a client of different educational or socioeconomic status. Well-established peer-counseling programs have even inspired the counselors to obtain further training as nurses' aides, licensed practical nurses, or registered nurses.

Peer-support programs have been developed in Britain and Canada.<sup>29</sup> In a randomized controlled trial of a telephone-based peer-support intervention, increased duration of breastfeeding and increased satisfaction with the experience were observed. Women valued the support of a counselor in another study in London and South Essex, but the impact on duration was not as dramatic, probably because mothers had to ask for help after discharge and were not routinely contacted.<sup>10</sup>

A peer counselor will complement the work of the health professionals but should never replace the role of the health care provider (*Table 22-1*).

A woman was more likely to initiate breastfeeding if she had a WIC peer counselor contact her before delivery and was more likely to continue breastfeeding with peer counselor support postpartum in a study of at-risk women enrolled in WIC in Texas.<sup>6</sup> A review of peer counseling publications to evaluate the effectiveness of breastfeeding peer counseling showed overwhelmingly improved rates of breastfeeding initiation, duration, and exclusivity. Secondary gains included a decreased incidence of infant diarrhea and a significant increase in the duration of lactational amenorrhea. These results were reported from both developed and underdeveloped countries. From these findings, a multifaceted breastfeeding promotion campaign was designed for new mothers, family members, health professionals, and the community at large. The Best Start Program proved to be extremely successful and has been replicated by others successfully.

The effectiveness of breastfeeding peer counseling has been shown by secondary gains including a decreased incidence of infant diarrhea and a significant increase in the duration of lactational amenorrhea. These results were reported from both developed and underdeveloped countries.

**TABLE 22-1**

Child Care Providers' Perceived Advantages and Disadvantages of Breast Milk Versus Formula

	Breast Milk % (N)	Formula % (N)
<b>Advantages</b>		
Better bonding with mother	86 (171)	3 (5)
Better nutritionally	83 (166)	5 (10)
Diapers not as "smelly"	29 (58)	15 (30)
Helps make infants smarter	34 (68)	2 (4)
Infant is easier to care for	22 (43)	31 (61)
It is easier (in general)	40 (79)	45 (89)
Less illness	77 (153)	3 (5)
Less risk for diseases in adult life	59 (118)	1 (1)
Less risk for obesity	36 (72)	1 (2)
Less trash	53 (105)	4 (8)
More convenient	41 (81)	45 (89)
No advantage	2 (4)	28 (56)
Not embarrassing	11 (22)	28 (55)
Saves family money	85 (170)	2 (3)
Other	2 (4)	7 (14)
<b>Disadvantages</b>		
Do not have a regular feeding schedule	29 (57)	3 (6)
Eat more frequently	42 (83)	3 (6)
Embarrassing	9 (17)	1 (2)
Harder for infants to leave mothers	55 (110)	1 (2)
More diaper changes	18 (35)	6 (4)
No disadvantage	25 (50)	38 (76)
Not as healthy	1 (1)	47 (94)
Uncomfortable for staff	13 (26)	1 (1)
Other	3 (6)	8 (3)

## WHO SHALL COUNSEL?

Among those working closely with people in critical life situations, some people make good counselors and some equally good people are not appropriate as counselors and should have other jobs in the organization.<sup>16</sup>

Counseling is a profession, and professional counselors are carefully screened, educated, and trained. Therefore, individuals who help mothers breastfeed should be screened, educated, and trained as well. They should have the following special abilities:

- To listen
- To avoid judgment

- To understand other lifestyles
- To admit it when they do not know
- To seek appropriate help from professionals
- To recognize incompatibility in a given relationship

In the past few decades, peer counseling has become widespread and has been successful, not only with breastfeeding and childbirth, but also with chronic diseases such as cystic fibrosis and with devastating illnesses such as cancer. The first fact that all these groups had to acknowledge is that just because one has experienced a life event, one is not automatically qualified to counsel others experiencing similar situations.

A candidate must first put personal experiences into perspective and understand the motivation for seeking this counseling role. Counseling is an opportunity to help by listening, and being a sympathetic listener is the most important quality. This is not a time to talk about the counselor's pregnancies. The counselor cannot have a personal agenda and press personal views or lifestyle choices on a mother being counseled, nor should counseling be used as a personal platform to promote organizational biases.

A counselor must understand that assuming a place on a health care team demands time and effort. One must be available at the convenience and need of a client, even when this is inconvenient to the counselor.

## LEARNING TO HELP MOTHERS

The suggestions to guide a counselor in training must be general guidelines about attitude. The emphasis is on listening, encouraging a mother to talk, and ultimately helping her to solve her own problem by understanding it. Professional counselors are trained using didactic sessions, role play, and supervisory sessions until skills are developed. Continued reinforcement of philosophy and techniques forms the basis of growth and improvement. A lay counselor should attend counselor-training sessions provided by the parent organization and work closely with the supervisor. Sharing counseling situations with others with more experience will give further insight. Returning to reference materials again and again will bring to light new thoughts that have been read before but not truly assimilated initially because of lack of experience.<sup>24</sup>

A peer counselor does not provide medical advice. A counselor can encourage a mother to contact her physician. When an infant is doing poorly or is sick, the pediatrician should be consulted promptly. The rare condition of failure to thrive while breastfeeding is increasing in frequency,

paralleling the increased incidence of breastfeeding. It has serious implications for infants and for the continuation of breastfeeding unless treatment is initiated promptly by the physician. A counselor must be able to recognize when a situation is beyond her skills. A physician is powerless to help if not consulted. When an infant's problem is identified and it is prudent to continue breastfeeding, a counselor can be an invaluable asset in supporting and reassuring the mother.

Maternal problems such as mastitis should respond well if treated early, but recurrent mastitis may develop when home remedies are substituted for proper treatment. The role of a counselor in such situations is significant. Encouraging a mother to seek medical care promptly is most important. Reinforcing medical advice will further enhance its effectiveness. For example, if rest is prescribed, a counselor can help a mother to understand how critical rest is to recovery and then help her determine how she is going to cope at home with family responsibilities and a newborn and still rest.

The role of a counselor is support of a mother. A counselor should work in concert with the medical health care team as a team player, not as a competitor or as an adversary, but as a facilitator. The mission of the team is successful lactation, a satisfying mothering experience, and a healthy infant. The health care team will continue to be responsible for a family long after lactation has been discontinued. The confidence and trust developed between the health team and family will be critical to lasting success. The counselor should be remembered as a gentle facilitator and a caring support person who was present and supportive through the rite of passage of matrescence.

A physician working with a lactation counselor or consultant needs to recognize this specialist's skills and limitations. As in other, similar situations, the physician is the leader of the health care team and carries the ultimate responsibility.

## CHAPTER 23

# *Educating and Training the Medical Professional*

---

The 1984 Surgeon General's Workshop on Breastfeeding and Human Lactation<sup>19</sup> was the first national meeting to focus exclusively on breastfeeding. The breastfeeding strategies developed at that workshop are still being used as the United States and the world move toward the breastfeeding objectives set in *Healthy People 2010: National Health Promotion and Disease Prevention Objective*.<sup>10</sup>

Although many of the objectives have been addressed, the education of the health care professional remains a challenge.<sup>13</sup> A second meeting of the National Planning Committee of the Surgeon General's Workshop convened in Washington, District of Columbia in 1985 to address the issue of that education. The leaders of major professional organizations attended, including the American College of Obstetricians and Gynecologists, American Academy of Pediatrics (AAP), American Academy of Family Physicians, National Association of Pediatric Nurse Practitioners, American Dietetic Association, Nurses of American College of Obstetricians and Gynecologists, National Association of Nurse-Midwives, and National Board of Medical Examiners. These organizations developed and ratified a policy in support of educating and certifying its membership in human lactation and breastfeeding. Discussion was initiated about developing a curriculum appropriate to each professional level of training and specialization.

In June 2009, 25 years later, an anniversary meeting commemorating the first Surgeon General's Workshop was held in Washington, District of Columbia to review the progress that had been made and look at the gaps. Professional education was once again a workshop. The challenges were similar but the strategies more aggressive. It was

suggested that federal funds be allocated specifically for professional education. Consistency of curriculum and a system of accreditation were urged. Accountability for professional training on the part of the educational institutions was deemed essential through all professional levels.

### *Continuing Efforts*

---

Most physicians who are supportive of breastfeeding have breastfed their own children but acknowledge their training was insufficient.<sup>1</sup> Work continues in scattered ad hoc special presentations that may or may not have some affiliation with a medical school or hospital. However, no central unified program has been developed to change the curriculum at the seat of learning: United States medical schools and nursing schools.

Lack of support or encouragement from physicians and nurses was a continuing barrier, and no substantive progress had been made in developing curricula or credentialing. Excellent programs have been provided by Wellstart International<sup>25,27</sup> for teams consisting of a physician, a nurse, a nutritionist, and a hospital administrator from the same institution. Wellstart's programs have been international, and they provide resources around the world. Many other universities have served as co-sponsors for a program, seminar, or workshop in their own geographic area. However, the programs have not been integrated into the total medical school curriculum or the training in a residency program, and they are not taught by medical school faculty at all levels of training.

The failure of medical schools to address the issue of education about the breast and training in the clinical issues of breastfeeding was addressed at the University of Texas at San Antonio by Newton.<sup>15</sup> He initiated a program on the obstetric service for medical students and residents. He also reported the results of his national survey of medical schools' curricula: 55% of the 127 United States obstetric and pediatric departments had no didactic lectures for medical students. Of obstetric and pediatric residencies, 30% provided no didactic lectures to their students. Most programs relied on clinical opportunities for learning.

When Freed et al.<sup>9</sup> investigated the attitudes and education of pediatric house staff concerning breastfeeding, they found that third-year residents did not know any more than interns about the subject. Furthermore, only personal experience seemed to provide any in-depth knowledge about simple problems, such as sore nipples.

## *The Problem*

That breastfeeding is important to infants and their mothers for nutritional, immunologic, psychologic, and other health reasons is an established fact. Since the first Surgeon General's Workshop, United States health goals have been to increase the incidence and duration of breastfeeding. Little formal education is provided on the topic in medical schools and residency training programs. No planned curricula or testing mechanisms have been available.

Breastfeeding has another unique problem of interest to the lay persons who have become involved. Many nonphysicians have become involved in training. Some attempts at educating physicians have been made by nonphysicians and sometimes by people who are not health care professionals.<sup>3,5</sup> The message to medical students is that understanding and encouraging breastfeeding are not in a physician's job description. When other care providers give presentations to medical students or residents, it is assumed the provider is describing the work for information only and not for its role in a physician's work. Childbirth is of great interest to the lay public and to consumer advocacy groups as well, but they do not provide physicians' training in childbirth. This training is provided by skilled specialists who have doctoral degrees, residency training, board certification, and, in many cases, additional fellowship training and subspecialty certification, which are minimal qualifications for medical school faculty.

How much do residents and physicians know about managing breastfeeding? The data suggest the answer is "very little." In a study of obstetric

residents, Freed et al.<sup>6</sup> mailed a survey to more than 600 residents, and 64% responded. Only 38% had any education from the faculty about breastfeeding and indicated what little they knew came from other residents and nurses. All participants agreed, however, that they should have a role in the management of breastfeeding for their patients. A survey of 87 of a possible 108 pediatric residents (81%) evenly distributed among levels I, II, and III in a large hospital reported that level III residents were no more competent than their PL-1 counterparts.<sup>8</sup> If they or their spouse breastfed, they were more confident in their knowledge base. No differences were found between men and women or between those breastfed or not breastfed as an infant.<sup>8,9</sup>

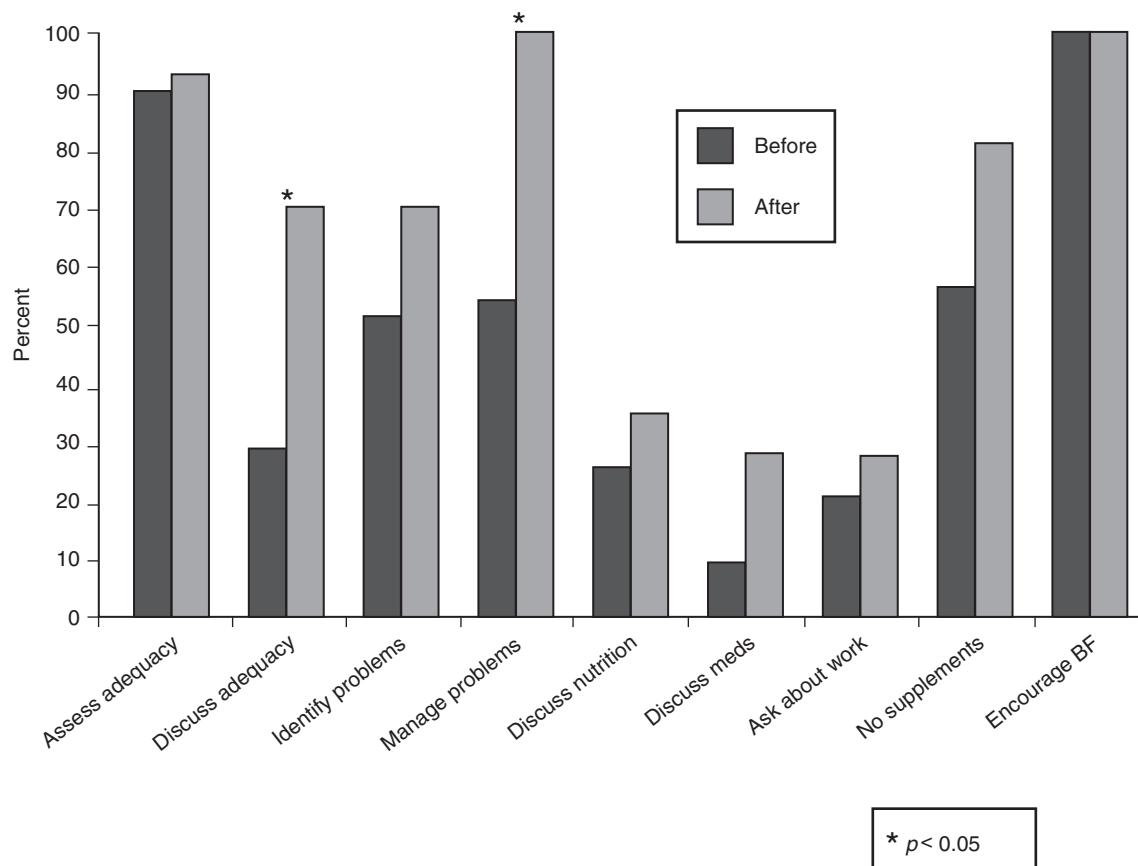

The knowledge, training, and attitudes of obstetricians concerning the management of breastfeeding were evaluated by the American College of Obstetricians and Gynecologists.<sup>17</sup> A survey was sent to 1200 fellows of the college, and only 397 (33%) practitioners responded. Obstetricians considered counseling their patients and managing breastfeeding care an important part of their clinical responsibilities. They thought that they were very qualified to treat mastitis, prescribe maternal medications, and advise their lactating patients about contraception. They were less confident about educating their patients about breastfeeding and solving any problems. Personal breastfeeding experience for the women was a predictor of confidence. Four of ten physicians thought their training was inadequate in lactation.<sup>17</sup>

A subsequent study confirmed that residents' knowledge was low and their misinformation disturbingly high.<sup>8</sup> The authors concluded that residency training programs must provide comprehensive education on breastfeeding to prepare residents to meet the needs of patients and other parents. Another study of pediatricians in training given a 15-minute, self-administered, and anonymous questionnaire resulted in 53% participation (29 respondents).<sup>26</sup> On a six-point scale of support of breastfeeding, the group averaged 2.6 (1 being most supportive), revealing an attitude barely above neutral. They averaged only 53% on the management questions, and their confidence in their skills was low, confirming the need for didactic and clinical training in breastfeeding.

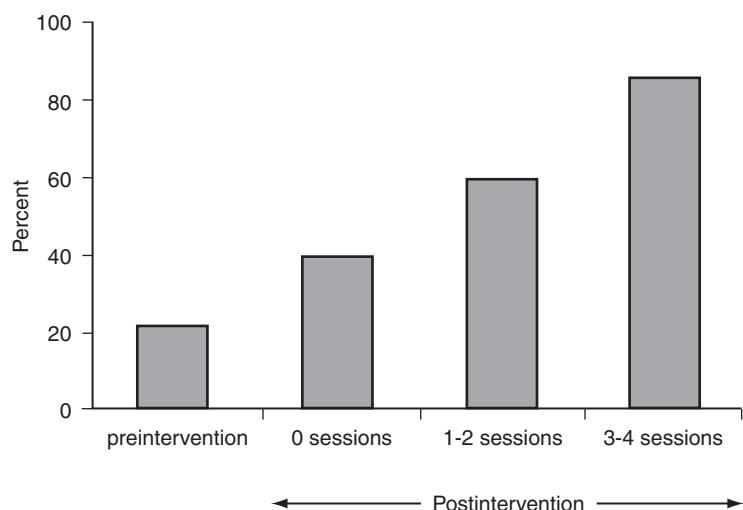

The effect of an educational intervention about breastfeeding on the knowledge, confidence, and behaviors of pediatric resident physicians was evaluated using before and after questionnaires. Their behaviors in the clinical setting were also measured before and after an interactive multimedia curricular intervention to increase their knowledge about common lactation issues. The investigators also telephoned the mothers after the clinic visit.

Acceptable management of breastfeeding adequacy and the correct management went from 22% to 65% after the training. The resident physicians especially improved in assessing of problems<sup>11</sup> (Figures 23-1 and 23-2).

A national survey of 1099 family medicine residents, 71% of whom responded, indicated that they thought they should be involved in breastfeeding promotion and support.<sup>7</sup> They demonstrated significant deficits, however, in knowledge about benefits

**Figure 23-1.** Change in resident behaviors: Percentage of residents demonstrating each behavior before and after the educational intervention. *BF*, Breastfeeding. (From Hillenbrand KM, Larsen PG: Effect of educational intervention about breastfeeding on the knowledge, confidence, and behaviors of pediatric resident physicians, *Pediatrics* 110:e59, 2002.)

**Figure 23-2.** Percentage of residents with "acceptable performance" of desired behaviors (at least 6 of 9) compared with number of sessions attended. (From Hillenbrand KM, Larsen PG: Effect of educational intervention about breastfeeding on the knowledge, confidence, and behaviors of pediatric resident physicians, *Pediatrics* 110:e59, 2002.)

and clinical management. These same investigators also polled practitioners regarding their beliefs and knowledge base.<sup>8</sup> The results indicated a similar level of support and lack of knowledge.

Others have investigated the level of knowledge of physicians in training in other countries. A self-administered questionnaire was returned by 76 obstetric residents (84%) in metropolitan areas of South Korea.<sup>12</sup> Korean breastfeeding rates have decreased, especially among well-educated women; the rate was only 17% in 1994. The questionnaire responses indicated that the residents were neutral about breastfeeding. They considered themselves competent to handle breastfeeding situations, but they scored only 38% on the management quiz.

Improved breastfeeding education clearly is needed in obstetrics, pediatrics, and family medicine, the physicians who should be most involved in supporting and promoting breastfeeding.

## *The Solution*

---

To begin to solve this educational problem, a curriculum should be developed. It should span all 4 years of medical school, being carefully woven into the fabric of medical school for all students, as well as into the residency years for those specializing in obstetrics, pediatrics, and family medicine.

The program should be taught by physicians who are qualified faculty members recognized by their peer group and certified by specialty examining boards. The classes should be part of the total curriculum and not something a student can elect to do only in the fourth year, when most of the assignments are by electives. Graduate physicians in practice rarely will go to a teaching day exclusively on breastfeeding, and they rarely attend programs directed at a broad-based audience of nonphysicians. It does not serve their educational needs when they are also responsible for keeping up to date on the constant flow of advancements in every branch of medicine.

Breastfeeding topics should become part of a well-rounded continuing education program that includes a number of other important issues, such as infectious diseases, endocrine problems, growth, development, and perinatology. When breastfeeding is included in programs on infant nutrition and presented by a physician, it will gain the status it needs.

## *Suggested Curriculum for Medical Students*

---

If first-year students have a program in human nutrition, breastfeeding can be presented in the section on child nutrition, and the discussion should

provide information about the reasons breastfeeding and human milk are superior to formula feeding.

When second-year students have a program on women's health issues, including hormonal maturation, menarche, sex, contraception, childbearing, menopause, and the breast, the additional curriculum can be dedicated to the use of the breast, that is, the anatomy and physiology of lactation. The pathology, including augmentation mammoplasty, reduction mammoplasty, and benign and malignant tumors, is an additional topic.

The third year begins with the general clerkship, wherein skills in history taking and physical examination are sharpened. Obstetrics and gynecology concentrates on breast and pelvic examinations. It is expected that all students, residents, and practitioners will always make these physical examinations part of the physical examination of women.

Third-year medical students spend time on obstetrics, treating patients prenatally, intrapartum, at delivery, and postpartum. Breastfeeding should be part of that continuum, from the discussion of infant feeding prenatally through the postpartum checks for physiologic engorgement and the mother's questions about her afterpains, for example.

The third-year students also spend time on the pediatric service, including the ward, the outpatient, and emergency service. Each student spends a short time in the newborn nursery going crib to crib, checking the newborn's adaptation to extrauterine life. The student also examines infants and talks to mothers. Observing a feeding is part of all discharge examinations on the nursery service and mandatory if the infant is breastfed. The student learns about the breastfed infants' feeding and weight patterns and early lactation. The student learns to identify problems and treat them.

The weeks in the clinic provide additional experience when seeing well babies. The students are exposed to the early weeks and months of breastfeeding and learn about infant weight gain and any problems that arise. The preceptors are experienced, board-certified pediatricians. The daily lecture series, which starts the day for all the residents and students assigned to the outpatient service, is directed at reviewing routine clinical issues. At least one of ten lectures should be about breastfeeding. Students are encouraged to visit their patients while they breastfeed and to accompany the mother-baby nurse when assisting the nursing dyad. They also attend the breastfeeding classes for mothers given by the lactation consultants, who are college-prepared nurses and board-certified lactation consultants (IBCLC).

Fourth-year medical students have a few required courses but the rest of the year is given to electives. A student may elect extra time in the

newborn nursery or the outpatient service or even at the Lactation Study Center. Summer fellowships are available to medical students throughout the 4 years to do a research project with a faculty member. Reports of the questions on the national board examination confirm that human lactation and breastfeeding are included. The recent qualifying examinations have had questions about breastfeeding and human lactation.

Residents in obstetrics and pediatrics can be assigned to the nursery and receive experience in managing the breastfeeding mother-baby dyad. The obstetric house officer may receive additional experiences by following patients prenatally and postpartum. Formal lectures should be provided in the grand round series of both departments. Special lectures directed specifically at the house officer on topics in breastfeeding and lactation are scheduled as part of attending rounds (e.g., drugs in breast milk, mastitis, failure to thrive).

The breastfeeding and lactation curriculum for medical students is not unlike the approach to studying other organ systems, such as the cardiovascular system or the renal system. It includes the anatomy, physiology, biochemistry, pharmacology, normal function, pathology, and finally the clinical application in a wide range of clinical settings.

## EXPERTISE AND LEADERSHIP ISSUES

As in other medical issues, physicians learn about interacting with patients and families and study all the psychosocial implications. When a medical school offers a visible clinical and research program that focuses attention on a subject, it improves the image of the subject matter. Cancer centers, poison centers, and sports medicine clinics are examples of how certain medical problems have been elevated to positions of importance in education and training by pooling resources and expertise. The Breastfeeding and Human Lactation Study Center at the University of Rochester School of Medicine has served as an information center, a resource of expertise for the educational matrix, and an ongoing research program that allows students, residents, and fellows to develop their own investigational work. Newton's work in East Carolina University Medical School, Neifert's at the University of Colorado at Denver, and that of many others are examples of medical school-based programs that are developing models for physician training.

The greatest obstacle to initiating a self-sustaining program on human lactation in medical schools is the need for leadership among the faculty. At least one interested, knowledgeable, credible faculty member must emerge to develop the

curriculum so that it becomes part of the permanent learning plan. Faculty more recently trained are more interested in breastfeeding than senior faculty trained in the heyday of formula feeding.

The physician does not put the infant to the breast; that is the responsibility of the mother-baby nurse. The physician does, however, have to understand the process so that problems in clinical outcome can be solved. The nurse does not choose the medications prescribed to a lactating woman, but should understand the importance of lactation in those selections. The mother should be reminded to notify her internist that she is lactating should it impact her medical condition or its treatment. The health management of breastfeeding and lactation is a team effort, and it is the job of the physicians, nurses, and nutritionists working in perinatal medicine to assist in the process.

The AAP Section on Breastfeeding has developed and tested a residency curriculum on breastfeeding directed at all residents and tested in university hospitals with obstetrics, pediatrics, and family medicine residency programs.<sup>4</sup> It begins with the evidence that breastfeeding matters. There are three major sections to the program: advocacy, clinical management, and delivering culturally competent breastfeeding care. The program is organized to be delivered flexibly over a 1-year period and is organized to meet the core competencies of the Accreditation Council for Graduate Medical Education. The evaluation tools are designed to facilitate review and tracking by the residency director. This curriculum has been pilot tested at seven sites with seven matched control sites. Each test site had at least 20 residents participating. The site directors attended a training meeting at the AAP and an evaluation meeting at the end. Each site hosted a teaching day with a visiting professor. The residents took a pretest and a posttest; 100 charts were reviewed at each site and breastfeeding stats were collected, including a 6-month follow-up. The comparison sites administered the pretest and posttest and collected breastfeeding statistics.

Required activities included completing the Wellstart Self-Study Module, Level I. The residents also watched Jane Morton's *15 Minutes of Breastfeeding* help video as well as the Jane Morton video: *Breastfeeding: A Guide to Getting Started* (available at [www.Breastfeeding.com](http://www.Breastfeeding.com)). Other activities with patients were also mandated.

Outcome measures included pre- and posttest scores (mean difference posttest minus pretest).

Test sites showed an increase in breastfeeding rates. Calculated cost saving in health care was \$303 per baby per year. Cost saving at the seven sites for 1 year was estimated to be \$2,488,311. This breastfeeding residency curriculum has its

own website and is available for downloading at <http://www.aap.org/breastfeeding/curriculum/>.<sup>4</sup>

## WELLSTART PROGRAM

Wellstart International<sup>25</sup> has developed a multidisciplinary approach to breastfeeding education that includes various health professionals, such as nurses, midwives, nutritionists, and physicians. The training materials are predicated on training the team together. This model works well when an institution can send a team simultaneously to the training with the intent that the team members will return and each train members of their own discipline, thus ensuring credible expertise across medicine, nursing, and nutrition. Naylor et al.<sup>14</sup> point out that "for the continuum of health care and the safety of the mother and infant, the physician has the final responsibility for diagnosis and medical management, including the treatment of illnesses, lactation problems and growth abnormalities." The authors agree that the material must be integrated into courses that already exist, whether in traditional didactic curricula or problem-based models. Table 23-1 presents the curriculum recommended in the Wellstart model, and Box 23-1 provides the model's breastfeeding policy for hospitals.

The Normal Pregnancy Virtual Patient program available at many medical schools can be utilized to train physician management of lactation. The program enhances behavior in medical management but also improves counseling skills.<sup>20</sup>

Wellstart has introduced the third edition of the Lactation Management Self-Study Module, Level I, incorporating new evidence-based information

germane to entry-level study. This edition is on its website as a downloadable teaching and learning tool without charge. The authors ask only that users take the opportunity seriously and take responsibility for providing the good care that is taught through the module (Box 23-2). It is available to all professionals.

The educational objectives and skills for the physician with respect to breastfeeding have been developed. The Academy of Breastfeeding Medicine (ABM) has the complete guidelines recommended for the education and training of physicians. ABM recommends high quality breastfeeding education throughout the continuum of medical education and training. The medical professional plays a critical role in the promoting, protecting, and supporting of breastfeeding. This ABM statement is available in Appendix K and on the ABM website.

## *Curriculum for Nurses' Training in Breastfeeding and Lactation*

A number of programs have been developed for the training of health professionals.<sup>22,24</sup> According to their titles, they have been developed by nurses for nurses or by nutritionists for nutritionists. Several of these programs were sponsored by the Maternal and Child Health Bureau, and their materials are available through the National Center for Education in Maternal and Child Health. *Lactation Education for Health Professionals*, edited by Rodriguez-Garcia, Schaefer, and Yunes<sup>22</sup> of the

**TABLE 23-1** Impact of Curriculum on Breastfeeding Initiation and Continuation

Type of Feeding	Pretest	Posttest	Change	Sig
<b>Breastfeeding rates at initiation pre- and postimplementation (% infants)</b>				
<b>Intervention sites</b>				
Exclusive breastfeeding	15.5	23.1	+7.45	0.002

**BOX 23-1. Wellstart International Model Hospital Breastfeeding Policies for Full-Term Normal Newborn Infants**

**Definition and purpose:** To promote a philosophy of maternal and infant care that advocates breastfeeding and supports the normal physiologic functions involved in this maternal-infant process. The goal is to ensure that all families who elect to breastfeed their infants will have a successful and satisfying experience.

1. Hospital administrative, medical, nursing, and nutrition staff should establish a strategy that promotes and supports breastfeeding through the formation of an interdisciplinary team responsible for the implementation of hospital policies and provision of ongoing educational activities.
2. All pregnant women should receive information before delivery regarding the benefits and management of breastfeeding.
3. Every mother should be allowed to have a close companion stay with her continuously throughout labor.
4. Infants are to be put to breast as soon after birth as feasible for both mother and infant. This is to be initiated in either the delivery room or the recovery room, and every mother is to be instructed in proper breastfeeding technique and reevaluated before discharge.
5. Breastfeeding mother-infant couples are to room-in together on a 24-hour basis.
6. The infant is to be encouraged to nurse at least 8 to 12 times or more in 24 hours, for a minimum of 8 feedings per 24 hours.
7. Specific timing at the breast is not necessary. Infants usually fall asleep or release the nipple spontaneously when satiated.
8. Infants should spontaneously finish at the first breast, then should be encouraged to try the second breast at each feed.
9. If a feeding at the breast is incomplete or ineffective, the mother should be instructed to begin regular expression of her breasts in conjunction with continued assistance by an experienced staff member. The colostrum or milk obtained by expression should be given to the baby.
10. No supplementary water or milk is to be given unless specifically ordered by a physician or nurse practitioner.
11. Pacifiers are not to be given to any breastfeeding infant unless specifically ordered by a physician or nurse practitioner. The use of bottle nipples and nipple shields should be discouraged.
12. Breastfeeding mothers are to have breasts examined for evidence of lactation or breastfeeding problems at least once every nursing staff shift.
13. Discharge gift packs offered to breastfeeding mothers should contain only noncommercial materials that provide educational information and promote breastfeeding.
14. All breastfeeding mothers are to be advised to arrange for an appointment for their baby's first checkup within 1 week after discharge.
15. At discharge, each mother is to be given a phone number to call for breastfeeding assistance.
16. Mothers who are separated from their babies are to be instructed on how to maintain lactation.

From Naylor AJ, Creer AE, Woodward-Lopez G, et al: Lactation management education for physicians, *Semin Perinatol* 18:525, 1994.

Pan American Health Organization of the World Health Organization, provides an excellent description of such a program. This text is directed at nursing school faculties. The target audience is undergraduate nursing students, although the text could serve as a guide for postgraduate and continuing education programs. A well-trained student will be able to teach mothers optimal breastfeeding and weaning techniques. Students will also be able, within the scope of the total health team, to promote, maintain, and protect breastfeeding.<sup>18</sup>

The learning objectives for nurses include being able to do the following:

- Apply acquired knowledge and skills
- Assist mothers in initiating and continuing breastfeeding
- Promote breastfeeding
- Organize and conduct breastfeeding education seminars for other members of the nursing staff
- Plan and implement breastfeeding services in clinical sites

A training guide for experienced health care professionals was prepared by Best Start and Bryant and Roy.<sup>2</sup> The work is culturally sensitive and is based on a thorough study of social marketing.

Other resources for education and training are listed in Appendix K. Nursing schools should seek the same quality in their lactation resources as they have in all other phases of nursing. When the professional nursing certifying organizations develop appropriate certification for lactation throughout perinatal nursing to accompany the certification already established for labor and delivery, normal newborn, postpartum care, and other areas, the curriculum will come into place quickly.

The Ontario Public Health Association, Toronto, Canada, has developed a series of modules covering the basic essential information regarding breastfeeding, which it recommends be incorporated into the undergraduate curricula of all health care professionals who work with childbearing families. Breastfeeding resource material can be accessed on its website at <http://www.hc-sc.gc.ca>.

**BOX 23-2. Lactation Management Self-Study Modules****MODULE ONE****Breastfeeding: A Basic Health Promotion Strategy in Primary Care***Objectives*

After completing this module, you will be able to:

1. Describe the reasons why breastfeeding is important as well as evidence-based risks of not breastfeeding for the infant, mother, family, and community at large.
2. Identify factors that contribute to the breastfeeding decision.
3. Counsel a woman about breastfeeding.

**Introduction**

All mothers want to provide what's best for their babies and often turn to their health care provider for advice. This module will help prepare you for this discussion by reviewing human milk composition and some of the major benefits of breastfeeding for infant, mother, family, and the community. Some of the factors that influence how women make their infant feeding choice will also be described.

**MODULE TWO****Basics of Breastfeeding: Getting Started***Objectives*

After completing this module, you will be able to:

1. Describe the process of milk production and removal.
2. Recognize correct attachment and effective suckling at the breast.
3. Identify components of anticipatory guidance for all women.
4. Recognize the impact of perinatal hospital practices on breastfeeding.

**Introduction**

Although the mother's body produces milk as a normal part of the reproductive cycle, the technique of breastfeeding is a learned skill enhanced by practice and support. While parents need helpful information prenatally to know what to expect, the opportunity

postpartum to practice attaching the baby to the breast and assessing the baby's breastfeeding effectiveness can provide the family with confidence as they embark on this particular experience of parenthood.

The key to helping new breastfeeding families is an understanding of the basic anatomy of the breast and physiology of the milk production and removal process. This module will focus on the science of lactation and practical clinical skills to help mothers get started. The module is applicable to both the obstetric and pediatric sides of the equation, as the management of the peripartum course and newborn care can profoundly affect the early breastfeeding experience and later infant feeding outcomes. As far as breastfeeding is concerned, the mother and baby are a biologic unit; whatever influences one affects the other.

**MODULE THREE****Common Breastfeeding Problems***Objectives*

After completing this module, you will be able to:

1. Discuss causes and prevention of common breastfeeding problems.
2. Recognize that infants and mothers with special health care needs can breastfeed.
3. Recommend treatment options compatible with breastfeeding.
4. Recognize when and how lactation can be sustained during mother-infant separation.

**Introduction**

From time to time, mothers encounter problems with breastfeeding. Most problems are preventable with good breastfeeding practices: correct positioning and attachment, frequent unlimited feeds, and attention to the effectiveness of the infant's suckling. When problems do occur, early recognition and treatment enable a mother to begin or continue to enjoy breastfeeding and help reach the recommended goals of exclusive breastfeeding for six months and continued breastfeeding for a year and beyond.

## **POSTGRADUATE LEARNING OPPORTUNITIES FOR NURSES AND LACTATION CONSULTANTS**

Numerous programs across the United States are geared toward nurses and often are provided by nurses. Many of these focus on curricula designed to assist the participant in passing the certifying examination provided by the International Board of Lactation Consultant Examiners. Postgraduate teaching for lactation consultants is provided by the International Lactation Consultants Association and by independent professional groups.

## **POSTGRADUATE LEARNING OPPORTUNITIES BY MEDICAL GROUPS FOR PHYSICIANS**

Postgraduate educational opportunities are one of the major goals of the ABM, an international organization founded in 1994 and limited to physicians from all disciplines and physician trainees. The ABM holds an annual meeting with plenary sessions, workshops, and submitted papers and posters on the wide range of topics involving breastfeeding and human lactation. ABM's mission is to encourage and support breastfeeding, especially through

physician education. ABM has developed a program—*What Every Physician Needs to Know About Breastfeeding* (WEPNKAB)—which is presented by a team of experts every year preceding the annual meeting. It has been recorded on video and is available from the ABM on its website as well.

The Milk Club is a group that meets in conjunction with the American Pediatric Society, Society for Pediatric Research, and Academic Pediatric Association. Their mission is to bring new science in the field to the attention of all investigators. The format is usually a symposium with discussion and a poster session at the Pediatric Academic Society (PAS) annual meeting.

The International Society for Research in Human Milk and Lactation is an organization of investigators who meet annually in conjunction with the Federation of American Societies for Experimental Biology and meet biannually and independently at international sites to discuss current knowledge of laboratory and clinical research. Membership is limited to qualified investigators in the field. Appendix K provides the addresses for these organizations.

The AAP, American College of Obstetricians and Gynecologists, and American Academy of Family Practice have increased their programming about human lactation at their annual and regional meetings. The AAP established a Work Group on Breastfeeding that became the section on Breastfeeding of the AAP. The section has prepared a position paper on breastfeeding every five years that was most recently published in *Pediatrics*. It is available at <http://www.AAP.org/breastfeeding>.

The statement has been updated and published in 2010.<sup>23</sup> It includes the additional AAP recommendation for vitamin D to be given to breastfed infants by 2 months of age because of a deficiency of sunlight exposure in present lifestyles. The dose is 400 IU of vitamin D daily starting shortly after birth. Members of the AAP are welcome to join the section. The section is the sponsor of the Program on Breastfeeding in Pediatric Offices, which is now offered to the American College of Obstetricians and Gynecologists and all obstetricians as well as to the American Academy of Family Practice and its members. The section has also prepared a speaker's kit on breastfeeding with presentation slides for a physician to present his or her own lecture in the practice area. The section has authored a book for parents edited by Joan Meek, MD now in its second edition, and a handbook for physicians edited by Richard Schanler, MD, also in its second edition.

## Physicians Who Breastfeed

Pregnancy is becoming more common in residency and over 50% are female in new millennium. A study

of Obstetric Residency reported 80% of the residents are female whereas in pediatrics 63% are female and in family medicine 53% are female. In a study by Orth et al.<sup>16</sup> 404 responded, and of those, 22% had personal experience with breastfeeding, all of whom felt support from faculty and fellow residents. Resident mothers felt it placed extra burden on their colleagues. Two thirds of the breastfeeding residents struggled with low milk supply and stopped breastfeeding before they planned to, in spite of the supportive atmosphere. Sustaining breastfeeding was also reported by Riggins et al.<sup>21</sup> in a Pediatric Residency Program. The rate of initiation was high (98%) above state averages and national goals. At 6 months 68% were breastfeeding, also higher than state averages (38%) and national goals (61%), but at one year it was 12% below averages and goals. Three quarters of the women had difficulties and 73% were able to continue. Twenty-seven percent were unsuccessful and did not meet their breastfeeding goals, and most felt they had failed. Suggestions they made to improve outcome were: on-site daycare, need for pumping facilities, or better facilities with a phone. They tended to seek help from books, lactation consultants, or friends but not other physicians.

## Summary

To establish breastfeeding and human lactation as an integral part of medical student education, the topic should be inserted into the present curriculum at the appropriate natural points, whether it is a class on anatomy, physiology, nutrition, endocrinology, women's health, or infant care. The class should be taught by recognized faculty who also teach the other parts of the subject material. Finally, the material should be included in the examination for the subject. When it is not on the examination it is ignored. Much remains to be learned in modern medicine, and lactation should be part of it. The residency training programs in obstetrics, pediatrics, and family medicine can access the residency curriculum from the AAP website and introduce it into their residency programs. It is available at <http://aap.org/breastfeeding/curriculum/> (Tables 23-2 and 23-3).

As more and more education is available electronically, breastfeeding resources need to be available. An Internet-based program called "Breastfeeding Basics" is available free of charge. This source was evaluated. Of the 3456 who accessed the program, 2237 (65%) completed one or more pretests. The mean pretest/posttest scores showed improvement. The lowest scores were on vitamin D, breastfeeding physiology, infant growth, and infant problems. Pre- and posttests are an important factor in the value of learning over the Internet.

**TABLE 23-2** Comparison of Intervention Differences (I) to Control Site Differences (C) by Specialty: Mean Difference (p)

		Pediatrics	OB/GYN	Family Practice
Knowledge	I	14 (0.057)	18 (0.007)	18 (0.009)
	C	9.0	5.0	2.0

Composition of Human Colostrum and Mature Breast Milk—cont'd

Constituent (per 100 mL)	Colostrum 1-5 Days	Mature Milk >30 Days
Urea (mg)	10	30
Creatine (mg)	—	3.3
Total fat (g)	2.9	4.2
<b>Fatty acids (% total fat)</b>		
12:0 tauric	1.8	5.8
14:0 myristic	3.8	8.6
16:0 palmitic	26.2	21.0
18:0 stearic	8.8	8.0
18:1 oleic	36.6	35.5
18:2, n-6 linoleic	6.8	7.2
18:3, n-3 linolenic	—	1.0
C <sub>20</sub> and C <sub>22</sub> polyunsaturated	10.2	2.9
Cholesterol (mg)	27	16
<b>Vitamins</b>		
<b>Fat soluble</b>		
Vitamin A (retinol equivalents) (mcg)	89	67
β-Carotene (mcg)	112	23
Vitamin D (mcg)	—	0.05
Vitamin E (total tocopherols) (mcg)	1280	315
Vitamin K (mcg)	0.23	0.21
<b>Water soluble</b>		
Thiamin (mcg)	15	21
Riboflavin (mcg)	25	35
Niacin (mcg)	75	150
Folic acid (mcg)	—	8.5
Vitamin B <sub>6</sub> (mcg)	12	93
Biotin (mcg)	0.1	0.6
Pantothenic acid (mcg)	183	180
Vitamin B <sub>12</sub> (ng)	200	26
Ascorbic acid (mg)	4.4	4.0
<b>Minerals</b>		
Calcium (mg)	23	28
Magnesium (mg)	3.4	3.0
Sodium (mg)	48	18
Potassium (mg)	74	58
Chlorine (mg)	91	42
Phosphorus (mg)	14	15
Sulfur (mg)	22	14
<b>Trace elements</b>		
Chromium (ng)	—	50
Cobalt (mcg)	—	1
Copper (mcg)	46	25
Fluorine (mcg)	—	16
Iodine (mcg)	12	11
Iron (mcg)	45	40
Manganese (mcg)	—	0.6±
Nickel (mcg)	—	2
Selenium (mcg)	—	2.0
Zinc (mcg)	540	120

Data from multiple references (see Chapter 4). Figures have been averaged.

## APPENDIX B

# Normal Serum Values for Breastfed Infants

**TABLE B-1** Serum Chemical Values of Normal Breastfed Infants\*

Concentration/100 mL of Serum	Age 28 Days			Age 56 Days			Age 84 Days			Age 112 Days		
	N	Mean	SD	N	Mean	SD	N	Mean	SD	N	Mean	SD
<b>Males</b>												
Total protein (g)	22	5.87	0.50	36	5.96	0.42	29	6.16	0.57	51	6.29	0.51

**TABLE B-2**

Leptin Levels in Infants

	Leptin (ng mL <sup>-1</sup> )	In (Leptin) (ng mL <sup>-1</sup> )	In (Leptin)/Weight (ng mL <sup>-1</sup> per kg)	In (Leptin)/BMI (ng m <sup>-2</sup> mL <sup>-1</sup> per kg)
Total (n=35)	7.35±6.87	1.19±0.89	0.21±0.20	0.08±0.06
M (n=18)	6.92±5.72	0.96±1.01	0.13±0.22	0.05±0.07
F (n=17)	7.79±8.02	1.43±0.73	0.29±0.17	0.1±0.05
BF (n=13) (7M, 6F)	8.04±5.01	1.62±0.73*	0.30±0.13*	0.11±0.05*
FF (n=22) (11M, 11F)	6.93±7.91	0.94±0.95*	0.16±0.20*	0.06±0.07*

Data are mean±SD.

BF, Breastfed; BMI, body mass index; F, female; M, male.

\*p<0.05.

From Savino F, Costamagna M, Prino A, et al: Leptin levels in term breastfed (BF) and formula-fed (FF) infants, *Acta Paediatr* 91:897, 2002.

## APPENDIX C

# *Herbals and Natural Products*

Herb Common Name/Rating*	Synonyms	Active Ingredient	Uses	Present in Milk	Safety/Efficacy
Aloe vera AAP – H L3 W –	<i>Aloe barbadensis, A. capensis, vera</i>	Polysaccharide, glucomannan	Wound healing and small burns	Unknown, probably none when applied to skin	Orally is a strong purgative; oral dosing not recommended during lactation. Dermal use ok. <sup>11,12</sup>
Asparagus Blessed thistle AAP – H L3 W –	Wild asparagus root <i>Borage officinalis</i> Toxin	<i>Asparagus racemosus</i> Many chemicals and volatile oils	Gastrointestinal symptoms Pain therapy	Unknown	Nourishing herb; used in those debilitated or conv galactagogue (1 g powdered root per day in milk or juice). <sup>17</sup>
Borage AAP – H L5 W –		Pyrrolizidine alkaloid			This is not a galactagogue. It is a different plant from milk thistle. No known toxicity. <sup>11</sup> Many uses. Contraindicated in pregnancy and lactation. <sup>30</sup>
Botulism AAP – H L3 W –					In natural cases of botulism toxin does not get into the milk. Pharmaceutical product Botox treatment unlikely to reach milk. <sup>23</sup>
Cannabis AAP 2 H L5 W –	Marijuana <i>Capsicum</i>	Δ9-Tetrahydro-cannabinol (THC)	Sedative, hallucinogen	Yes	Remains in infant's system for weeks, especially in fat. <sup>2,11,13,32</sup> Available as a cream, lotion, or oral tablets. Used where vasodilation or warmth is needed. Can cause burning, stinging. Do not use on breasts. <sup>12,28</sup>
Capsaicin AAP – H L3 W –			Topical anesthesia	Unknown	
Chamomile AAP – H L3 W –	<i>Matricaria recutita</i> , Aster Aceae family	Terpenoids (coumarins), flower heads	Antiinflammatory, carminative, antiseptic, sedative (all unproved)	Unknown	Potential for allergic reaction. Animal studies question safety in pregnancy and lactation. <sup>2,6</sup>
Cohosh (black) AAP – H L4 W –	<i>Cimicifuga racemosa</i> , black cohosh, black snakeroot, found in Lydia Pinkham's compound	Estrogenic compounds, tannins, terpenoids, use roots and rhizome	Dysmenorrheal, dyspepsia, rheumatism, menopause	Unknown	May cause hypotension; could decrease milk production? Efficacy and safety in lactation. <sup>31</sup>
Cohosh (blue) AAP – H L5 W –	<i>Caulophyllum</i> , blue cohosh, squaw root	Roots and rhizome, methylcytosine, caulosaponin	Uterine stimulant, emmenagogue, increased blood pressure, like nicotine, induces labor		Safety of concern, can constrict coronary vessels; leaves and seeds are known to be toxic. Can induce labor. <sup>30</sup>
Comfrey FDA banned AAP – H L5 W –	<i>Symphytum officinale</i>	Roots and rhizome and leaves, allantoin, hepatotoxic, pyrrolizidine alkaloids	"Wonder drug," heals wounds, used as poultice, used as tea	Yes	Venoocclusive disease causing hepatic failure. Banned in many countries; unsafe. <sup>1,5,4,11,15,24,26</sup>

Continued

Herb Common Name/Rating*	Synonyms	Active Ingredient	Uses	Present in Milk	Safety/Efficacy
Echinacea AAP – H L3 W –	<i>Echinacea angustifolia</i> , coneflower	Whole plant, flowers, dried roots	Immunostimulant, antiinfective, tested for upper respiratory infections	Unknown	Has been studied; effective in short courses, not continual use. No known toxicity; probably safe during lactation. <sup>8,11,12,21</sup>
Evening primrose AAP – H L3 W –	<i>Oenothera biennis</i>	Biennis, oil from seeds, cis-gamma-linoleic acid (GLA), a precursor of prostaglandin E <sub>1</sub> , essential fatty acids (EFA)	Lower cholesterol, lower blood pressure, lower dysmenorrhea, mastalgia, eczema	Yes	Efficacy: conflicting reports. Safety: +/– probably in small amounts. Supplements increase EFA in milk <sup>9</sup> ; increase bleeding time. <sup>27</sup> Do not use with phenol thiazines.
Fennel AAP – H L4 W –	<i>Foeniculum vulgare</i>	Dried ripe fruit, volatile oil, transanethole estrogenic effect	Carminative, loosen phlegm, galactagogue, increase libido	Probable	Volatile oil can be toxic; use only fruits (seeds). Because of estrogenic effect, its reputation as a galactagogue is questioned. <sup>11</sup>
Fenugreek AAP – H L3 W –	<i>Trigonella foenum-graecum</i> , Greek hayseed	Dried ripe seeds, diosgenin, and alkaloids smell like maple syrup	Hypoglycemia, galactagogue, anticoagulant, see text	Probable Unknown	Risk: cross allergy to chrysanthemum family. Probably in milk; infants smell of maple syrup. No studies of efficacy. <sup>13,14,17,22,25,29</sup> Enhances effect of warfarin contraindicated during pregnancy. Value as galactagogue undocumented; decreases platelet aggregation. <sup>30</sup>
Feverfew Not rated	<i>Chrysanthemum partenium</i> Bachelor's button	Leaves extract tincture	Associated with migraines. Menstrual irregularity antiinflammatory		
Garlic (Supplement form) AAP – H L3 W –	Lily family: <i>Allium sativum</i> , poor man's treacle, clove garlic, common garlic, allium, stinking rose	Alliin, ajoens	Has 125 different uses, some contradictory, both high and low blood pressure, antibacterial, antithrombotic, lower cholesterol	Yes	Can cause colic in breastfed infants. Can enhance warfarin. Not tolerated by some infants. <sup>7</sup>
Galactagogues: increase milk supply Fenugreek (Greek hayseed) Goats rue ( <i>Galega officinalis</i> ) Alfalfa (member pea family) seeds can be toxic Borage contains amabilene/ relieves pain can cause venoocclusive disease			Antigalactagogues: decrease milk supply. Fennel and estrogenic effects; oil is toxic. Peppermint, sage, parsley (tabbouleh salad) agnus castus (monk's pepper) Jasmine flowers applied to breast		

Ginkgo AAP – H L3 W –	<i>Ginkgo biloba</i>	Flavones and glycosides, seeds, ginkgotoxin, ginkgo biloba extract (GBE), leaves for tea	Herbal antioxidant	Unknown	Placebo-controlled studies suggest no efficacy in young adults. Use in elderly more effective. Conflicting reports of safety. Not recommended in lactation. <sup>7,31</sup> Enhances the effect of warfarin. Can cause bleeding even alone.
Ginseng AAP – H L3 W –	Panax ginseng ( <i>P. quinquefolius</i> ), Asian ginseng	Root and extracts	Panacea, cure-all, adaptogen, strengthening, increasing mental capacity	Unknown	Too much has been written, with considerable conflict of opinion. Ginseng abuse syndrome; research done mostly by manufacturers. Safety: not long-term use; efficacy questionable. <sup>3,16,20</sup> Not recommended in lactation. <sup>7</sup> Reduces effect of warfarin.
Grapefruit seed extract AAP – H – W – Grape seed AAP – H – W –		Flavonols Capsules, tablets (50-100 mg daily supplementation/ 150-300 mg daily therapeutic)	Antimicrobial inhibits intestinal cytochrome 450		Noted to have autoinfection, antiviral, antibacterial, and antifungal effects. Grapefruit is known to contain quinine, especially in the bitter skin and section fibers. Recommended as an extract for use by direct application on sore nipples. If it has antiinfectious properties, it should be effective when traumatized nipples have become infected. <sup>26</sup> Antioxidant, anticancer agent for varicose veins, circulatory problems. May increase risk for bleeding.
Herbal teas	Tablets, powders, tea leaves	May include Gerry mander, comfrey, mistletoe, skull cap, pennyroyal, all of which are toxic. Always check constituents.			Many cause hepatotoxicity and/or venous occlusive disease. Many associated with hemorrhagic disease. <sup>9,31</sup>
Kava AAP – H L5 W –  Licorice root	Piper methysticum, Kew, tonga  <i>Glycyrrhiza glabra</i> family	Roots/rhizomes, dihydropyrones with central nervous system activity, kavapyrones Glycyrrhizin acid rhizomes and roots	Inebriation, muscle relaxants, alternative to benzodiazepines  Laxative and cure for gastritis	Unknown Laxative, gastritis, hypokalemia	Unsafe in pregnancy and lactation. Numbs the mouth; nauseating. Causes yellow discoloration of the skin, hair, nails. <sup>11,12</sup> Known for 4000 years; large doses: weakness, edema, weight loss, hypertension, hypokalemia, and confusion. Consumption should be avoided in pregnancy and lactation. <sup>7,33</sup>

*Continued*

Herb Common Name/Rating*	Synonyms	Active Ingredient	Uses	Present in Milk	Safety/Efficacy
Milk thistle (holy thistle) (not blessed thistle) AAP – H L3 W – Raspberry root AAP – H – W –	<i>Silybum marianum</i> , St. Mary's thistle <i>Rubis idaeus</i> leaves	Fruits, flavolignans, inhibits oxidative damage to cells Promote diverse urinary tract infections, morning sickness, ease labor	Protective effect, concentrates in the liver	Unknown	Galactagogue. Problem: can cause allergy; low oral bioavailability. Probably safe. <sup>11</sup> Poor oral bioavailability. Safe in pregnancy and lactation. <sup>28</sup>
Sage AAP – H L4 W –	<i>Salvia officinalis</i>	Fresh leaves and fresh flowering aerial parts, dried leaves, and oils prepared as extracts and teas	Loss of appetite, inflammation of mouth and pharynx, excessive perspiration	Unknown	Contraindicated in pregnancy. Suppresses lactation. Okay as a flavoring. <sup>23</sup>
St. John's wort AAP – H L2 W –	<i>Hypericum perforatum</i> <i>Hyperforin</i> Flavonolignans seeds <i>Silybum marianum</i> , Milk thistle, BIO-C	Naphthodianthrone, phloroglucinols Antioxidant	Depression	Not detected Galactagogue	Can cause photosensitivity. Risk for self-medication for a serious psychiatric problem. Can reduce the effect of warfarin, induce cytochrome P-450 enzyme system. <sup>18,19,31</sup> Dose variable in different products. Poorly soluble in water micronized for oral use as galactagogue. <sup>9,10,28</sup>
Silymarin (micronized) AAP – H L3 W –		Liver protectant possibly			
Valerian root AAP – H L3 W –	<i>Valeriana officinalis</i> , all-heal, Amantilla, setwell, setewale, capon's tail, heliotrope, vandal root	Liquid, tablets, tea, volatile oil	Nervousness and insomnia	Unknown	Not recommended in lactation. Used as a sedative, hypnotic. <sup>12</sup>

\*Ratings for each drug represent three classification systems. American Academy of Pediatrics (AAP), Hale (H), and Weiner (W). See text for a complete listing of categories in each system. A dash indicates that the drug is not listed in that system.

## APPENDIX D

# Precautions and Breastfeeding Recommendations for Selected Maternal Infections

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections\*

Organism, Syndrome, or Condition†,‡	Empiric Precautions§	Breastfeeding Acceptable¶	Compatibility of Medications with Breastfeeding
Adenoviruses			
Conjunctivitis	Contact		
Upper/lower respiratory infections	Droplet	Yes <sup>#</sup>	
Gastroenteritis	Standard		
Amebiasis			
<i>Entamoeba histolytica</i>			
Intestinal	Standard	Yes	Iodoquinol, paromomycin, metronidazole, tinidazole
Extraintestinal	Standard	Yes	
Anthrax			
<i>Bacillus anthracis</i> (cutaneous, inhalation, gastrointestinal)	Standard, add contact precautions for draining cutaneous lesions	Yes, if cutaneous lesion is not on the breast and can be covered	Ciprofloxacin
Arboviruses			
Arthropod-borne infections, meningoencephalitis, hemorrhagic fevers, hepatitis	Standard	Yes**	
California encephalitis	Standard	Yes	
Colorado tick fever	Standard	Yes	
Dengue fever	Standard	Yes	

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd			
Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Eastern equine encephalitis	Standard	Yes	
Japanese encephalitis	Standard	Yes	
St. Louis encephalitis	Standard	Yes	
West Nile virus	Standard	Yes**	
Yellow fever	Standard	Yes	
Yellow fever vaccine virus	Standard	No**	
<i>Arcanobacterium haemolyticus</i>			
Pharyngitis, skin infections	Standard	Yes	Erythromycin, azithromycin, clindamycin, cefuroxime, tetracycline
<i>Ascaris lumbricoides</i>			
Gastrointestinal infections, pneumonitis	Standard	Yes	Pyrantel pamoate, mebendazole, albendazole, piperazine
Aspergillosis			
Bronchopulmonary, sinus, or invasive infections	Standard	Yes	Amphotericin B, flucytosine, rifampin
Astroviruses			
Gastroenteritis	Standard, but contact for incontinent individuals	Yes	
Babesiosis			
<i>Babesia microti</i>			
Subacute/chronic febrile illness	Standard	Yes	Clindamycin + quinine, atovaquone + azithromycin
<i>Blastocystis hominis</i>			
Gastrointestinal infection	Standard	Yes	Metronidazole, nitazoxanide, trimethoprim-sulfamethoxazole (TMP-SMX)
Blastomycosis			
<i>Blastomyces dermatitidis</i>			
Pulmonary, cutaneous, or invasive infection	Standard	Yes	Amphotericin B, fluconazole, itraconazole
<i>Borrelia</i>			
Relapsing fever			
<i>Borrelia hermsii</i>	Standard (tick-borne)	Yes	Penicillin, erythromycin, tetracycline
<i>Borrelia recurrentis</i>	Contact (louse-borne)	Yes	
<i>Borrelia turicatae</i>	Standard (tick-borne)	Yes	Doxycycline
Botulism			
<i>Clostridium botulinum</i>			
Hypotonia, progressive weakness, toxin-mediated paralysis	Standard	Yes	

Continued

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Breast abscess (see Mastitis)			
<i>Staphylococcus aureus</i> <i>Enterobacteriaceae</i> <i>Streptococcus pyogenes</i>	Contact (24 h)	Yes (after 24 h if no drainage into breast milk; discard breast milk for first 24 h after surgery)	First-generation cephalosporin, amoxicillin/clavulanate, ampicillin/sulbactam
Brucellosis			
Febrile illness with variable manifestations	Standard	Yes (after 48 h of therapy in mother; discard breast milk for 48 h)	Doxycycline, TMP-SMX, rifampin, gentamicin, streptomycin, tetracycline
<i>Brucella abortus</i> <i>Brucella melitensis</i> <i>Brucella suis</i>	Contact (for draining wounds)	Yes	
Caliciviruses			
Gastroenteritis	Standard, but contact for incontinent individuals	Yes	
<i>Campylobacter</i>			
Gastrointestinal infection <i>Campylobacter fetus</i> <i>Campylobacter jejuni</i>	Standard, but contact for incontinent individuals	Yes	Erythromycin, azithromycin, ciprofloxacin
Candidiasis			
Mucocutaneous infection, vulvovaginitis, invasive infections <i>Candida albicans</i> <i>Candida krusei</i> <i>Candida tropicalis</i>	Standard	Yes (therapy for the infant simultaneous with mother's therapy)**	Topical agents, fluconazole, ketoconazole, itraconazole, amphotericin B, flucytosine
Cat-scratch disease			
Skin infection, regional lymphadenitis, and rarely, invasive infection <i>Bartonella henselae</i>	Standard	Yes	Azithromycin, TMP-SMX, rifampin, ciprofloxacin, gentamicin, doxycycline, erythromycin
Chlamydia			
<i>Chlamydophila pneumoniae</i>	Standard	Yes	Tetracycline, doxycycline, erythromycin, azithromycin
Pharyngitis, pneumonia			
<i>Chlamydophila psittaci</i> Psittacosis, pneumonia, rarely invasive infection	Standard	Yes	Tetracycline, doxycycline, erythromycin, azithromycin
<i>Chlamydia trachomatis</i> Urethritis, vaginitis, endometritis, salpingitis, lymphogranuloma venereum, conjunctivitis, pneumonia	Standard	Yes (consider treating the infant simultaneously)	Erythromycin, azithromycin, doxycycline, sulfonamide, levofloxacin, ofloxacin
Clostridia			
<i>Clostridium botulinum</i>	Toxin-mediated paralysis	Standard	Antibiotic therapy not indicated

**TABLE D-1**

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Clostridium difficile</i>			
Antimicrobial-associated diarrhea, pseudomembranous colitis	Contact	Yes	Metronidazole, vancomycin, fidaxomicin
<i>Clostridium perfringens</i>			
Food poisoning, wound infection, gas gangrene, myonecrosis	Standard	Yes	
<i>Coccidioides immitis</i>			
Pulmonary, invasive infections rarely, extrapulmonary	Standard, but contact for draining lesions	Yes	Amphotericin B, fluconazole, itraconazole
Conjunctivitis			
Adenovirus	Contact	Yes	
<i>Chlamydia trachomatis</i>	Standard	Yes	Tetracycline, doxycycline, erythromycin
<i>Neisseria gonorrhoeae</i>	Standard	Yes <sup>††</sup>	Penicillin, ceftriaxone
<i>Cryptococcus neoformans</i>			
Meningitis, pneumonia	Standard	Yes	Amphotericin B, flucytosine, fluconazole
Cryptosporidiosis			
<i>Cryptosporidium parvum</i>			
Diarrhea	Contact	Yes	Nitazoxanide, paromomycin, azithromycin
Cytomegalovirus (CMV)			
Asymptomatic infection	Standard	Yes (for full-term infants)	
Infectious mononucleosis	Standard	No (for premature or immunodeficient infants, do not give expressed breast milk) <sup>**</sup>	
Dengue fever			
Acute febrile illness, hemorrhagic fever	Standard	Yes	
Diphtheria			
<i>Corynebacterium diphtheriae</i>			
Membranous nasopharyngitis	Droplet (DI)	Yes (with infant receiving chemoprophylaxis-P)	Erythromycin, penicillin
Obstructive laryngotracheitis	Droplet (DI)		
Cutaneous infection, toxin-mediated myocarditis, or neurologic disease	Contact (cover lesions)	No (only if skin lesion involves breast)	
Diarrhea			
<i>Campylobacter fetus</i>	Standard	Yes	Azithromycin
<i>Campylobacter jejuni</i>	Standard + Contact for infants	Yes	Erythromycin, ciprofloxacin
<i>Escherichia coli</i> (O157:H7)	Contact	Yes	None indicated
<i>Giardia lamblia</i>	Standard	Yes	Metronidazole, tinidazole, nitazoxanide
<i>Rotavirus</i>	Contact	Yes	
<i>Salmonella enteritidis</i>	Standard	Yes	

*Continued*

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Shigella boydii</i>	Contact	Yes	Ciprofloxacin, ceftriaxone, TMP-SMX
<i>Shigella dysenteriae</i>	Contact	Yes	Ciprofloxacin, ceftriaxone, TMP-SMX
<i>Shigella flexneri</i>	Contact	Yes	Ciprofloxacin, ceftriaxone, TMP-SMX
<i>Shigella sonnei</i>	Contact	Yes	Ciprofloxacin, ceftriaxone, TMP-SMX
<i>Vibrio cholerae</i>	Standard	Yes	Doxycycline, azithromycin, tetracycline, ciprofloxacin, furazolidone
<i>Vibrio parahaemolyticus</i>	Standard	Yes	None
<i>Yersinia enterocolitica</i>	Standard + Contact for incontinent persons	Yes	For sepsis or invasive disease—ciprofloxacin, norfloxacin, ceftriaxone, TMP-SMX, doxycycline
<i>Yersinia pseudotuberculosis</i>	Standard	Yes	
Ebola virus	Contact, droplet, and airborne	No (do not give expressed breast milk)	
Encephalitis			
Enteroviruses	Standard	Yes	
Lyme disease ( <i>Borrelia burgdorferi</i> )	Standard	Yes	Ceftriaxone, doxycycline, amoxicillin
Rabies	Standard	No (BM+)	Rabies immune globulin, rabies vaccine
Endometritis, pelvic inflammatory disease			
Anaerobic organisms	Standard	Yes	Clindamycin, metronidazole, cefoxitin, cefmetazole
<i>Chlamydia trachomatis</i>	Standard	Yes	Erythromycin, azithromycin, tetracycline, levofloxacin
<i>Enterobacteriaceae</i>	Standard	Yes	Ampicillin, aminoglycosides, cephalosporins
Group B streptococci	Standard	Yes** (after 24 h of therapy for mother, breast milk is permissible with observation of infant) No** (if infant is sick with suspected or proven group B streptococcal infection and the breast milk is being cultured to identify a source of infection; permissible if breast milk is culture negative)	Penicillin, cephalosporin, macrolides

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd			
Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Mycoplasma hominis</i>	Standard	Yes	Clindamycin, tetracycline
<i>Neisseria gonorrhoeae</i>	Standard	Yes <sup>††</sup>	Ceftriaxone, spectinomycin, doxycycline, azithromycin
<i>Ureaplasma urealyticum</i>	Standard	Yes	Erythromycin, azithromycin, clarithromycin, tetracycline
<b>Enteroviruses</b>			
Myocarditis: respiratory, gastrointestinal, skin, central nervous system, and eye infections	Adults: standard Children: contact		
Coxsackievirus		Yes	
Echovirus		Yes	
Polioviruses		Yes	
Epstein-Barr virus			
Infectious mononucleosis, broad range of infections	Standard	Yes	
<b>Erythema infectiosum</b>			
Parvovirus B19	Standard	Yes (no infectious risk after the appearance of the rash in immune-competent individuals)	
<b>Food poisoning</b>			
<i>Bacillus cereus</i>			
Toxin mediated	Standard	Yes	
<i>Clostridium perfringens</i>			
Toxin mediated	Standard	Yes	
<i>Escherichia coli</i> (O157:H7)	Contact	Yes	
Enterohemorrhagic			
Hepatitis A	Standard	Yes (immune serum globulin and hepatitis A vaccine for the infant)	
Norwalk virus	Standard	Yes	
<i>Salmonella enteritidis</i>	Standard	Yes	
<i>Shigella</i>	Contact	Yes	Ciprofloxacin, TMP-SMX
<i>Staphylococcus aureus</i>			
Enterotoxin	Standard	Yes	
<b>Gastroenteritis (see Diarrhea or Food Poisoning)</b>			
Giardiasis			
<i>Giardia lamblia</i>	Standard, no contact with incontinent individuals	Yes	Metronidazole, tinidazole, nitazoxanide
<b>Gonorrhea</b>			
Genital, pharyngeal, conjunctival, or disseminated infection			
<i>Neisseria gonorrhoeae</i>	Standard	Yes <sup>††</sup>	Ceftriaxone, azithromycin, erythromycin, doxycycline

Continued

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Haemophilus influenzae</i>			
Meningitis, epiglottitis, pneumonia, cellulitis, sinusitis, bacteremia	Droplet	Yes (24 h after initiating therapy in mother; breast milk <sup>†</sup> ; <i>P</i> ** if infant has not been fully immunized, observation)	Cefotaxime, ceftriaxone, ampicillin
Hantavirus			
Pulmonary syndrome, hemorrhagic fever with renal syndrome	Standard	Yes	Intravenous ribavirin is investigational
Hemorrhagic fevers			
African hemorrhagic fever			
Ebola virus	Contact	No (no expressed breast milk)	
Marburg virus	Contact	No (no expressed breast milk)	
Dengue virus (1–4)	Standard	Yes (breast milk +)	
Hantavirus	Standard	Yes (breast milk +)	
Lassa fever	Contact	No (no expressed breast milk)	Intravenous ribavirin?
Yellow fever	Standard	Yes** (breast milk +)	Vaccine
Yellow fever vaccine virus immunization in mother**	Standard	No**	
Hepatitis*			
A Acute only	Standard, but contact for incontinent individuals	Yes (after immune serum globulin [ISG] and vaccine)	
B Chronic hepatitis, cirrhosis, hepatocellular carcinoma	Standard	Yes (after hepatitis B immunoglobulin [HBIG] and vaccine)	
C Chronic hepatitis, cirrhosis, hepatocellular carcinoma	Standard	Yes	
D Associated with hepatitis B	Standard	Yes (after HBIG and vaccine)	
E Severe disease in pregnant women	Standard	Yes	
G	Standard	Inadequate data	
Herpesviruses			
Cytomegalovirus (CMV)	Standard	Yes for full-term infants	Ganciclovir, valganciclovir, foscarnet
Asymptomatic, infectious mononucleosis-like syndrome: severe disease in the immunodeficient person		No for premature or immunodeficient infants (infant of CMV-negative mother should not receive milk from CMV-positive mothers)	
Epstein-Barr virus			
Asymptomatic, infectious mononucleosis, associated with chronic fatigue syndrome, African Burkitt lymphoma, and nasopharyngeal carcinoma	Standard	Yes	
Herpes simplex			
Types 1, 2 (HSV <sub>1,2</sub> )			
Mucocutaneous	Contact	Yes (in the absence of breast lesions)	Acyclovir, valacyclovir, famciclovir
Neonatal	Contact		
Encephalitis	Standard		

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd			
Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Varicella-zoster virus**			
Varicella	Airborne	No (Breast milk + is permissible in absence of lesions on the breast). Give VariZIG for the exposed infant.	Acyclovir, valacyclovir, famciclovir
Zoster	Standard in normal patient Airborne/contact in immunocompromised individuals	No, VariZIG for the exposed infant, especially less than 1 month of age**	
Human herpesvirus 6 (HHV-6)			
Roseola (exanthema subitum, sixth disease), acute febrile illness	Standard	Yes	
Histoplasmosis			
Acute pulmonary disease, disseminated	Standard	Yes	Amphotericin B, itraconazole, fluconazole
Human immunodeficiency viruses (HIV)**			
HIV-1	Standard	Yes/no**	Limited information on antiretrovirals in breast milk** Antiretroviral medications for the mother and/or infant through period of lactation
HIV-2	Standard	Yes/no**	
Human T-cell leukemia viruses (HTLV)			
HTLV-I			
T-cell leukemia/lymphoma, myelopathy, dermatitis, adenitis, Sjögren's syndrome	Standard	No**	
HTLV-II			
Myelopathy, arthritis, glomerulonephritis	Standard	No**	
Impetigo	Contact	Yes	Oxacillin, dicloxacillin, erythromycin, first-generation cephalosporins
Infectious mononucleosis (see CMV, EBV)			
Influenza	Droplet	Yes	Oseltamivir, zanamivir, amantadine, rimantadine
Junin virus			
Argentine hemorrhagic fever	Contact	No (do not give expressed breast milk)	
Lassa fever	Contact	No (do not give expressed breast milk)	Intravenous ribavirin
Legionnaires' disease			
<i>Legionella pneumophila</i>	Standard	Yes	Azithromycin, erythromycin, levofloxacin

*Continued*

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd			
Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Pneumonia ± gastrointestinal, central nervous system, or renal involvement			
Leprosy			
<i>Mycobacterium leprae</i>	Standard	Yes	Dapsone, rifampin, clofazimine
Chronic disease of skin, peripheral nerves, and respiratory mucosa			
Leptospirosis			
Abrupt febrile illness, often biphasic, with multiple organ involvement			
<i>Leptospira interrogans</i>	Standard	Yes (no mother-infant contact except for breastfeeding)	Penicillin, cefotaxime, ceftriaxone
<i>Leptospira icterohaemorrhagiae</i>			
<i>Leptospira canicola</i>			
<i>Listeria monocytogenes</i>			
In adults: Nonspecific febrile illness; in neonates: meningitis, pneumonia, sepsis, granulomatosis infantisepticum	Standard	Yes	Ampicillin, penicillin, TMP-SMX
Lyme disease			
<i>Borrelia burgdorferi</i>			
Multistaged illness of skin, joint, and peripheral or central nervous system	Standard	Yes, with informed discussion**	Ceftriaxone, ampicillin, doxycycline
Lymphocytic choriomeningitis			
Aseptic meningitis to severe encephalitis, with variable presentation of other symptoms	Standard	Yes	
Malaria	Standard	Yes	Pyrimethamine-sulfadoxine, chloroquine, quinidine, quinine, tetracycline, mefloquine
Marburg virus			
Hemorrhagic fever	Contact	No (no expressed breast milk)	
Mastitis			
<i>Candida albicans</i>	Standard	Yes, with simultaneous treatment of the infant**	Nystatin, ketoconazole, fluconazole
Enterobacteriaceae	Standard	Yes	First-generation cephalosporin,
<i>Staphylococcus aureus</i>	Contact	Yes** (after 24 h of therapy, during which milk must be discarded) (If infant becomes ill during evaluation and treatment of mother, infant should be treated for presumed staphylococcal infection, and breast milk should be withheld until proven to be culture negative.)	Dicloxacillin, oxacillin, erythromycin

**TABLE D-1**

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition*	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Group A streptococcus	Contact	Yes** (after 24 h of therapy, during which milk must be discarded) (If infant becomes ill during evaluation and treatment of mother, infant should be treated for presumed streptococcal infection, and breast milk should be withheld until proven to be culturally negative.)	Ampicillin, third-generation cephalosporin
<i>Mycobacterium tuberculosis</i>	Standard (if mother has pulmonary involvement, then airborne precautions as well)	No** (breastfeeding for 2 weeks of maternal therapy, consider prophylactic INH for infant [see Figures 16-1 and 16-2], breast milk permissible with INH)	Isoniazid, rifampin, ethambutol, pyrazinamide, ethionamide
<b>Measles</b>			
Febrile illness with coryza, conjunctivitis, cough, and an erythematous maculopapular rash	Airborne	Yes (after 72 h of rash in mother and after infant receives ISG, expressed breast milk is permissible)	Ribavirin is experimental
<b>Meningitis</b>			
Aseptic meningitis (nonbacterial, viral meningitis)	Standard	Yes	
Fungal meningitis	Standard	Yes	Amphotericin, itraconazole, flucytosine
<i>Haemophilus influenzae</i>	Droplet (for first 24 h of appropriate therapy and carrier eradication with ceftriaxone or rifampin)	Yes (after 24 h of maternal therapy, with the infant receiving prophylaxis, P; begin infant vaccination; expressed breast milk is permissible)	Ceftriaxone, ampicillin, chloramphenicol, rifampin
<i>Neisseria meningitidis</i>	Droplet (24 h of appropriate therapy and carrier eradication with ceftriaxone or rifampin)	Yes (after 24 h of maternal therapy, with the infant receiving prophylaxis, P; expressed breast milk is permissible)	Ceftriaxone, penicillin, chloramphenicol
<i>Streptococcal pneumoniae</i>	Standard	Yes	Ceftriaxone, penicillin, vancomycin
Mumps	Droplet	Yes	
<i>Mycobacterium tuberculosis</i> **	Standard and airborne	Yes	Antituberculosis medications are acceptable during breastfeeding (see Chapter 13, section on Tuberculosis and ** Red Book, 30th Edition)
<b><i>Mycoplasma pneumoniae</i></b>			
Bronchitis, pneumonia, pharyngitis, otitis media, and a broad range of unusual manifestations, including central nervous system, cardiac, skin, muscle, and joint involvement	Droplet	Yes	Erythromycin, clarithromycin, azithromycin, tetracycline

*Continued*

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Neisseria meningitidis</i>			
Meningitis, meningococcemia	Droplet (for 24 h of appropriate therapy and carrier eradication with ceftriaxone or rifampin)	Yes (after 24 h of appropriate therapy, and with prophylaxis for the infant)	Penicillin, ceftriaxone, chloramphenicol, rifampin
Norwalk agent			
Gastroenteritis	Standard	Yes	
Papillomaviruses			
Skin or mucous membrane warts, laryngeal papillomas	Standard	Yes (in the absence of breast involvement)	
Parainfluenza viruses			
Laryngotracheobronchitis, upper and lower respiratory infections	Standard (contact for infants and children)	Yes	
Parvovirus B19			
Erythema infectiosum, fifth disease, aplastic crisis, arthritis	Standard Droplet for mothers with aplastic crisis or immunodeficient and prolonged illness	Yes (no infectious risk after the appearance of the rash in immune-competent individuals) No (for aplastic crisis or infection in individuals with hemoglobinopathy or immune deficiency infection for the duration of the illness [DI]) <sup>§</sup>	
Pelvic inflammatory disease (see Endometritis)			
Pertussis			
Whooping cough, pneumonia, bronchitis, encephalitis			
<i>Bordetella parapertussis</i> and <i>Bordetella pertussis</i>	Droplet (for 5 days of appropriate therapy)	Yes (after 5 days of appropriate therapy and chemoprophylaxis for the infant, expressed breast milk is permissible) If no appropriate Rx is given then 3 weeks of droplet precautions	Erythromycin, clarithromycin, TMP-SMX
<i>Pneumocystis jirovecii</i> pneumonia (previously <i>Pneumocystis carinii</i> pneumonitis)	Standard	Yes, but suspect HIV infection if mother develops symptoms and reassess breastfeeding with HIV infection in mind	Pentamidine, TMP-SMX, atovaquone, prednisone
Pneumonia (see specific causative agents)			
Poliomyelitis	Standard	Yes	
Rabies			
Severe, progressive central nervous system infection, generally fatal	Standard	No** (when mother is clinically sick) Yes** (BM+) (during postexposure immunization of mother without symptoms; yes if both mother and infant are receiving postexposure immunization)	Rabies immune globulin, rabies vaccine
Rat-bite fever			
<i>Spirillum minus</i>	Standard	Yes	Tetracycline, chloramphenicol, streptomycin
<i>Streptobacillus moniliformis</i>	Standard	Yes	Penicillin

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd			
Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Relapsing fever <i>Borrelia recurrentis</i>	Standard (tick-borne) Contact if louse infested	Yes Yes with simultaneous treatment of mother and infant for lice	Tetracycline, doxycycline, TMP-SMX, streptomycin, rifampin
Respiratory syncytial virus Upper respiratory infection, pneumonia, bronchiolitis	Contact	Yes	Ribavirin
Retroviruses (see Human immunodeficiency viruses 1, 2 and Human T-cell leukemia viruses I, II)			
Rickettsial diseases			
Fever, rash, vasculitis; arthropod, louse-borne			
Ehrlichiosis, leukopenia	Standard	Yes	Doxycycline, tetracycline
<i>Ehrlichia chaffeensis</i>			
Q fever			
<i>Coxiella burnetii</i>			
Pneumonia, hepatosplenomegaly, endocarditis	Standard	Yes	Doxycycline, tetracycline, TMP-SMX
Rickettsial pox			
<i>Rickettsia akari</i>			
Scab or eschar, rash, regional lymphadenopathy, self-limited	Standard	Yes	Doxycycline, tetracycline, fluoroquinolones
Rocky Mountain spotted fever			
<i>Rickettsia rickettsii</i>	Standard	Yes	Doxycycline
Typhus (flea-borne)			
<i>Rickettsia typhi</i>	Standard	Yes	Doxycycline, fluoroquinolones
Typhus (louse-borne)			
<i>Rickettsia prowazekii</i>	Standard	Yes	Doxycycline (in epidemic situations a single dose may be adequate), chloramphenicol
Rotavirus			
Diarrhea, vomiting, "winter vomiting disease"	Contact	Yes	
Rubella virus			
Self-limited, mild exanthem with fever: congenital rubella syndrome	Contact	Yes	
Salmonella (see Diarrhea/gastroenteritis)			
SARS-associated coronavirus, severe acute respiratory syndrome	Droplet	Yes	

*Continued*

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Shigella</i> (see <i>Diarrhea</i> )			
Smallpox			
Variola virus (variola major)	Contact, airborne	No (no expressed breast milk)	
Vaccinia virus (smallpox vaccine) secondary contact infection	Contact	Yes, except if breast involved with lesions	
<i>Staphylococcus aureus</i>			
Cellulitis, abscess	Contact	Yes	Oxacillin, dicloxacillin, first-generation cephalosporins, erythromycin, vancomycin
Enterocolitis, diarrhea	Standard	Yes	
Scalded-skin syndrome	Contact	Yes (after 24 h of effective therapy; discard breast milk for 24 h)	
Toxic shock syndrome	Standard	Yes**	
Methicillin-resistant <i>S. aureus</i> (MRSA)	Contact	Yes** (after 24 h of therapy, during which milk must be discarded) (If infant becomes ill during evaluation and treatment of mother, infant should be treated for presumed MRSA infection, and breast milk should be withheld until proven to be culture negative.)	Vancomycin, TMP-SMX, clindamycin, linezolid
<i>Staphylococcus epidermidis</i>			
Opportunistic infections	Standard	Yes	Oxacillin, dicloxacillin, vancomycin
Streptococcus			
Group A: Cellulitis, pharyngitis, pneumonia, myositis/fasciitis, scarlet fever	Standard	Yes (24 h after beginning appropriate therapy; discard breast milk for 24 h)	Penicillin, erythromycin, cephalosporin
	Contact (for extensive skin infection unable to be covered until after 24 h of therapy)	Yes (24 h after beginning appropriate therapy; discard breast milk for 24 h)	
Group B: Urinary tract infection, endometritis, mastitis; infants: sepsis, pneumonia, meningitis, osteomyelitis, arthritis	Standard	Yes** (after 24 h of therapy, during which milk must be discarded) (If infant becomes ill during evaluation and treatment of mother, infant should be treated for presumed Streptococcal infection, and breast milk should be withheld until proven to be culture negative.)	Penicillin, ampicillin, third-generation cephalosporin
<i>Streptococcus pneumoniae</i>			
Pneumonia, occult bacteremia, otitis media, sinusitis	Standard	Yes	Penicillin, ceftriaxone, vancomycin, cefotaxime, rifampin

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd			
Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Syphilis			
<i>Treponema pallidum</i>			
Multisystem, multistage infection with widely varying presentations, congenital infection	Standard	Yes (after 24 h of effective therapy; discard breast milk for 24 h)	Penicillin, doxycycline, tetracycline
Open skin lesions of breast or nipples	Contact	No, until 24 h of effective therapy in mother if open skin lesions involve breasts	Penicillin, doxycycline, tetracycline
Tetanus			
<i>Clostridium tetani</i>	Standard	Yes (age-appropriate vaccination of the child, no tetanus immunoglobulin [TIG] necessary for infant)	Penicillin, metronidazole
Tinea capitis			
<i>Microsporum audouinii</i>	Standard	Yes	Griseofulvin, terbinafine, selenium sulfide shampoo, prednisone
<i>Microsporum canis</i>			
<i>Trichophyton tonsurans</i>			
Tinea corporis, cruris, pedis			
<i>Epidermophyton floccosum</i>	Standard	Yes	Topical agents
<i>Trichophyton canis</i>			
<i>Trichophyton rubrum</i>			
Tinea versicolor			
<i>Malassezia furfur</i>	Standard	Yes	Topical agents, ketoconazole, itraconazole
Toxoplasmosis			
<i>Toxoplasma gondii</i>	Standard	Yes	Pyrimethamine, sulfadiazine, TMP-SMX, dapsone, atovaquone, clindamycin
Asymptomatic or mononucleosis-like illness with lymphadenopathy, ocular symptoms; congenital infection			
Toxic shock (see <i>S. aureus</i> , <i>Streptococcus</i> [group A])			
Toxin-mediated illness (see specific agents)			
<i>Bacillus cereus</i>			
Botulism			
Food poisoning			
Staphylococcal scalded-skin syndrome (SSSS)			
Trichinosis			
<i>Trichinella spiralis</i>			
Asymptomatic, or may cause myalgia, periorbital edema, myocardial failure, CNS involvement, or pneumonitis	Standard	Yes	Albendazole, mebendazole, thiabendazole, prednisone

Continued

**TABLE D-1** Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
<i>Trichomonas vaginalis</i>			
Vaginitis, urethritis, or asymptomatic infections	Standard	Yes	Metronidazole, tinidazole
Trypanosomiasis			
<i>Trypanosoma brucei</i>			
"Sleeping sickness"; tsetse fly vector (African)	Standard	No	Suramin, pentamidine, eflornithine, melarsoprol
<i>Trypanosoma cruzi</i>			
Chagas disease (American)	Standard	Yes	Nifurtimox, benznidazole
TT virus			
Hepatitis	Standard	Yes	
Tuberculosis (see <i>mycobacterium</i> in this Appendix; see Chapter 13, Figures 13-2 and 13-3 and Table 13-1; see ** Red Book, 30th Edition)			
Tularemia			
<i>Francisella tularensis</i>			
Acute febrile illness with various syndromes; oculoglandular, ulceroglandular, glandular, oropharyngeal, typhoidal, pneumoniae	Standard	Yes	Streptomycin, gentamicin, doxycycline, ciprofloxacin
<i>Ureaplasma urealyticum</i>			
Nongonococcal urethritis (NGU), endometritis, pelvic inflammatory disease	Standard	Yes	Doxycycline, erythromycin, azithromycin, clarithromycin, ciprofloxacin
Urinary tract infection			
Group B streptococcus (see <i>Streptococcus</i> [group B])	Standard	Yes	Ampicillin, aminoglycosides, cephalosporin
Enterobacteriaceal	Standard	Yes	Ampicillin, cephalosporins, fluoroquinolones
<i>Staphylococcus saprophyticus</i>	Standard	Yes	Vancomycin, clindamycin + rifampin
Vaginitis			
Bacterial	Standard	Yes	Metronidazole, clindamycin
<i>Candida albicans</i> (see Candidiasis)			
Varicella-zoster virus (see Herpesviruses)			
West Nile virus	Standard	Yes**	
Asymptomatic, fever, meningoencephalitis			
Whooping cough			
<i>Bordetella parapertussis</i> and <i>Bordetella pertussis</i> ; see also Adenovirus, <i>Chlamydia</i> ( <i>Chlamydia pneumoniae</i> , <i>Chlamydia trachomatis</i> ), <i>Mycoplasma pneumoniae</i> as other agents may mimic the clinical picture of whooping cough	Droplet (for 5 days of appropriate therapy and chemoprophylaxis for infant)	Yes, after 5 days of appropriate therapy, breast milk+, P**	Erythromycin, clarithromycin, TMP-SMX

**TABLE D-1**

Precautions and Breastfeeding Recommendations for Selected Maternal Infections—cont'd

Organism, Syndrome, or Condition <sup>a</sup>	Empiric Precautions	Breastfeeding Acceptable	Compatibility of Medications with Breastfeeding
Yellow fever			
Yellow fever virus	Standard	Yes**	
Yellow fever vaccine virus	Standard	No**	Avoid yellow fever vaccine virus immunization during lactation if possible**
<i>Yersinia enterocolitica</i>			
Diarrhea, pseudoappendicitis, focal infections, and bacteremia	Contact precautions for incontinent individuals	Yes	Cefotaxime, aminoglycosides, TMP-SMX, fluoroquinolones
<i>Yersinia pseudotuberculosis</i>			
Fever, rash, abdominal symptoms	Standard	Yes	TMP-SMX

\*To ensure that appropriate empiric precautions are always implemented, hospitals must have systems in place to routinely evaluate patients according to these criteria as part of their preadmission and admission care.

<sup>a</sup>Patients with the syndromes or conditions listed may present with atypical signs and symptoms (e.g., pertussis in neonates and adults may not have paroxysmal or severe cough). A clinician's index of suspicion should be guided by the prevalence of specific conditions in the community as well as clinical judgment.

<sup>b</sup>The organisms listed are not intended to represent the complete, or even most likely diagnoses, but rather possible etiologic agents that may require additional precautions, beyond *standard precautions*, until they can be excluded.

<sup>c</sup>These are the usual precautions (Standard, Airborne, Contact, and Droplet) outlined in the text, as proposed by the Centers for Disease Control and Prevention. Symbols for duration of precautions: 24 hours, 24 hours of antibiotic therapy; CN, until off antibiotics and culture negative; DI, duration of the illness; PI, period of infectivity.

<sup>d</sup>Yes means that if, in a hospitalized mother and infant, the proposed precautions are followed, breastfeeding is acceptable and may be beneficial to the infant. Any infant breastfeeding during a maternal infection should be observed closely for signs or symptoms of illness.

<sup>e</sup>See Chapter 12 on medications in breast milk, in this book, and refer to LactMed at <http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>.

<sup>f</sup>Adenovirus types 4 and 7 have been known to cause severe respiratory disease in premature infants or individuals with immunodeficiency or underlying respiratory disease. In certain situations, feeding of expressed breast milk to an infant may not be advisable.

<sup>g</sup>See text for more complete explanation. P, Prophylactic antibiotics for the infant. See the 2015 Report of the Committee on Infectious Diseases, *Red Book*, 30th edition, for current recommendations on the specific antibiotics for the specific condition.

<sup>h</sup>Breastfeed immediately if mother receives ceftriaxone intramuscularly or intravenously. Breastfeed after 24-hour antibiotic therapy for other treatment regimens, with feeding expressed breast milk for the first 24 hours.

Modified from Garner JS: Hospital Infection Control Practices Advisory Committee guidelines for isolation precautions in hospitals, *Infect Control Hosp Epidemiol* 17:53, 1996.

## APPENDIX E

# *Manual Expression of Breast Milk*

A health care professional should be familiar with the technique of manual expression and be able to diagnose improper technique.

### *Technique*

All breastfeeding women should be familiar with the basic technique of manual expression of milk from the breast, and ideally this technique is acquired before discharge from the hospital and with the assistance of the nursery or postpartum nursing staff.

Reasons to express breast milk include the following:

1. To initiate flow and assist an infant to grasp the breast properly
2. To encourage production of milk early in lactation when an infant is premature or ill
3. To relieve engorgement
4. To remove milk when it is not possible to nurse an infant at a given feeding
5. To maintain lactation when an infant cannot be fed
6. To pump and save milk for feeding an infant at another time
7. To contribute to a milk bank
8. To pump and discard milk while temporarily on a specific medication

Manual expression is appropriate to initiate flow before applying a hand pump or an electric pump. Not many women can manually pump large volumes over time without mechanical assistance.

The breast should always be massaged, and flow initiated, before applying any pump.

### *Procedure*

*Step 1.* Always wash hands before handling a breast.  
*Step 2.* Breast massage: Whether planning to manually express or mechanically pump, preparing the breast for ejecting the milk facilitates the process. The release of oxytocin and the ejection reflex are stimulated by external stimuli: a baby's cry, a picture of the baby, or gentle handling of the breast. Prolactin release and milk production are stimulated by "sucking" stimulation.

After the mother finds a comfortable sitting position and is relaxed, the breast is exposed and gently stroked with the fingertips from periphery to areola ([Figure E-1](#)). As this stroking is intensified, one should avoid slipping the hand across skin and irritating tissues. Gently massage. A warm washcloth soak is also helpful in initiating flow through the ducts. Gentle fingertip massage around all quadrants should follow and be repeated several times during extended mechanical pumping. It should not leave red marks or hurt.

*Step 3.* Position hands on the breast: Usually placing the fingers below and thumb on top is natural for most women. One hand placed above and one hand placed below the areola may be easier when the hand is small compared with breast size. The target area is beyond the ampullae, which are the collecting areas of the main ducts that radiate out from the nipple to the areola.

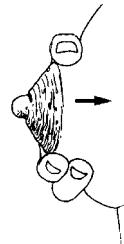

The ampullae are approximately 3 cm from the nipple base, which may not be at the edge of the areola. Press toward the chest wall, and then compress the thumb and fingers together (Figure E-2). Continue to compress the breast while moving the hand away from the chest wall in a "milking" action toward the nipple (Figure E-3). (Avoid pulling, squeezing, or rubbing motions.) Perform this motion in a repeated rhythmic manner at a comfortable, but not abrasive, rate. Infant suckling does not involve movement (stroking) of the tongue along the elongated areola and nipple, but an undulating motion of the tongue itself. Simulating that motion is the goal of manual expression. This action is similar to a peristaltic motion. The hand should be rotated around the breast to massage and stroke all quadrants, including the periphery and the axillae.

Use one or both hands to find the most productive grasp. Preventing trauma is essential; thus, avoid squeezing, rubbing, or pulling the breast tissue. Every mother develops her own natural pattern, so rigid adherence to methods may be counterproductive. Effectiveness is measured by the comfortable release of milk.

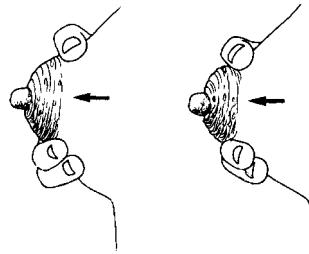

Total emptying of the breast will require 20 to 30 minutes of manual stimulation. Warm compresses, hot showers, or suspending the breast in a bowl of warm water may help, especially if engorgement or mastitis is present. Leaning over and gently shaking the breast may help stimulate flow. Manual expression while leaning over may help empty the lower quadrants.

## APPENDIX F

# *The Storage of Human Milk*

---

### *Academy of Breastfeeding Medicine's Human Milk Storage Information for Home Use for Healthy Full-Term Infants*

---

Please see [Appendix J-8](#), [Table F-1](#), and [Box F-1](#) for guidelines on milk storage and thawing.

### *Human Milk Banking and the HMBANA*

---

The Human Milk Banking Association of North America (HMBANA) was established in 1985, drawing together representatives of donor milk banks and members of the medical community. The goals of HMBANA are as follows:

1. Provide a forum for networking among experts in the field on issues relating to human milk banking;
2. Provide information to the medical community on the benefits and appropriate uses of banked human milk;
3. Develop and annually review guidelines for milk banking practices in North America;
4. Communicate among member milk banks to ensure adequate supplies for all patients;
5. Encourage research into the unique properties of human milk and its uses;
6. Act as a liaison between member institutions and governmental regulatory agencies;
7. Ensure quality control of donor human milk banking among member banks through adherence to the mandatory guidelines and periodic inspection of member banks.

### **WHAT IS A HUMAN MILK BANK?**

A donor human milk bank is a service established for the purpose of collecting, screening, processing, storing, and distributing donated human milk to meet the specific medical needs of individuals for whom human milk is prescribed by physicians. A small processing fee is charged by each milk bank on a per-ounce basis.

### **HOW DOES A HUMAN MILK BANK OPERATE?**

Donor human milk banks solicit lactating mothers to donate milk. Donors are carefully screened for health behaviors and tested for communicable diseases before they are accepted as donors.

Donors are taught how to express their milk using sanitary collecting methods.

Donated milk is heat treated to destroy any bacteria or viruses that may be present.

Frozen, heat-treated milk is dispensed to recipients with a medical need for donor milk. A physician's prescription is required.

### *Frequent Reasons for Prescribing Donor Milk*

---

### **NUTRITIONAL USES**

Prematurity  
Failure to thrive  
Malabsorption syndromes  
Short-gut syndrome  
Renal failure  
Feeding intolerance  
Inborn errors of metabolism  
Postsurgical nutrition

**TABLE F-1**

Storage of Human Milk for Home Use

Breast Milk	Room Temperature	Refrigerator	Freezer
Freshly expressed into closed container	6-8 h (78°F or lower)	3-5 days (39°F or lower)	2 weeks in freezer compartment inside refrigerator 3 to 6 months in freezer section of refrigerator with separate door; 6-12 months in deep freeze (0°F or lower)
Previously frozen Thawed in refrigerator but not warmed or used	4 h or less (i.e., next feeding)	Store in refrigerator 24 h	Do not refreeze
Thawed outside refrigerator in warm water	For completion of feeding	Hold for 4 h or until next feeding	Do not refreeze
Infant has begun feeding	Only for completion of feeding; then discard	Discard	Discard

Developed from recommendations of the Human Milk Banking Association of North America and current literature. See References, Chapter 21.

#### **BOX F-1. Suggestions for Milk Storage for Infant at Home**

- Wash hands thoroughly.
- Polyethylene bags are acceptable for home use.
- Refrigerate or freeze milk after expressing.
- Use fresh milk whenever possible.
- Freeze milk that will not be used within 2 days.
- Use milk stored in a self-defrosting freezer within 3 months (top of refrigerator).
- Use milk stored in a deep freezer within 12 months.
- Use the oldest milk first. Date container at time of collection.

Cardiac problems

Bronchopulmonary dysplasia

Pediatric burn cases

#### **MEDICINAL/THERAPEUTIC USES**

Treatment for infectious diseases, such as intractable diarrhea, gastroenteritis, infantile botulism, sepsis, pneumonia, and hemorrhagic conjunctivitis

Postsurgical healing (omphalocele, gastroschisis, intestinal obstruction/bowel fistula, colostomy repair)

Immunodeficiency diseases (severe allergies, IgA deficiencies)

Inborn errors of metabolism

Solid-organ transplants (including use for adults)

Noninfectious intestinal disorders (ulcerative colitis, irritable bowel syndrome)

#### **PREVENTIVE USES**

Necrotizing enterocolitis

Crohn disease

Colitis

Allergies to bovine and soy milks/feeding intolerance

During immune suppression therapy

## DEFINITIONS

*Donor human milk bank:* A donor human milk bank is a service established for the purpose of collecting, screening, processing, storing, and distributing donated human milk to meet the specific needs of individuals for whom human milk is prescribed by health care providers who are licensed to prescribe.

*Donor milk:* Donor milk is voluntarily given by women other than the biologic mother of the recipient. Donors are not paid.

*Fresh-raw milk:* Milk stored continuously at approximately 4°C for use not longer than 72 hours after expression.

*Fresh-frozen milk:* Fresh-raw milk that has been frozen and held at approximately -20°C for not longer than 12 months from the date of collection.

*Heat-processed milk:* Fresh-raw or fresh-frozen milk that has been heated to a minimum of 62.5°C, but no more than 63°C, for 30 minutes, to minimize loss of the unique beneficial properties of the milk.

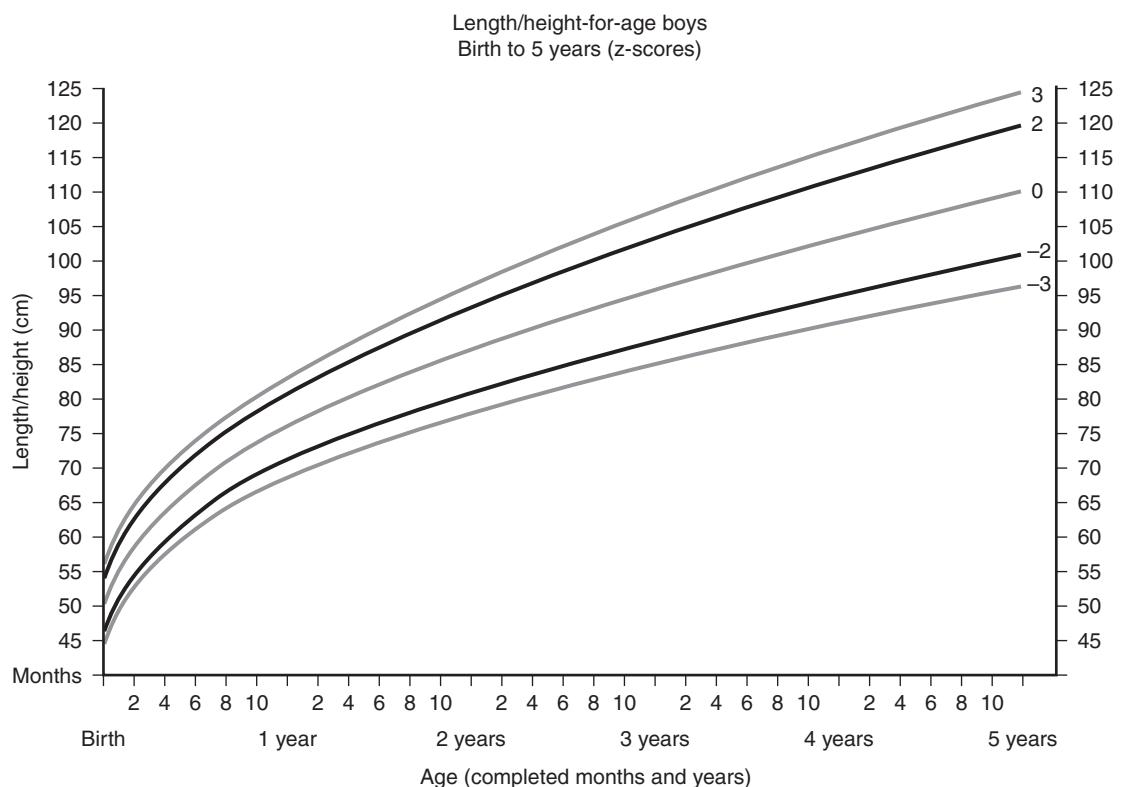

*Pooled milk:* Milk received from more than one donor.

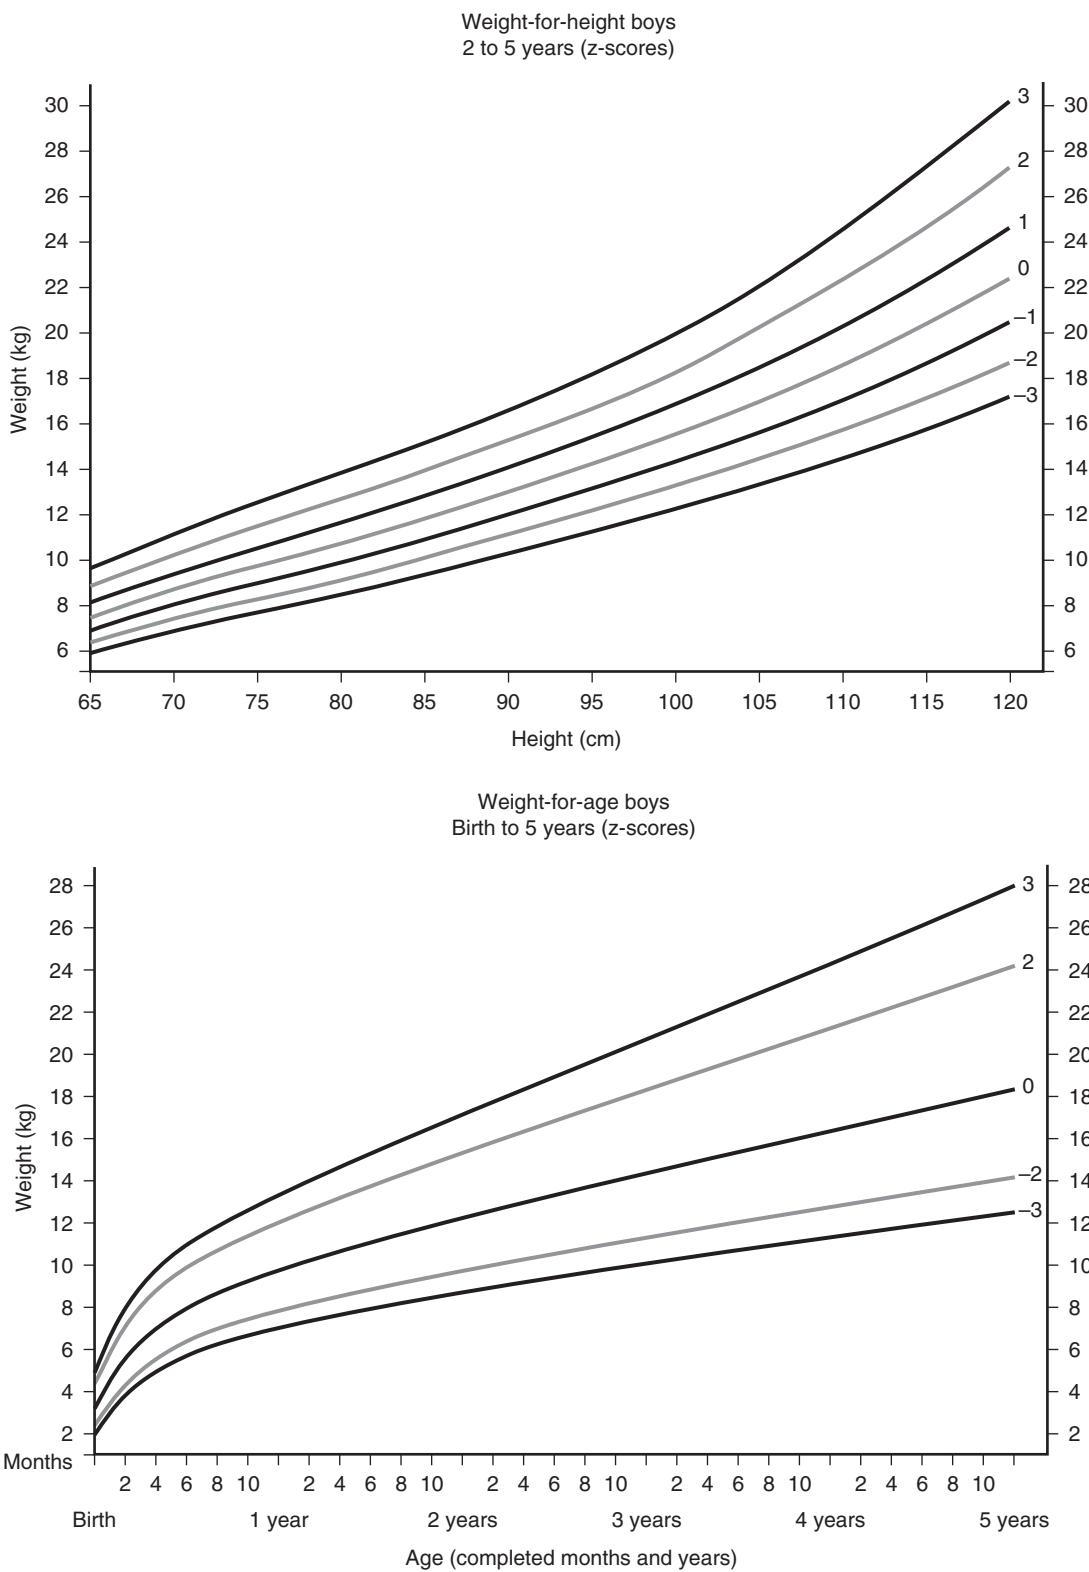

*Preterm milk:* Milk pumped within the first month postpartum by a mother who delivered at or before 36 weeks' gestation.

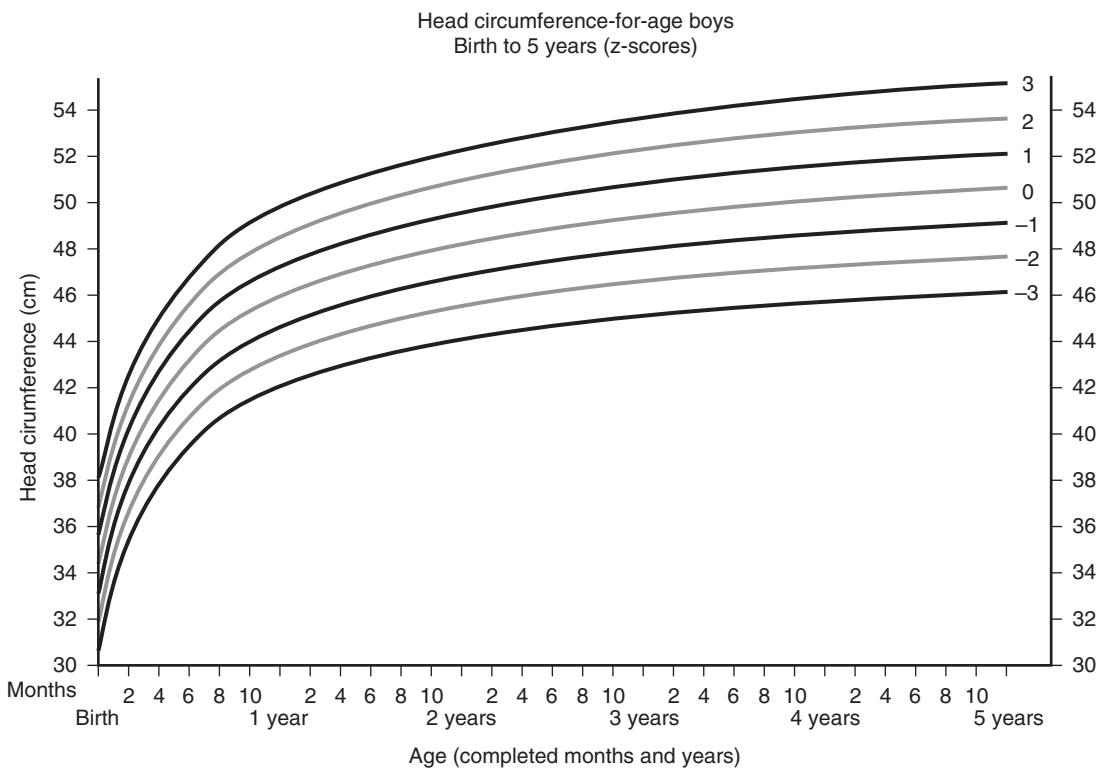

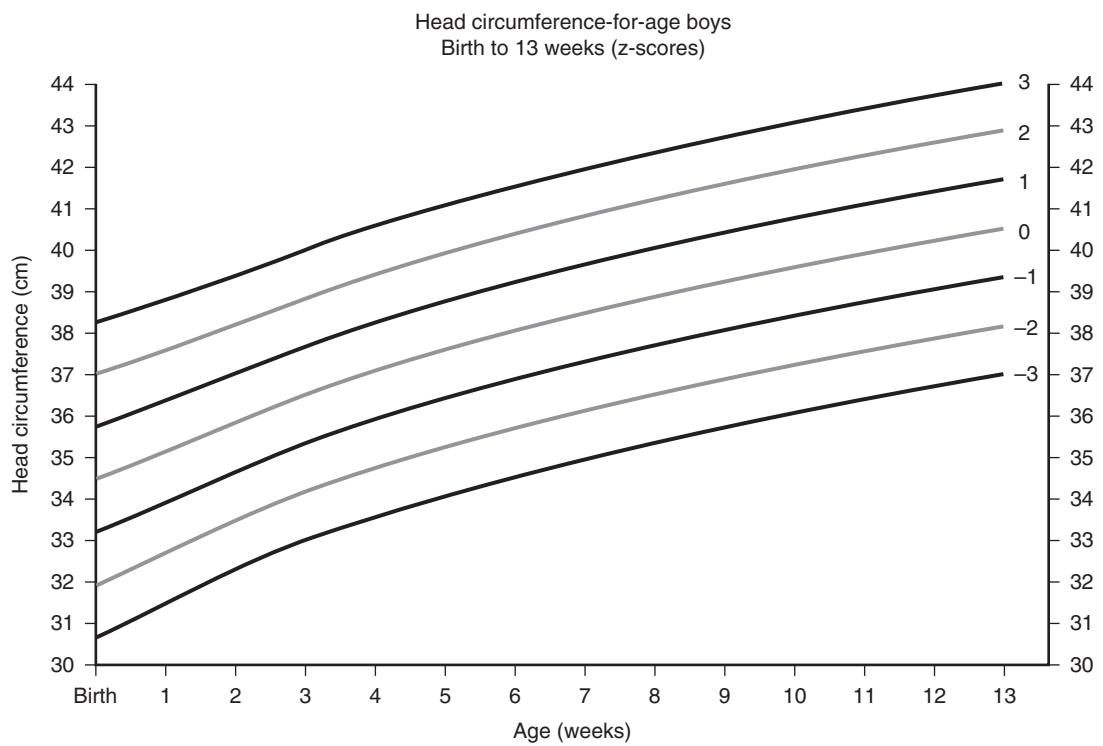

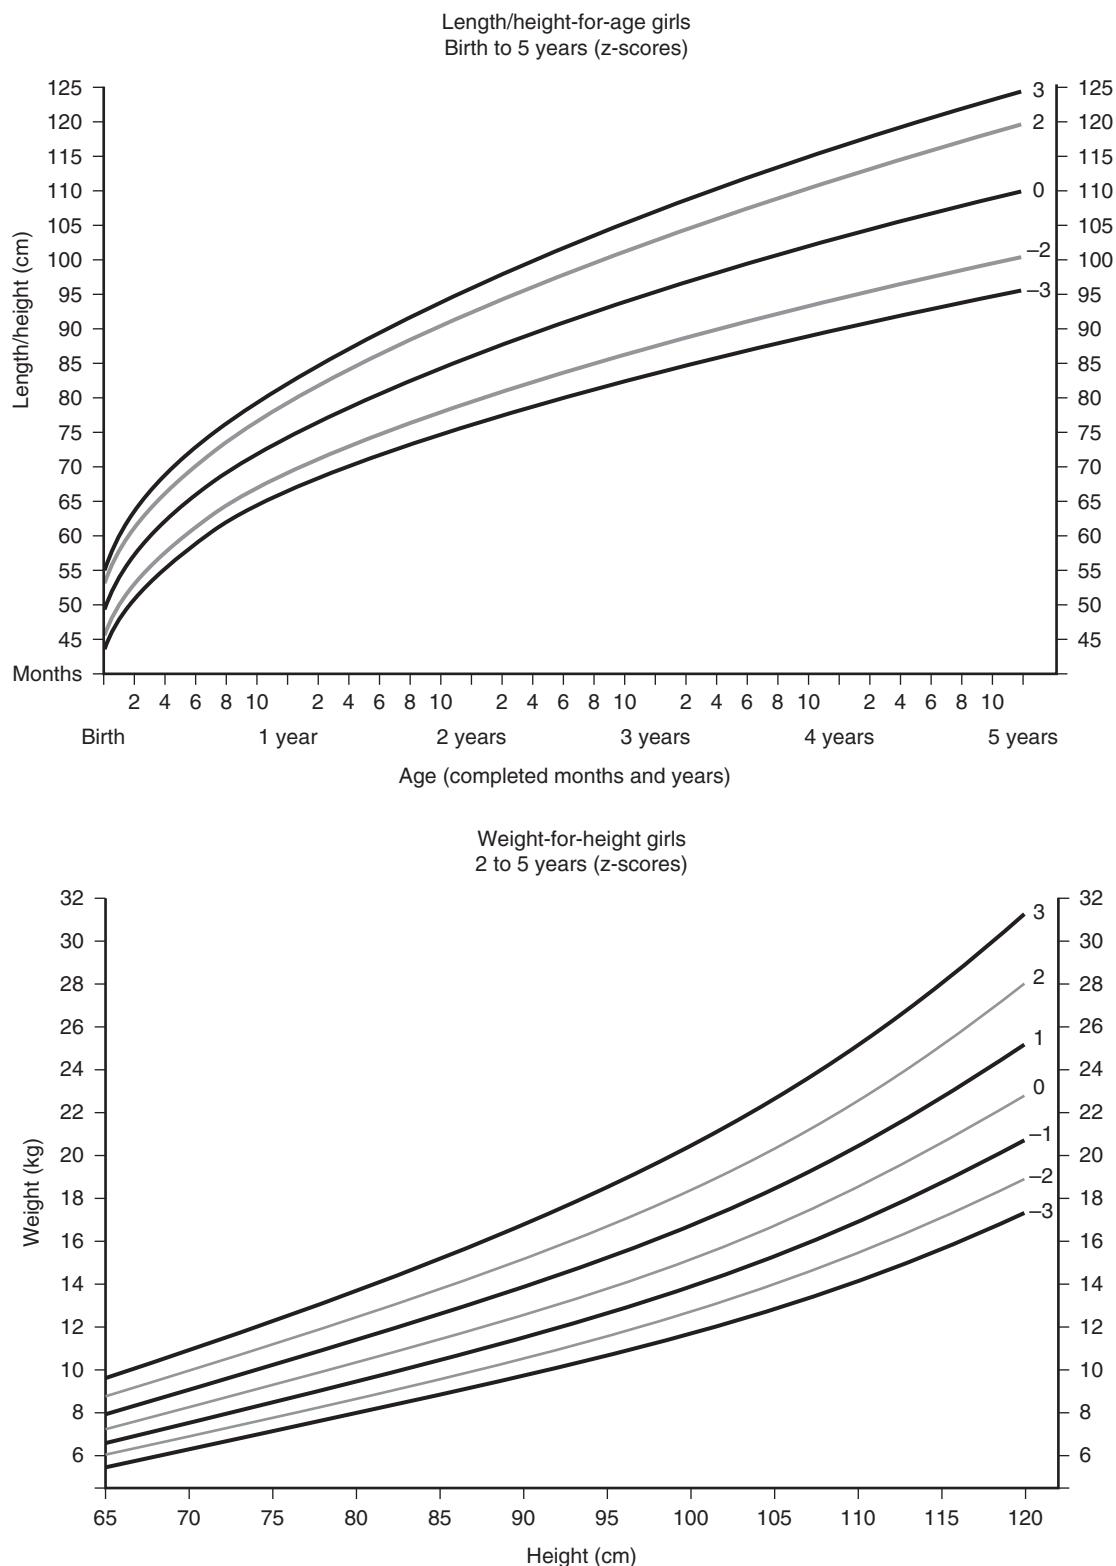

## APPENDIX G

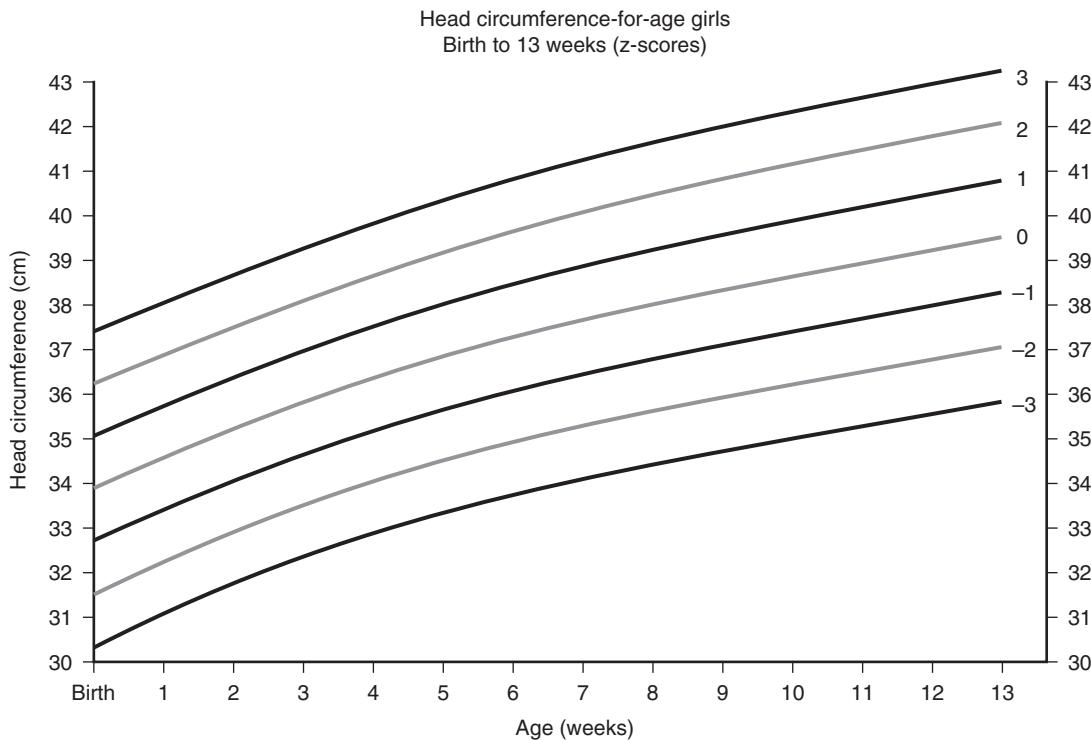

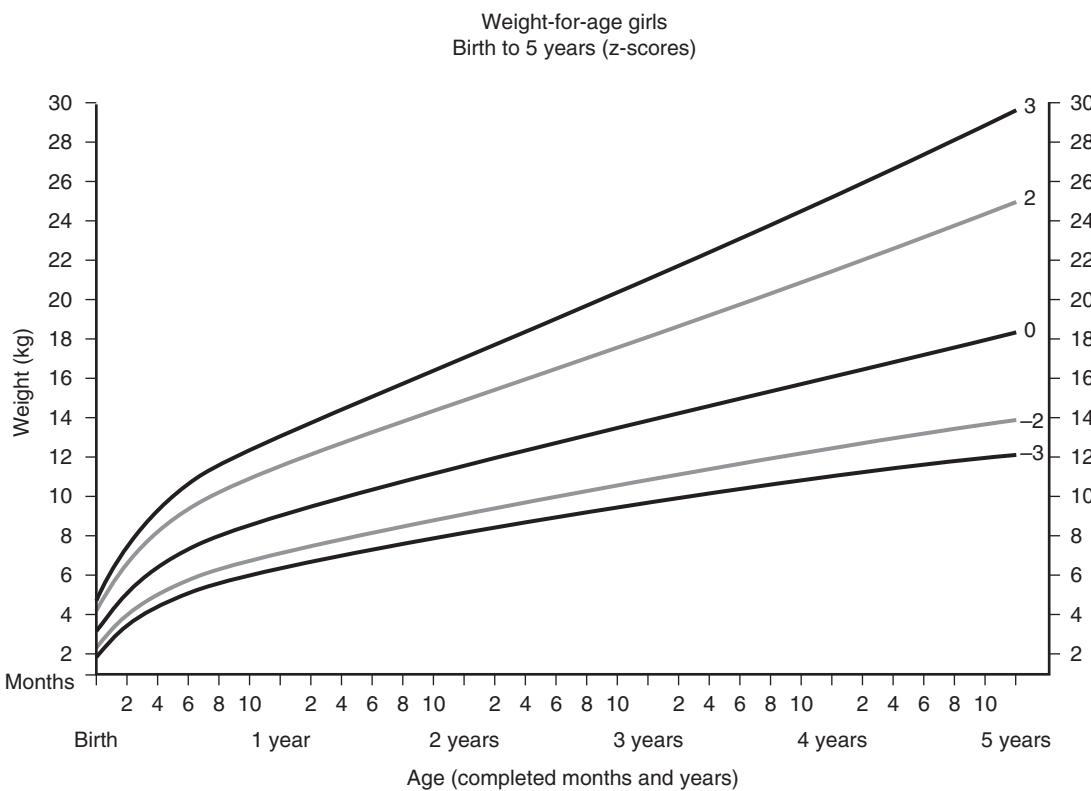

# *Measurements of Growth in Breastfed Infants*

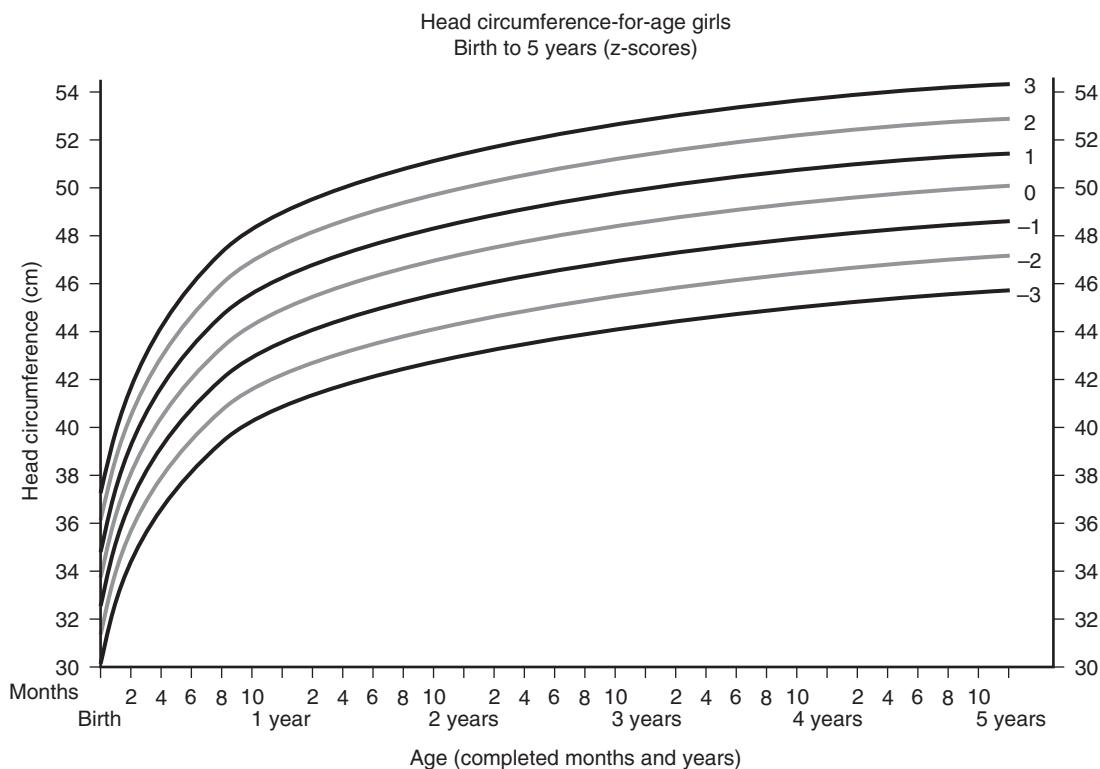

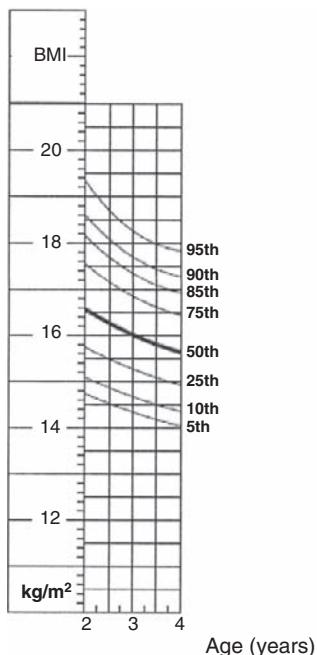

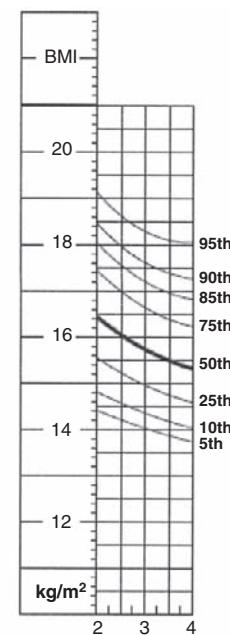

### Body mass index-for-age percentiles:

**Boys, 2 to 4 years**

**Girls, 2 to 4 years**

Published May 30, 2000.

Source: Developed by the National Center for Health Statistics in collaboration with the National Center for Chronic Disease Prevention and Health Promotion (2000).

## APPENDIX H

# *Organizations Interested in Supporting and Providing Materials for Breastfeeding*

### *Government Agencies*

**Food and Nutrition Information Center**  
Nutrient Data Laboratory  
USA-ARS  
10300 Baltimore Avenue  
Beltsville, MD 20705-2350  
Phone: 301-504-5414  
Fax: 301-504-6409  
E-mail: [ndlinfo@ars.usda.gov](mailto:ndlinfo@ars.usda.gov)  
Website: <http://ndb.nal.usda.gov>

The center serves the informational needs of people interested in human nutrition, nutrition education, food service management, consumer education, and food technology. It acquires and lends books, journal articles, and audiovisual materials dealing with these areas of concern, including breastfeeding research and education.

**International Nutrition Communication Service**  
Education Development Center  
43 Foundry Avenue  
Waltham, MA 02453-8313  
Phone: 617-969-7100  
Fax: 617-969-5979  
TTY: 617-964-5448  
Website: <http://www.edc.org>

Funded by the U.S. Agency for International Development, the service provides support and

assistance in designing, implementing, and evaluating nutrition training projects in Third World countries. It has also published the *Nutrition Training Manual Catalogue*, which contains reviews of 116 training manuals. The manuals focus on nutrition in developing countries. Breastfeeding training manuals are included.

**National Health Information Center**  
Office of the Assistant Secretary for Health, Office of the Secretary  
U.S. Department of Health and Human Services  
1101 Wootton Parkway, Suite LL100  
Rockville, MD 20852  
Phone: 240-453-8280  
Fax: 240-453-8282  
E-mail: [info@nhic.org](mailto:info@nhic.org)  
Website: <http://www.health.gov/NHIC/>

The Clearinghouse helps the public locate health information by identifying health information resources. Health questions are referred to appropriate health agencies that, in turn, respond directly to inquirers.

**World Health Organization**  
Publications Center, USA  
5 Sand Creek Rd.  
Albany, NY 12205-1400  
Phone: 518-436-9686  
Fax: 518-436-7433  
E-mail: [QCORP@compuserve.com](mailto:QCORP@compuserve.com)

Publications available include a statement on infant and young child feeding, a breastfeeding guide for use by community health workers, and a study on patterns of breastfeeding.

## *Private Educational and Support Organizations*

### **Clearinghouse on Infant Feeding and Maternal Nutrition**

American Public Health Association  
1015 Fifteenth Street, NW  
Washington, DC 20005  
Phone: 202-789-5712

The clearinghouse serves as a resource primarily for health professionals who work in Third World countries. It also responds to domestic requests as time and staffing permit. It has a large collection of materials of all types on breastfeeding. It makes available bibliographies and lists of resources on a variety of topics, and refers inquiries to appropriate sources for information.

### **Health Education Associates**

327 Quaker Meeting House Road  
East Sandwich, MA 02537-1300  
Phone: 888-888-8077 (toll-free); 508-888-8044  
Fax: 508-888-8050  
E-mail: [info@healthed.cc](mailto:info@healthed.cc)

Health Education Associates make inexpensive pamphlets and other materials available as teaching aids on breastfeeding. They sponsor training programs for breastfeeding counseling and promotion techniques.

### **International Childbirth Education Association**

1500 Sunday Drive, Suite 102  
Raleigh, NC 27607  
Phone: 919-863-9487  
Fax: 919-787-4916  
E-mail: [info@icea.org](mailto:info@icea.org)  
Website: <http://www.icea.org/info.htm>

The association's *Bookmarks* catalog has a large selection of books and inexpensive pamphlets on breastfeeding, childbirth, and parenting. It publishes *ICEA News*, with news about childbirth, prenatal, and parenting issues, and *ICEA Review*, which provides in-depth reviews of current perinatal issues. It also has a resource committee on breastfeeding.

### **International Lactation Consultant Association**

2501 Aerial Center Parkway, Suite 103  
Morrisville, NC 27560  
Phone: 919-861-5577  
Fax: 919-459-2075  
E-mail: [info@ilca.org](mailto:info@ilca.org)

The International Lactation Consultant Association (ILCA) provides many member services, including newsletters and annual conferences.

### **Lact-Aid International, Inc.**

P.O. Box 1066  
Athens, TN 37371-1066  
Phone: 423-744-9090 (orders outside U.S., information, and consulting); 866-866-1239 (toll-free ordering in the U.S.)  
Fax: 1-423-744-9116  
E-mail: [orders@lact-aid.com](mailto:orders@lact-aid.com)  
Website: <http://www.lact-aid.com>

Lact-Aid International, Inc. formerly published a quarterly journal, *Keeping Abreast, Journal of Human Nurturing*. It makes available back issues of the journal and reprints of selected articles. It also produces and markets the Lact-Aid Nursing Trainer and specializes in giving information and consultation on specific breastfeeding situations, including prematurity, relactation, adoptive nursing, and failure to thrive.

Also available is a special counseling service, LAMBS (Lact-Aid Mom's Buddies), which consists of peer counselors ready to assist a mother with the same special problem. Resource LAMBS who have personal experience nursing infants with a variety of problems (e.g., cleft palate, Down syndrome) can be reached by calling the Lact-Aid "Warmline."

### **La Leche League International, Inc.**

35 E. Wacker Drive, Suite 850  
Chicago, IL 60601  
Phone: 312-646-6260; 1-800-LaLeche  
Fax: 312-644-8557  
E-mail: [info@lli.org](mailto:info@lli.org)  
Website: <http://www.llli.org>

La Leche's publications catalog includes a large variety and broad scope of materials for mothers and health professionals to use in promoting and supporting breastfeeding. There is also a directory of league area coordinators by state and foreign country. The coordinators can give information about local support groups.

### **Nursing Mothers Counsel, Inc.**

P.O. Box 5024  
San Mateo, CA 94402-0024  
Phone: 650-327-6455  
Website: <http://www.nursingmothers.org>

The counsel makes available a variety of publications on breastfeeding for mothers and health professionals.

**Wellstart International**  
 Corporate Headquarters  
 P.O. Box 602  
 Blue Jay, CA 92317-0602  
 Phone: 714-724-1675  
 Fax: 802-985-8794  
 E-mail: [info@wellstart.org](mailto:info@wellstart.org)  
 Website: <http://www.wellstart.org>

Wellstart International is a private, nonprofit organization dedicated to the global promotion of healthy families through breastfeeding. Its purpose is to promote breastfeeding for future generations, to expand and share knowledge and understanding of breastfeeding and its benefits to families throughout the world, and to provide leadership for global change.

Wellstart International uses the following methodologies to build on existing resources and ensure quality and sustainability:

- Knowledge and skill transfer
- Development of health professional faculty as core resources of in-country expertise
- Short- and long-term technical assistance, follow-up, and field support
- Assessment of infant feeding practices
- Program evaluation, impact appraisal, and trends monitoring
- Network development and utilization
- Policy and economic analyses
- Information dissemination, including publications and meetings
- Funding support for national program activities

These methodologies are used to spread knowledge, skills, and information in the following subject areas:

- Clinical lactation management
- Scientific fundamentals of lactation and breastfeeding
- Communication and social marketing
- Community outreach and mother-to-mother support
- Evaluation and research methodologies
- Education and training methodologies

Wellstart International has been designated as a WHO Collaborating Center on Breastfeeding Promotion and Protection, with particular emphasis on lactation management education. The organization has also been involved in a variety of global breastfeeding initiatives, including preparation for the Innocenti Declaration, the World Summit for Children, and the Baby-Friendly Hospital Initiative.

## *Other National and International Breastfeeding Support Programs*

For information about Baby-Friendly Hospital Initiative, contact:

**Baby Friendly, USA**  
 Corporate Headquarters  
 125 Wolf Rd, Suite 402  
 Albany, NY 12205  
 Phone: 518-621-7982  
 Fax: 518-621-7983  
 E-mail: [info@babyfriendlyusa.org](mailto:info@babyfriendlyusa.org)  
 Website: <http://www.babyfriendlyusa.org>

The World Alliance for Breastfeeding Action (WABA) is a network of organizations and individuals dedicated to protecting, promoting, and supporting breastfeeding as a right of all children and women. For information, contact:

**WABA Secretariat: World Alliance for Breastfeeding Action**  
 P.O. Box 1200  
 10850 Penang  
 Malaysia  
 Fax: 60-4-657 2655  
 E-mail: [waba@waba.org.my](mailto:waba@waba.org.my)  
 Website: <http://www.waba.org.my>

Other international support organizations are:

**Australian Breastfeeding Association (ABA)**  
 P.O. Box 4000  
 Glen Iris, Victoria 3146  
 Australia  
 Phone: 03-9885-0855, or from outside Australia +61-3-98850855  
 Fax: 03-9885-0866, or from outside Australia +61-3-98850866  
 E-mail: [info@breastfeeding.asn.au](mailto:info@breastfeeding.asn.au)  
 Website: <http://www.breastfeeding.asn.au>

**Baby Milk Action Group**  
 34 Trumpington St.  
 Cambridge CB2 1QY, United Kingdom

## *International Organization for Physicians*

---

**Academy of Breastfeeding Medicine**  
 140 Huguenot Street, 3rd floor  
 New Rochelle, New York 10801  
 Phone: 800-990-4ABM (toll-free); 914-740-2115  
 Fax: 914-740-2101, attn: ABM  
 E-mail: [ABM@bfmed.org](mailto:ABM@bfmed.org)  
 Website: <http://www.bfmed.org>

The Academy of Breastfeeding Medicine is a worldwide organization of physicians dedicated to the promotion, protection, and support of breastfeeding and human lactation. Its mission is to unite into one association members of the various medical specialties with this common purpose. The academy's goals are:

- Physician education
- Expansion of knowledge in both breastfeeding science and human lactation
- Facilitation of optimal breastfeeding practices
- Encouragement of the exchange of information among organizations

## *Lactation Study Center*

---

**Lactation Study Center: Encouraging and Promoting Breastfeeding**  
 Phone: 585-275-0088, 8 AM to 5 PM EST

The Lactation Study Center at the University of Rochester Medical Center encourages and promotes human lactation and breastfeeding through physician education and support. The goal is to provide the information that will help the practitioner encourage and support breastfeeding for all patients.

Ruth A. Lawrence, MD, Professor of Pediatrics and of Obstetrics/Gynecology, is responsible for the program's development and operation.

## *The Computer Data Bank*

---

The core of the Lactation Study Center program is a networked computer system, offering physicians information on issues critical to the success of lactation and breastfeeding.

The bibliography data bank, which is constantly updated, provides immediate access to the latest published references on the subject by searching for an article's primary author, for any author, or for a word in the title, or by using the keyword code (the keyword categorizes papers by subject areas).

The center can, for example, look up all papers in the collection discussing "anticonvulsant drugs," by using a single keyword that will generate a comprehensive list.

The subject data bank has been divided into major category areas, each of which is summarized from thousands of articles from the medical literature.

The drug data bank includes all the available information about the drug in question, including, if known, its oral availability, whether it appears in the milk, the half-life in maternal plasma and milk, peak time in the maternal plasma and milk, percent protein bound in plasma, percentage of adult dose in milk, the maximum amount in a liter of milk, and the ratio of the concentration in milk to the concentration in the maternal plasma.

The biochemistry information can be accessed by the compound name and gives the amount of the compound in various milk fractions; its molecular weight, its solubility properties, including a discussion of the function of the compound in milk; variations related to diet and other factors; the source of the compound; and pertinent references in the literature.

The information on conditions of mother or infant can be identified by name. The information focuses on the effect the condition has on nursing and lactation and what compensatory actions are needed to facilitate the process. The presentation is geared for the professional.

## *Equipment Companies*

# *Medical Education for Basic Proficiency in Breastfeeding*

---

C.B. Rosen-Carole

Despite the large body of evidence concerning practices and behaviors that support breastfeeding and the positive effect of residency and primary care curricula on breastfeeding rates,<sup>1–12</sup> there remains no information concerning the appropriate and complete education of medical students. It is imperative to ensure that every health care provider graduates medical school with a basic understanding of breastfeeding. The following guide was created in order to support the development of such a curriculum:

### **Learning objective/transfer goal**

*By the end of medical school, medical students should have a basic understanding of the histology, anatomy, physiology, pathology, pharmacology, public health and clinical issues surrounding breastfeeding; be able to understand relevance of this knowledge to clinical scenarios, and begin to apply this knowledge in clinical decision-making (see Chapter 23).*

(C.B. ROSEN-CAROLE)

### **The following topics should be included:**

1. *Histology:* The histology of the breast, including the acinar cells, ductal cells, and hormonal stimuli of milk release. Impact of breast milk on the newborn gut cells.
2. *Anatomy:* Location of the milk ducts, their proximity to surgical incision sites. Surgeries and surgical sites with varying impacts on breastfeeding. Suspension ligaments. NO lactiferous sinuses. Role of the interstitial spaces that fill with fluid during engorgement to prevent release ("let down") of milk.
3. *Physiology:* Seeing the newborn and mother as a "dyad" biophysically during the first year of life. Normal hormonal stimulation of milk ejection, mechanisms of milk expression by mechanics of neonatal tongue, and differences with milk ejection by artificial methods (hand expression and pumps). Impact of breast milk on the newborn gut, biomes, hormones, and digestion.
4. *Pathology:* Mastitis causes and prevention, and appropriate management of breast abscess while not interrupting ductal tissue. Few contraindications to breastfeeding. Infant malformations associated with difficulty breastfeeding. Diseases impacted by breastfeeding. Genetic and epigenetic influences of breast milk.
5. *Pharmacology:* Impact of artificial infant formula on newborn gut, especially premature gut. Risks of artificial infant formula and proposed mechanisms (e.g., changed microbiota leading to increased inflammation, increased permeability of mucosal membranes, decreased host defenses, and increased infection). Breast milk fortifiers and their role in growth and nutrition of premature babies (both human- and cow-milk-based fortifiers). Considerations of the transfer of medications into human milk. Determining the safety of medications for breastfeeding. Role of certain medications in decreasing breast milk production.
6. *Nutrition and immunology:* Nutritional impact of breastfeeding and breastmilk as species-specific. Co-factors for absorption, presence of cells, and

- immunoglobulins for immunologic support. Colostrum as first nutrition and first vaccine.
7. *Public health:* Breastfeeding as a health disparities and access issue. Low rates of breastfeeding and impact on cost of health care and burden of disease.
  8. *Primary care clerkship preparation:* How to discuss breastfeeding in a supportive manner with families, the importance of breastfeeding education and physician recommendation. The basics of a good latch and positioning.

#### **Curriculum design considerations:**

- Material included should meet the highest standards of evidence-based medicine. Involving a physician with advanced training in breastfeeding medicine is recommended, if available, for this process.
- Curricula should be designed by a multidisciplinary team, including basic science and clinical faculty (obstetric, pediatric, family medicine, surgical, etc.), medical student leaders, patients, and administrators. This is likely to improve buy-in, humanism, and applicability to all parts of the curriculum.
- Each phase of the medical school curriculum should include some information on breastfeeding: basic science, preclinical, and clinical years.
- Material should be considered for inclusion in an integrated manner with other course topics (e.g., a discussion of the role of breastfeeding in breast cancer prevention could be included in a problem-based-learning cancer case or in a traditional lecture on breast cancer).
- Dedicated sessions on breastfeeding should be considered to focus on the clinical skills necessary for the clinical years (e.g., latch, positioning, motivational interviewing).
- In schools that utilize a systems-based integrative model, or modular, problem-based learning, a case/unit on breastfeeding should be strongly

considered or should be included as a teaching point of a related case (e.g., bronchiolitis, diabetes, etc.).

## APPENDIX J

# *Protocol 1: Academy of Breastfeeding Medicine Protocols Guidelines for Blood Glucose Monitoring and Treatment of Hypoglycemia in Term and Late-Preterm Neonates*

Nancy Wight, Kathleen A. Marinelli, and the Academy of Breastfeeding Medicine Protocol Committee

A central goal of the Academy of Breastfeeding Medicine is the development of clinical protocols for managing common medical problems that may impact breastfeeding success. These protocols serve only as guidelines for the care of breastfeeding mothers and infants and do not delineate an exclusive course of treatment or serve as standards of medical care. Variations in treatment may be appropriate according to the needs of an individual patient.

### **Purpose**

To provide guidance in the first hours/days of life to:

- Prevent clinically significant hypoglycemia in infants
- Appropriately monitor blood glucose levels in at-risk term and late-preterm infants
- Manage documented hypoglycemia in infants

- Establish and preserve maternal milk supply during medically necessary supplementation for hypoglycemia or during separation of mother and baby

### **Background**

### **PHYSIOLOGY**

The term "hypoglycemia" refers to a low blood glucose concentration. Clinically significant neonatal hypoglycemia reflects an imbalance between the supply and utilization of glucose and alternative fuels and may result from several disturbed regulatory mechanisms.<sup>1</sup> Transient hypoglycemia in the first hours after birth is common, occurring in almost all mammalian newborns. In healthy term human infants, even if early enteral feeding is withheld, this phenomenon is self-limited, without clinical signs, and considered to be part of adaptation

to postnatal life, as glucose levels spontaneously rise within the first 24 hours after birth (for some, it is even longer but still physiological).<sup>60,33,15,37,40</sup> Most neonates compensate for this "physiological" low blood glucose with endogenous fuel production through gluconeogenesis, glycogenolysis, and ketogenesis, collectively called "counter-regulation." Even in those situations where low blood glucose concentrations do develop secondary to prolonged intervals (>8 hours) between breastfeeding, a marked ketogenic response occurs. The enhanced capability of the neonatal brain to utilize ketone bodies provides glucose-sparing fuel to the brain, protecting neurological function.<sup>33,47,23,68</sup> The compensatory provision of alternate fuels constitutes a normal adaptive response to transiently low nutrient intake during the establishment of breastfeeding,<sup>33,13</sup> resulting in most breastfed infants tolerating lower plasma glucose levels without any significant clinical manifestations or sequelae.<sup>13</sup>

No studies have shown that treating transiently low blood glucose levels results in better short-term or long-term outcomes compared with no treatment, and in fact there is no evidence at all that hypoglycemic infants with no clinical signs benefit from treatment.<sup>8,46</sup> Increases in neurodevelopmental abnormalities have been found in infants who have hypoglycemia associated with abnormal clinical signs, especially those with severe, persistent hyperinsulinemic hypoglycemia.<sup>8,45,20,9,49</sup> Rozance and Hay<sup>52</sup> have delineated the conditions that should be present before considering that long-term neurologic impairment might be related to neonatal hypoglycemia. Transient, single, brief periods of hypoglycemia are unlikely to cause permanent neurologic damage.<sup>64,24,35,65</sup> Therefore, the monitoring of blood glucose concentrations in healthy, term, appropriately grown neonates is unnecessary and potentially harmful to parental well-being and the successful establishment of breastfeeding.<sup>64,24,35,65,34,31</sup>

## DEFINITION OF HYPOGLYCEMIA

The definition of hypoglycemia in the newborn infant has remained controversial because of a lack of significant correlation among plasma glucose concentration, clinical signs, and long-term sequelae.<sup>13,44,58</sup> An expert panel convened in 2008 by the U.S. National Institutes of Health concluded that there has been no substantial evidence-based progress in defining what constitutes clinically important neonatal hypoglycemia, particularly regarding how it relates to brain injury.<sup>36</sup> Multiple reviews have concluded that there is no specific plasma or blood glucose concentration or duration of low blood glucose level that can be linked to either clinical signs

or permanent neurologic injury.<sup>52,58,51</sup> In addition, blood glucose test results vary enormously with the source of the blood sample, the assay method, and whether whole blood, plasma, or serum glucose concentration is determined. Plasma or serum glucose concentrations are 10% to 15% higher than in whole blood.<sup>7,16</sup>

Breastfed, formula-fed, and mixed-fed infants follow the same pattern of glucose values, with an initial fall in glucose level over the first 2 hours of life, followed by a gradual rise in glucose level over the next 96 hours, whether fed or not.<sup>60,37,40</sup> Artificially fed infants tend to have slightly higher levels of glucose and lower levels of ketone bodies than breastfed infants.<sup>33,37,64,63,22,14</sup>

The incidence of "hypoglycemia" varies with the definition.<sup>56,28</sup> Many authors have suggested numeric definitions of hypoglycemia, usually between 30 and 50 mg/dL (1.7 to 2.8 mmol/L) and varying by postnatal age.\* There is no scientific justification for the value of <47 mg/dL (2.6 mmol/L) that has been adopted by some clinicians.<sup>13,58,36,51,48</sup> Cornblath et al.<sup>13</sup> summarized the problem as follows:

Significant hypoglycemia is not and cannot be defined as a single number that can be applied universally to every individual patient. Rather, it is characterized by a value(s) that is unique to each individual and varies with both their state of physiologic maturity and the influence of pathology.

A meta-analysis of studies published from 1986 to 1994 looked at low plasma glucose thresholds in term healthy newborns who were mostly mixed-fed (breastfed and formula-fed) or formula-fed. It presented statistical ranges of low thresholds for plasma glucose level based on hours after birth in healthy term infants (Table J-1).<sup>3</sup> The authors specifically noted that given the known lower plasma glucose levels in healthy term breastfed infants as compared with formula-fed infants, the low thresholds for exclusively breastfed infants might even be lower. Table J-1 gives recommendations for this timed threshold approach.

This information is translated into guidelines for clinical intervention by the operational treatment

TABLE J-1 Population Low Thresholds: Plasma Glucose Level <sup>13</sup>	
Hour(s) After Birth	≤5th Percentile Plasma Glucose Level
1-2 (nadir)	28 mg/dL (1.6 mmol/L)
3-47	40 mg/dL (2.2 mmol/L)
48-72	48 mg/dL (2.7 mmol/L)

\*Refs. 60,37,64,44,36,56,12,61,54,2.

**TABLE J-2** Operational Thresholds for Treatment of Plasma Glucose Levels<sup>13</sup>

Infant	Plan/PGL	Treatment
Infant with clinical signs	If <45 mg/dL (2.5 mmol/L)	Clinical interventions to increase blood glucose concentration
Infants with risk factors*	Initiate glucose monitoring as soon as possible after birth, within 2-3 hours after birth and before feeding, or at any time there are abnormal signs. If plasma glucose concentration is <36 mg/dL (2.0 mmol/L), close surveillance should be maintained. Intervention is recommended if plasma glucose remains below this level, does not increase after a feed, or if abnormal clinical signs develop.	Clinical interventions to increase blood glucose concentration: at very low glucose concentration (20-25 mg/dL, 1.1-1.4 mmol/L), intravenous glucose infusion to raise plasma glucose levels to >45 mg/dL (2.5 mmol/L) is indicated.

PGL, Plasma glucose level.

\*See Table J-3.

guidance of Cornblath et al.<sup>13</sup> As they stated, an operational threshold is that concentration of plasma or whole blood glucose at which clinicians should consider intervention, based on the evidence currently available in the literature (Table J-2). It needs to be underscored that the therapeutic objective (45 mg/dL [2.5 mmol/L]) is different from the operational threshold for intervention (36 mg/dL [2.0 mmol/L]), which is different from the population low thresholds in normal babies with no clinical signs or risk factors who do not need to be treated (Table J-1). The higher therapeutic goal was chosen to include a significant margin of safety in the absence of data evaluating the correlation between glucose levels in this range and long-term outcome in full-term infants.<sup>13</sup>

Given this information, it is clear that routine monitoring of blood glucose in healthy term infants is not only unnecessary, but is instead potentially harmful to the establishment of a healthy mother-infant relationship and successful breastfeeding patterns.<sup>1,35,34,31,55,30</sup> This recommendation has been supported by the World Health Organization,<sup>64</sup> the American Academy of Pediatrics,<sup>1,55</sup> the U.S. National Institutes of Health,<sup>36</sup> and the National Childbirth Trust of the United Kingdom.<sup>50</sup> These organizations all conclude that (1) early and exclusive breastfeeding is safe to meet the nutritional needs of healthy term infants and that (2) healthy term infants do not develop clinically significant hypoglycemia simply as a result of a time-limited duration of underfeeding.

## TESTING METHODS

Bedside glucose reagent test strips are inexpensive and practical but are not reliable, with significant variance from true blood glucose levels, especially at low glucose concentrations.<sup>34,2,4,39,41</sup> Bedside glucose tests may be used for screening, but laboratory levels sent STAT (immediate determination, without delay) (e.g., glucose oxidase, hexokinase,

or dehydrogenase method) must confirm results before a diagnosis of hypoglycemia can be made, especially in infants with no clinical signs.<sup>1,64,34</sup> Other bedside rapid measurement methods such as reflectance colorimetry and electrode methods may be more accurate.<sup>25,19,57,53</sup> Continuous subcutaneous glucose monitoring, as is used in diabetic patients, has been used experimentally in neonates with good correlation with laboratory glucose values but is not currently recommended for screening.<sup>29,27</sup>

## RISK FACTORS FOR HYPOGLYCEMIA

Neonates at increased risk for developing neonatal hypoglycemia should be routinely monitored for blood glucose levels irrespective of the mode of feeding. At-risk neonates fall into two main categories:

1. Excess utilization of glucose, which includes the hyperinsulinemic states
2. Inadequate production or substrate delivery<sup>14,21,17</sup>

Infant risk factors for hypoglycemia are listed in Table J-3.<sup>†</sup>

## CLINICAL MANIFESTATIONS OF HYPOGLYCEMIA

The clinical manifestations of hypoglycemia are nonspecific, occurring with various other neonatal problems. Even in the presence of an arbitrary low glucose level, the physician must assess the general status of the infant by observation and physical examination to rule out other disease entities and processes that may need additional laboratory evaluation and treatment. Some common clinical signs are listed in Table J-4.

<sup>†</sup>Refs. 33,13,64,24,65,63,14,28,21,17,62,43.

**TABLE J-3**

At-Risk Infants for Whom Routine Monitoring of Blood Glucose Is Indicated: Small for Gestational Age: <10th Percentile for Weight Commonly Cited in the United States; <2nd Percentile Cited in the United Kingdom as Above This Considered Small Normal\*

Babies with clinically evident wasting of fat and muscle bulk
LGA: >90th percentile for weight and macrosomic appearance <sup>†</sup>
Discordant twin: weight 10% < larger twin
All infants of diabetic mothers, especially if poorly controlled
Low birth weight (<2500 g)
Prematurity (<35 weeks, or late-preterm infants with clinical signs or extremely poor feeding)
Perinatal stress: severe acidosis or hypoxia-ischemia
Cold stress
Polycythemia (venous Hct > 70%)/hyperviscosity
Erythroblastosis fetalis
Beckwith-Wiedemann's syndrome
Micropthalmus or midline defect
Suspected infection
Respiratory distress
Known or suspected inborn errors of metabolism or endocrine disorders
Maternal drug treatment (e.g., terbutaline, beta-blockers, oral hypoglycemics)
Infants displaying signs associated with hypoglycemia (see Table J-4)

Hct, hematocrit.

\*As per Dr. Jane Hawdon (personal communication).

<sup>†</sup>Unnecessary to screen all large for gestational age (LGA) babies. Glucose monitoring is recommended for infants from maternal populations who were unscreened for diabetes during the pregnancy where LGA may represent undiagnosed and untreated maternal diabetes.

**TABLE J-4**

Clinical Manifestations of Possible Hypoglycemia

Irritability, tremors, jitteriness
Exaggerated Moro reflex
High-pitched cry
Seizures or myoclonic jerks
Lethargy, listlessness, limpness, hypotonia
Coma
Cyanosis
Apnea or irregular breathing
Tachypnea
Hypothermia; temperature instability
Vasomotor instability
Poor suck or refusal to feed

A recent study found that of the 23 maternal/infant risk factors and infant signs/symptoms studied, only jitteriness and tachypnea were statistically significant at predicting low blood glucose—not even maternal diabetes!<sup>38</sup> A diagnosis of hypoglycemia also requires that signs abate after normoglycemia is restored (the exception being if brain injury has already been sustained).

## General Management Recommendations (Table J-5)

Any approach to management needs to account for the overall metabolic and physiologic status of the infant and should not unnecessarily disrupt the mother-infant relationship and breastfeeding.<sup>1,65</sup> Because severe, prolonged hypoglycemia with clinical signs may result in neurologic injury,<sup>8,20,9,67</sup> immediate intervention is needed for infants with clinical signs. Several authors have suggested algorithms for screening and treatment.<sup>1,52,36,51,42</sup> (Quality of evidence [levels of evidence I, II-1, II-2, II-3, and III] is based on the U.S. Preventive Services Task Force Appendix A Task Force Ratings<sup>6</sup> and is noted in parentheses.)

### A. Initial management

Early and exclusive breastfeeding meets the nutritional and metabolic needs of healthy term newborn infants. Healthy term infants do not develop clinically significant hypoglycemia simply as a result of time-limited underfeeding.<sup>64,24,65</sup> (III)

**TABLE J-5**

General Management Recommendations for All Term Infants

- A. Early and exclusive breastfeeding meets the nutritional and metabolic needs of healthy term newborn infants.
1. Routine supplementation is unnecessary.
2. Initiate breastfeeding within 30-60 minutes of life and continue on demand.
3. Facilitate skin-to-skin contact of mother and infant.
4. Feedings should be frequent, 10-12 times per 24 hours in the first few days after birth.
- B. Glucose screening is performed only on at-risk infants or infants with clinical signs.
1. Routine monitoring of blood glucose in all term newborns is unnecessary and may be harmful.
2. At-risk infants should be screened for hypoglycemia with a frequency and duration related to the specific risk factors of the individual infant.
3. Monitoring continues until normal, prefeed levels are consistently obtained.
4. Bedside glucose screening tests must be confirmed by formal laboratory testing.

1. Healthy, appropriate weight for gestational age, term infants should initiate breastfeeding within 30 to 60 minutes of life and continue breastfeeding on cue, with the recognition that crying is a very late sign of hunger.<sup>55,5,66</sup> (III)
2. Initiation and establishment of breastfeeding, and reduction of hypoglycemia risk, are facilitated by skin-to-skin contact between the mother and her infant immediately after birth for at least the first hour of life and continuing as much as possible. Such practices will maintain normal infant body temperature and reduce energy expenditure (thus enabling maintenance of normal blood glucose) while stimulating suckling and milk production.<sup>22,55</sup> (II-2, III)
3. Feedings should be frequent, at least 10 to 12 times per 24 hours in the first few days after birth.<sup>55</sup> (III) However, it is not unusual for term infants to feed immediately after birth and then sleep quite a long time (up to 8 to 12 hours) before they become more active and begin to suckle with increasing frequency. They mount protective metabolic responses throughout this time so it is not necessary to try to force-feed them. However, an unusually, excessively drowsy baby must undergo clinical evaluation.
4. Routine supplementation of healthy term infants with water, glucose water, or formula is unnecessary and may interfere with the establishment of normal breastfeeding and normal metabolic compensatory mechanisms.<sup>33,63,55,50</sup> (II-2, III)

#### B. Blood glucose screening

Glucose screening should be performed only on at-risk infants and those with clinical signs compatible with hypoglycemia. Early breastfeeding is not precluded just because the infant meets the criteria for glucose monitoring.

1. At-risk infants should be screened for hypoglycemia with a frequency and duration related to the specific risk factors of the individual infant.<sup>1,24</sup> (III) Monitoring should begin no later than 2 hours of age for infants in risk categories.<sup>1</sup> Hawdon<sup>32</sup> recommended blood glucose monitoring should commence before the second feeding (i.e., not so soon after birth that the physiologic fall in blood glucose level causes confusion and overtreatment). (III)
2. Monitoring should continue until acceptable, prefeed levels are consistently obtained, meaning until the infant has had at least two consecutive satisfactory measurements.<sup>32</sup> A reasonable (although arbitrary) goal is to maintain plasma glucose concentrations between 40 and 50 mg/dL (between 2.2 and 2.8 mmol/L)<sup>1</sup> or >45 mg/dL (2.5 mmol/L).<sup>13</sup> (III)

3. Bedside glucose screening tests must be confirmed by formal laboratory testing, although treatment should begin immediately in infants with clinical signs.

**Table J-5** summarizes these recommendations.

## Management of Documented Hypoglycemia (**Table J-6**)

- A. Infant with no clinical signs (absence of clinical signs can only be determined by careful clinical review)
  1. Continue breastfeeding (approximately every 1 to 2 hours) or feed 1 to 3 mL/kg (up to 5 mL/kg)<sup>64</sup> of expressed breastmilk or substitute nutrition (pasteurized donor human milk, elemental formulas, partially hydrolyzed formulas, or routine formulas). Glucose water is not suitable because of insufficient energy and lack of protein. Recent reports of mothers

**TABLE J-6** Management of Documented Hypoglycemia

- |   |  |
|---|--|
| A. Infant with no clinical signs  | <ol style="list-style-type: none"> <li>1. Continue breastfeeding (approximately every 1-2 hours) or feed 1-5 mL/kg of expressed breastmilk or substitute nutrition.</li> <li>2. Recheck blood glucose concentration before subsequent feedings until the value is acceptable and stable.</li> <li>3. Avoid forced feedings (see above).</li> <li>4. If the glucose level remains low despite feedings, begin intravenous glucose therapy.</li> <li>5. Breastfeeding may continue during intravenous glucose therapy.</li> <li>6. Carefully document response to treatment.</li> </ol>  |
| B. Infant with clinical signs or plasma glucose levels <20-25 mg/dL (<1.1-1.4 mmol/L) | <ol style="list-style-type: none"> <li>1. Initiate intravenous 10% glucose solution with a mini-bolus.</li> <li>2. Do not rely on oral or intragastric feeding to correct extreme or clinically significant hypoglycemia.</li> <li>3. The glucose concentration in infants who have had clinical signs should be maintained at &gt;45 mg/dL (&gt;2.5 mmol/L).</li> <li>4. Adjust intravenous rate by blood glucose concentration.</li> <li>5. Encourage frequent breastfeeding.</li> <li>6. Monitor glucose concentrations before feedings while weaning off the intravenous treatment until values stabilize off intravenous fluids.</li> <li>7. Carefully document response to treatment.</li> </ol> |

with diabetes expressing and freezing colostrum prenatally (beginning at 34 to 36 weeks of gestation) to have it available after birth to avoid artificial feedings should their infant become hypoglycemic are mixed in terms of association with earlier births, and currently this procedure is not widely recommended.<sup>18,26,59,10,11</sup> (III)

2. Recheck blood glucose concentration before subsequent feedings until the value is acceptable and stable (usually  $>40$  mg/dL [ $2.2$  mmol/L]). If staff is unavailable to check blood glucose and an infant has no clinical signs, breastfeeding should *never* be unnecessarily delayed while waiting for the blood glucose level to be checked.
  3. If the infant is simply worn out and not otherwise ill, nasogastric feeds of human milk can be initiated, watching carefully for signs of intolerance or evidence of significant underlying illness. If the neonate is too ill to suck or enteral feedings are not tolerated, avoid forced oral feedings (e.g., nasogastric tube) and instead begin intravenous (IV) therapy (see below). Such an infant is not normal and requires a careful examination and evaluation in addition to more intensive therapy. Term babies should not be given nasogastric feedings. They are much more likely to fight and aspirate.
  4. If the glucose level remains low despite feedings, begin IV glucose therapy and adjust the IV rate by blood glucose concentration. Avoid bolus doses of glucose unless blood glucose is unrecordable or there are severe clinical signs (e.g., seizures or coma). If a bolus dose is given, use  $5$  mg/kg of glucose in  $10\%$  dextrose preparation.
  5. Breastfeeding should continue during IV glucose therapy when the infant is interested and will suckle. Gradually wean from the IV glucose as the serum glucose level normalizes and feedings increase.
  6. Carefully document physical examination, screening values, laboratory confirmation, treatment, and changes in clinical condition (i.e., response to treatment).
  7. The infant should not be discharged until reasonable levels of blood glucose are maintained through a fast of 3 to 4 hours. Monitoring must be recommenced if there are adverse changes in feeding.
- B. Infants with clinical signs or with plasma glucose levels  $<20$  to  $25$  mg/dL ( $<1.1$  to  $1.4$  mol/L)**
1. Initiate IV  $10\%$  glucose solution with a bolus of  $3$  mL/kg and continuous IV treatment at  $5$  to  $8$  mg/kg/minute.
  2. Do not rely on oral or intragastric feeding to correct extreme or symptomatic hypoglycemia.

Such an infant most likely has an underlying condition and, in addition to IV glucose therapy, requires an immediate and careful examination and evaluation.

3. The glucose concentration in infants with clinical signs should be maintained at  $>45$  mg/dL ( $>2.5$  mmol/L).
4. Adjust the IV rate by blood glucose concentration.
5. Encourage frequent breastfeeding after initiation of IV therapy.
6. Monitor glucose concentrations before feedings while gradually weaning from the IV solution, until values are stabilized off IV fluids.
7. Carefully document physical examination, screening values, laboratory confirmation, treatment, and changes in clinical condition (i.e., response to treatment).

## Supporting the Mother

---

Giving birth to an infant who develops hypoglycemia is of concern to both the mother and family and thus may jeopardize the establishment of breastfeeding. Mothers should be explicitly reassured that there is nothing wrong with their milk and that supplementation is usually temporary. Having the mother hand-express or pump milk that is then fed to her infant can overcome feelings of maternal inadequacy as well as help establish a full milk supply. It is important for the mother to provide stimulation to the breasts by manual or mechanical expression with appropriate frequency (at least eight times in 24 hours) until her baby is latching and suckling well to protect her milk supply. Keeping the infant at breast or returning the infant to the breast as soon as possible is important. Skin-to-skin care is easily accomplished with an IV line in place and may lessen the trauma of intervention, while also providing physiologic thermoregulation, thus contributing to metabolic homeostasis.

## Recommendations for Future Research

---

1. Well-planned, well-controlled studies are needed that look at plasma glucose concentrations, clinical signs, and long-term sequelae to determine what levels of blood glucose are the minimum safe levels.
2. The development and implementation of more reliable bedside testing methods would increase the efficiency of diagnosis and treatment of significant glucose abnormalities.

3. Studies to determine a clearer understanding of the role of other glucose-sparing fuels and the methods to measure them in a clinically meaningful way and time frame are required to aid in understanding which babies are truly at risk of neurologic sequelae and thus must be treated.
4. For those infants who do become hypoglycemic, research into how much enteral glucose, and in what form, is necessary to raise blood glucose to acceptable levels is important for clinical management.
5. Randomized controlled studies of prenatal colostrum expression and storage for mothers with infants at risk of hypoglycemia are important to determine if this is a practical and safe treatment modality.

## Summary

Healthy term infants are programmed to make the transition from their intrauterine constant flow of nutrients to their extrauterine intermittent nutrient intake without the need for metabolic monitoring or interference with the natural breastfeeding process. Homeostatic mechanisms ensure adequate energy substrate is provided to the brain and other organs, even when feedings are delayed. The normal pattern of early, frequent, and exclusive breastfeeding meets the needs of healthy term infants.

Routine screening and supplementation are not necessary and may harm the normal establishment of breastfeeding. Current evidence does not support a specific blood concentration of glucose that correlates with signs or that can predict permanent neurologic damage in any given infant. At-risk infants should be screened, followed up as needed, and treated with supplementation or IV glucose if there are clinical signs or suggested thresholds are reached. Bedside screening is helpful, but not always accurate, and should be confirmed with laboratory glucose measurement. A single low glucose value is not associated with long-term neurological abnormalities, provided the treating clinician can be assured that the baby was entirely well up until the time of the low value. Hypoglycemic encephalopathy and poor long-term outcome are extremely unlikely in infants with no clinical signs and are more likely in infants who manifest clinical signs and/or with persistent or repeated episodes of severe hypoglycemia.

## Acknowledgments

This work was supported in part by a grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

## APPENDIX J

# *Protocol 2: Guidelines for Hospital Discharge of the Breastfeeding Term Newborn and Mother: "The Going Home Protocol"*

---

Amy Evans, Kathleen A. Marinelli, Julie Scott Taylor, and the Academy of Breastfeeding Medicine

A central goal of the Academy of Breastfeeding Medicine is the development of clinical protocols for managing common medical problems that may impact breastfeeding success. These protocols serve only as guidelines for the care of breastfeeding mothers and infants and do not delineate an exclusive course of treatment or serve as standards of medical care. Variations in treatment may be appropriate according to the needs of an individual patient.

### *Background*

---

The ultimate success of breastfeeding is measured in part by both the duration of and the exclusivity of breastfeeding. Anticipatory attention to the needs of the mother and infant at the time of discharge from the hospital is crucial to ensure successful, long-term breastfeeding. The following principles and practices are recommended for consideration prior to sending a mother and her full-term infant home.

### *Clinical Guidelines*

---

1. A health professional trained in formal assessment of breastfeeding should perform and document an assessment of breastfeeding effectiveness at least once during the last 8 hours preceding discharge of the mother and infant. Similar assessments should have been performed during the hospitalization, preferably at least once every 8 to 12 hours. In countries such as Japan, where the hospital stay may last up to a week, assessment should continue until breastfeeding is successfully established and then may decrease in frequency. These should include evaluation of positioning, latch, milk transfer, clinical jaundice, stool color and transition, stool and urine output, and notation of uric acid crystals if present. Infant's weight and percentage weight loss should be assessed but do not need to be checked frequently. For example, in Australia, infants are weighed at birth and at discharge or

on day 3 of life, whichever comes first. All concerns raised by the mother such as nipple pain, inability to hand express, perception of inadequate supply, and any perceived need to supplement must also be addressed.<sup>35,43,5,24,7,1,36</sup>

(I; II-3; III) (Quality of evidence [levels of evidence I, II-1, II-2, II-3, and III] for each recommendation as defined in the U.S. Preventive Services Task Force [Appendix A](#) Task Force Ratings<sup>9</sup> is noted in parentheses.) It is important to ask detailed questions—many mothers may not bring up these concerns if not directly questioned.

- Prior to discharge, anticipation of breastfeeding problems should be assessed based on maternal and/or infant risk factors ([Tables J-7](#) and [J-8](#)). (III)

All problems with breastfeeding, whether observed by hospital staff or raised by the mother, should be attended to and documented in the medical record prior to discharge of the mother and infant. This includes prompt recognition and treatment plans for possible ankyloglossia, which can affect latch, lactogenesis, and future breastfeeding.<sup>17,10</sup> (An updated clinical protocol is in development.) (I) A plan of action that includes follow-up of the problem after discharge must be in place.<sup>51,3,12,20</sup> (II-3) If the mother's and infant's caregivers are not the same person, there needs to be coordinated communication of any issues between the obstetric and pediatric providers for optimal follow-up care (see Guideline #10).

- Physicians, midwives, nurses, and all other staff should encourage the mother to breastfeed exclusively for the first 6 months of the infant's life and to continue breastfeeding through at least the first year and preferably to 2 years of life and beyond.<sup>5,4,30</sup> (III) This is the recommendation of the World Health Organization, as well as organizations from many individual countries such as the National Health and Medical Research Council in Australia.<sup>39</sup> The Joint Commission, an organization that accredits hospitals and health care institutions in the United States and globally, is now mandating documentation of exclusive breastfeeding rates as part of its accreditation process for hospitals and birthing centers in the United States. The U.S. Centers for Disease Control and Prevention has similar recommendations.<sup>20,49,48,31,50</sup> (III) The addition of appropriate complementary food should occur at 6 months of life.<sup>34</sup> (I) Mothers benefit from education about the rationale for and practical advice on exclusive breastfeeding. The medical, psychosocial, and societal benefits for both mother and infant and why artificial milk supplementation is

<b>TABLE J-7</b> Maternal Risk Factors for Lactation Problems	
<b>Factors</b>	
History/social	<ul style="list-style-type: none"> <li>• Primiparity</li> <li>• Intention to both breastfeed and bottle or formula feed at less than 6 weeks</li> <li>• Intention to use pacifiers/dummies and/or artificial nipples/teats at less than 6 weeks</li> <li>• Early intention/necessity to return to school or work</li> <li>• History of previous breastfeeding problems or breastfed infant with slow weight gain</li> <li>• History of infertility</li> <li>• Conception by assisted reproductive technology</li> <li>• Significant medical problems (e.g., untreated hypothyroidism, diabetes, cystic fibrosis, polycystic ovaries)</li> <li>• Extremes of maternal age (e.g., adolescent mother or older than 40 years)</li> <li>• Psychosocial problems (e.g., depression, anxiety, lack of social support for breastfeeding)</li> <li>• Prolonged labor</li> <li>• Long induction or augmentation of labor</li> <li>• Use of medications during labor (benzodiazepines, morphine, or others that can cause drowsiness in the newborn)</li> <li>• Peripartum complications (e.g., postpartum hemorrhage, hypertension, infection)</li> <li>• Intended use of hormonal contraceptives before breastfeeding is well established (6 weeks)</li> <li>• Perceived inadequate milk supply</li> <li>• Maternal medication use (inappropriate advice about compatibility with breastfeeding is common)</li> </ul>
Anatomic/physiologic	<ul style="list-style-type: none"> <li>• Lack of noticeable breast enlargement during puberty or pregnancy</li> <li>• Flat, inverted, or very large nipples</li> <li>• Variation in breast appearance (marked asymmetry, hypoplastic, tubular)</li> <li>• Any previous breast surgery, including cosmetic procedures (important to ask—not always obvious on exam)</li> <li>• Previous breast abscess</li> <li>• Maternal obesity (body mass index <math>\geq 30 \text{ kg/m}^2</math>)</li> <li>• Extremely or persistently sore nipples</li> <li>• Failure of “secretory activation” lactogenesis II. (Milk did not noticeably “come in” by 72 hours postpartum. This may be difficult to evaluate if mother and infant are discharged from the hospital in the first 24–48 hours postpartum.)</li> <li>• Mother unable to hand-express colostrum</li> <li>• Need for breastfeeding aids or appliances (such as nipple shields, breast pumps, or supplemental nursing systems) at the time of hospital discharge</li> </ul>

<b>TABLE J-8</b> Infant Risk Factors for Lactation Problems	
<b>Factors</b>	
Medical/anatomic/physiologic	
• Low birth weight or premature (<37 weeks)	
• Multiples	
• Difficulty in latching on to one or both breasts	
• Ineffective or unsustained suckling	
• Oral anatomic abnormalities (e.g., cleft lip/palate, macroglossia, micrognathia, tight frenulum/ankyloglossia with trained medical assessment)	
• Medical problems (e.g., hypoglycemia, infection, jaundice, respiratory distress)	
• Neurologic problems (e.g., genetic syndromes, hypertonia, hypotonia)	
• Persistently sleepy infant	
• Excessive infant weight loss (>7-10% of birth weight in the first 48 hours)	
Environmental	
• Mother-infant separation	
• Breast pump dependency	
• Formula supplementation	
• Effective breastfeeding not established by hospital discharge	
• Discharge from the hospital at <48 hours of age <sup>16</sup>	
• Early pacifier use	

Adapted with permission from Neifert<sup>40,p.285</sup> and the *Breastfeeding Handbook for Physicians*.<sup>43,p.91</sup> (III)

- discouraged should be emphasized. Such education is a standard component of anticipatory guidance that addresses individual beliefs and practices in a culturally sensitive manner.<sup>45,19,44</sup> Special counseling is needed for those mothers planning to return to outside employment or school (see Guideline #7).<sup>27</sup> (II-2)
4. Families will benefit from appropriate, non-commercial educational materials on breastfeeding (as well as on other aspects of child health care).<sup>42</sup> (I) Discharge packs containing infant formula, pacifiers, commercial advertising materials specifically referring to infant formula and foods, and any materials not appropriate for a breastfeeding mother and infant should not be distributed. These products may encourage poor breastfeeding practices, which may lead to premature weaning.<sup>42</sup>
  5. Breastfeeding mothers and appropriate others (fathers, partners, grandmothers, support persons, etc.) will benefit from simplified anticipatory guidance prior to discharge regarding key issues in the immediate future. (I) Care must be given not to overload mothers. Specific information should be provided in written form to all parents regarding:

- a. prevention and management of engorgement
  - b. interpretation of infant cues and feeding "on cue"
  - c. indicators of adequate intake (evacuation of all meconium stools, three to four stools per day by day 4, transitioning to yellow bowel movements by day 5, at least five to six urinations per day by day 5, and regaining birth weight by day 10 to 14 at the latest)
  - d. signs of excessive jaundice<sup>24,6</sup> (III)
  - e. sleep patterns of newborns, including safe co-sleeping practices<sup>2</sup> (III)
  - f. maternal medication, cigarette, and alcohol use
  - g. individual feeding patterns, including normality of evening cluster feedings
  - h. regarding the use of pacifiers (in communities where the use of sanitary pacifiers is commonly recommended to prevent sudden infant death syndrome [SIDS]), discouraging their use until breastfeeding is well established, at least 3 to 4 weeks. (These recommendations are in accordance with the U.S.-based American Academy of Pediatrics recommendations for the use of pacifiers as a possible prevention of SIDS. Breastfeeding, in itself, is thought to be preventative for SIDS. The Japanese Ministry of Health, Labour and Welfare supports breastfeeding, no smoking, and back sleeping but does not encourage pacifier use.)<sup>33,46,47,11,28</sup> (I)
  - i. follow-up and contact information
6. Every breastfeeding mother should receive instruction on the technique of expressing milk by hand (whether or not she uses a pump) so she is able to alleviate engorgement, increase her milk supply, maintain her milk supply, and obtain milk for feeding to the infant should she and the infant be separated or if the infant is unable to feed directly from the breast.<sup>22,23,29</sup> (II-1)
  7. Every breastfeeding mother should be provided with the names and phone numbers of individuals and medical services that can provide advice, counseling, and health assessments related to breastfeeding, ideally on a 24-hour-a-day basis.<sup>35,5</sup> (I)
  8. Every breastfeeding mother should be provided with lists of various local peer support groups and services (e.g., mother-to-mother support groups such as La Leche League, Australian Breastfeeding Association, hospital/clinic-based support groups, governmental supported groups [e.g., Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) in the United States]

- with phone numbers, contact names, and addresses). (II-1; III) Mothers should be encouraged to contact and consider joining one of these groups.<sup>41,8,25,14,13,37,26</sup> (II-3; III)
9. If a mother is planning on returning to school or outside employment soon after delivery, she may benefit from additional information.<sup>23,29</sup> (II-1) This should include the need for ongoing social support, possible milk supply issues, expressing and storing milk away from home, the possibility of direct nursing breaks with the infant, and information about any relevant regional and/or national laws regarding accommodations for breastfeeding and milk expression in the workplace. It is prudent to provide her with this information in written form, so that she has resources when the time comes for her to prepare for return to school or work.
  10. In countries where hospital discharge is common within 72 hours after birth, appointments for the infant and mother where breastfeeding can be viewed should be made prior to discharge for an office or home visit within 3 to 5 days of age by a physician, midwife, or a physician-supervised breastfeeding-trained health care provider. All infants should be seen within 48 to 72 hours after discharge; infants discharged before 48 hours of age should be seen within 24 to 48 hours after discharge.<sup>35,5</sup> (III) In countries where discharge is 5 to 7 days after birth, the infant can be seen several times by the physician prior to discharge. In Japan, where this is the case, the next routine visit is recommended at 2 weeks unless there is a problem. Based on the mother's choice, her postpartum visit can be scheduled before discharge, or she can be given the information to make the appointment herself once she is settled at home. In many countries this appointment will be with the obstetrician, family physician, or midwife who participated in the birth of her infant. In other countries such as Australia, if she gave birth in a public hospital, it will be with her general practitioner or family practitioner, who did not attend her birth.
  11. Additional visits for the mother and the infant are recommended even if discharge occurs at later than 5 days of age, until all clinical issues such as adequate stool and urine output, jaundice, and the infant attaining birth weight by 10 to 14 days of age are resolved.

An infant who is not back to birth weight by the first 10 days of life, but who has demonstrated a steady, appropriate weight gain for several days, is likely fine. This baby needs continued close follow-up but may not need intervention.

Any baby exhibiting a weight loss approaching 7% of birth weight by 5 to 6 days of life needs to be closely monitored until weight gain is well established. Should 7% or more weight loss be noted after 5 to 6 days of life, even more concern and careful follow-up must be pursued. These infants require careful assessment. By 4 to 6 days infants should be gaining weight daily, which makes their percentage weight loss actually more significant when that lack of daily weight gain is taken into account. In addition to attention to these issues, infants with any of these concerns must be specifically evaluated for problems with breastfeeding and milk transfer.<sup>35,43,5,24,7,1,36</sup> (III)

12. If the mother is medically ready for hospital discharge but the infant is not, every effort should be made to allow the mother to remain in the hospital either as a patient or as a "mother-in-residence" with access to the infant to support exclusive breastfeeding. Maintenance of a 24-hour rooming-in relationship with the infant is optimal during the infant's extended stay.<sup>48,31,37</sup> (II-1)
13. If the mother is discharged from the hospital before the infant is discharged (as in the case of a sick infant), the mother should be encouraged to spend as much time as possible with the infant, to practice skin-to-skin technique and kangaroo care with her infant whenever possible, and to continue regular breastfeeding.<sup>21,15,18,32,38</sup> (I; II-2) During periods when the mother is not in the hospital, she should be taught to express and store her milk and to bring it to the hospital for the infant. At the least she should demonstrate successful expression of her milk before hospital discharge. If she has problems with her milk supply, early referral to a lactation consultant and/or a physician skilled in breastfeeding management and medicine is indicated. (III) Milk may be expressed at home and brought in to the hospital for use by the baby. Some countries discourage this practice, but there is no evidence to contradict this recommendation and much evidence to support the use of mother's milk for these fragile infants.<sup>5</sup>

## Suggestions for Future Research

---

Although the majority of the clinical recommendations in this policy are firmly evidence-based, areas for future study remain. We know that in some areas of the world, initiation rates are high in the hospital but fall precipitously after hospital discharge. Once mothers and infants receive the best

evidence-based information and assistance possible in the hospital, what best practices need to be established to ensure that the process of "going home" is a smooth one? What culturally appropriate safety nets of support, help, and advice need to be readily and easily available to them, regardless of where they live and their socioeconomic or educational level? There is much work that can be done in this area to develop and test model policies and plans of action that could then be replicated in similar areas to determine best practices to support exclusive breastfeeding.

A Cochrane Review was done in 2002<sup>16</sup> looking at the effect of "early discharge" (less than 48 to 72 hours) on maternal/infant outcomes, including breastfeeding out to 6 months. The results were equivocal, with no differences in sample and control groups, but there was no standardization of definitions or any attempt to quantify teaching in hospital and follow-up on "going home." This is an area ripe for examination as we try to discern when a dyad is ready for discharge home.<sup>7</sup> Finally, if future research deliberately uses the same primary and secondary outcome measures currently described in the literature, then meta-analysis of these data will become possible.<sup>38</sup>

## Acknowledgments

This work was supported in part by a grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

## APPENDIX J

# *Protocol 3: Hospital Guidelines for the Use of Supplementary Feedings in the Healthy Term Breastfed Neonate*

The Academy of Breastfeeding Medicine Protocol Committee

A central goal of the Academy of Breastfeeding Medicine is the development of clinical protocols for managing common medical problems that may impact breastfeeding success. These protocols serve only as guidelines for the care of breastfeeding mothers and infants and do not delineate an exclusive course of treatment or serve as standards of medical care. Variations in treatment may be appropriate according to the needs of an individual patient.

### **Definitions**

- *Supplementary feedings:* Feedings provided in place of breastfeeding. This may include expressed or banked breastmilk and/or breastmilk substitutes/formula. Any foods given prior to 6 months, the recommended duration of exclusive breastfeeding, are thus defined as supplementary.
- *Complementary feedings:* Feedings provided in addition to breastfeeding when breastmilk alone is no longer sufficient. This term is used to describe

foods or liquids given in addition to breastfeeding after 6 months, a "complement" to breastfeeding needed for adequate nutrition.

### **Background**

Given early opportunities to breastfeed, breastfeeding assistance, and instruction, the vast majority of mothers and babies will successfully establish breastfeeding. Although some infants may not successfully latch and feed during the first day (24 hours) of life, they will successfully establish breastfeeding with time, appropriate evaluation, and minimal intervention. Unfortunately, formula supplementation of healthy newborn infants in the hospital is commonplace, despite widespread recommendations to the contrary.<sup>13,28</sup> The most recent scientific evidence indicates that *exclusive breastfeeding* (only breastmilk, no food or water except vitamins and medications) for the first 6 months is associated with the greatest protection against major health problems for both mothers and infants.<sup>34,43,54</sup>

## NEWBORN PHYSIOLOGY

Small colostrum feedings are appropriate for the size of the newborn's stomach,<sup>58,75,94</sup> are sufficient to prevent hypoglycemia in the healthy term, appropriate for gestational age infant,<sup>88–90</sup> and easy to manage as the infant learns to coordinate sucking, swallowing, and breathing. Healthy term infants also have sufficient body water to meet their metabolic needs, even in hot climates.<sup>19,31,50,67,73,72,77</sup> Fluid necessary to replace insensible fluid loss is adequately provided by breastmilk alone.<sup>72,5,76</sup> Newborns lose weight because of a physiologic diuresis of extracellular fluid following transition to extrauterine life.<sup>94</sup> The normal maximal weight loss is 5.5% to 6.6% of birth weight in optimally exclusively breastfed infants<sup>50,67,48,52</sup> and occurs between days 2 and 3 of life (48–72 hours after birth).<sup>50,67,48</sup> Optimally, breastfed infants regain birth weight at an average (95% confidence interval) of 8.3 days (7.7 to 8.9) with 97.5% having regained their birth weight by 21 days.<sup>48</sup> Percentage weight loss should be followed closely for outliers in this regard, but the majority of breastfed infants will not require supplementation.

## EARLY MANAGEMENT OF THE NEW BREASTFEEDING MOTHER

Because some breastfeeding mothers question the adequacy of colostrum feedings and may receive conflicting advice, they may benefit from reassurance, assistance with breastfeeding technique, and education about the normal physiology of breastfeeding. Inappropriate supplementation may undermine a mother's confidence about her ability to meet her infant's nutritional needs<sup>8</sup> and give inappropriate messages that may result in continued supplementation of the breastfed infant at home.<sup>66</sup>

Postpartum mothers with low confidence levels are very vulnerable to external influences, such as advice to offer breastfeeding infants supplementation such as glucose water or artificial baby milk.<sup>8</sup> Well-meaning health care professionals often offer supplementation as a means of protecting mothers from tiredness or distress, although this at times conflicts with their role in promoting breastfeeding.<sup>17,46</sup> Inappropriate reasons for supplementation and associated risks are multiple (see Appendix for quick reference).

There are common clinical situations where evaluation and breastfeeding management may be necessary, but supplementation is not indicated, including:

1. The sleepy infant with fewer than 8 to 12 feedings in the first 24 to 48 hours with less than 7% weight loss and no signs of illness
  - Newborns are normally sleepy after an initial approximately 2-hour alert period after birth.<sup>25,80</sup> They then have variable sleep-wake cycles, with an additional one or two wakeful periods in the next 10 hours whether fed or not.<sup>25</sup>
  - Careful attention to an infant's early feeding cues and gently rousing the infant to attempt breastfeeding every 2 to 3 hours is more appropriate than automatic supplementation after 6, 8, 12, or even 24 hours.
  - The general rule in the first week is: "an awake baby is a hungry baby!"
  - Increased skin-on-skin time can encourage more frequent feeding.
2. The healthy, term, appropriate for gestational age infant with bilirubin levels less than 18 mg/dL (mol/L) after 72 hours of age when the baby is feeding well and stooling adequately and weight loss is less than 7%<sup>4</sup>
3. The infant who is fussy at night or constantly feeding for several hours
4. The tired or sleeping mother

For both points 3 and 4 above, breastfeeding management that optimizes infant feeding at the breast may make for a more satisfied infant and allow the mother to get more rest.

Before any supplementary feedings are begun, it is important that a formal evaluation of each mother-baby dyad, including a direct observation of breastfeeding, is completed. The following guidelines address indications for and methods of supplementation for the healthy, term (37- to 42-week), breastfed infant. Indications for supplementation in term, healthy infants are few<sup>65,23</sup> (Table J-9).

**TABLE J-9** Indications for Supplemental Feeding in Term, Healthy Infants (Situations Where Breastfeeding Is Not Possible)

- |  |   |
|--|---|
| 1. Separation  | <ul style="list-style-type: none"> <li>• Maternal illness resulting in separation of infant and mother (e.g., shock or psychosis)</li> <li>• Mother not at the same hospital</li> </ul> |
| 2. Infant with inborn error of metabolism (e.g., galactosemia)                         |   |
| 3. Infant who is unable to feed at the breast (e.g., congenital malformation, illness) |   |
| 4. Maternal medications (those contraindicated in breastfeeding) <sup>20</sup>         |   |

**TABLE J-10**

Possible Indications for Supplementation in Term, Healthy Infants

1. Infant indications

- a. Asymptomatic hypoglycemia documented by laboratory blood glucose measurement (not bedside screening methods) that is unresponsive to appropriate frequent breastfeeding. Symptomatic infants should be treated with intravenous glucose. (Please see ABM Hypoglycemia Protocol for more details.<sup>88,89</sup>)
- b. Clinical and laboratory evidence of significant dehydration (e.g., >10% weight loss, high sodium, poor feeding, lethargy, etc.) that is not improved after skilled assessment and proper management of breastfeeding.<sup>92,59</sup>
- c. Weight loss of 8-10% accompanied by delayed lactogenesis II (day 5 [120 hours] or later)
- d. Delayed bowel movements or continued meconium stools on day 5 (120 hours)<sup>59,40</sup>
- e. Insufficient intake despite an adequate milk supply (poor milk transfer)<sup>59</sup>
- f. Hyperbilirubinemia
  - i. "Neonatal" jaundice associated with starvation where breastmilk intake is poor despite appropriate intervention (please see ABM Jaundice in the Breastfed Infant Protocol)
  - ii. Breastmilk jaundice when levels reach >20-25 mg/dL (mol/L) in an otherwise thriving infant and where a diagnostic and/or therapeutic interruption of breastfeeding may be helpful
- g. When macronutrient supplementation is indicated

2. Maternal indications

- a. Delayed lactogenesis II (day 3-5 or later [72-120 hours]) and inadequate intake by the infant<sup>59</sup>
  - i. Retained placenta (lactogenesis probably will occur after placental fragments are removed)
  - ii. Sheehan's syndrome (postpartum hemorrhage followed by absence of lactogenesis)
  - iii. Primary glandular insufficiency, occurs in less than 5% of women (primary lactation failure), as evidenced by poor breast growth during pregnancy and minimal indications of lactogenesis
- b. Breast pathology or prior breast surgery resulting in poor milk production<sup>50</sup>
- c. Intolerable pain during feedings unrelieved by interventions

Adapted with permission from Powers and Slusser.<sup>65</sup>

## Recommendations

1. Healthy infants should be put skin-to-skin with the mother immediately after birth to facilitate breastfeeding,<sup>4,23,69</sup> because the delay in time between birth and initiation of the first breastfeed is a strong predictor of formula use.<sup>46,79</sup>
2. Antenatal education and in-hospital support can significantly improve rates of exclusive breastfeeding.<sup>82</sup> Both mothers and health care providers should be aware of the risks of unnecessary supplementation.
3. Healthy newborns do not need supplemental feedings for poor feeding for the first 24 to 48 hours, but babies who are too sick to breastfeed or whose mothers are too sick to allow breastfeeding are likely to require supplemental feedings.<sup>65</sup>
4. Hospitals should strongly consider instituting a policy regarding supplemental feedings to require a physician's order when supplements are medically indicated and informed consent of the mother when supplements are not medically indicated. It is the responsibility of the health professional to provide information, document parental decisions, and support the mother after she has made the decision.<sup>35</sup> When the decision is not medically indicated, efforts to educate the mother ought to be documented by the nursing and/or medical staff.
5. All supplemental feedings should be documented, including the content, volume, method, and medical indication or reason.
6. If mother-baby separation is unavoidable, established milk supply is poor or questionable, or milk transfer is inadequate, the mother needs instruction and encouragement to pump or manually express her milk to stimulate production and provide expressed breastmilk as necessary for the infant.<sup>5,65,23,40</sup>
7. When supplementary feeding is necessary, the primary goals are to feed the baby and also to optimize the maternal milk supply while determining the cause of poor feeding or inadequate milk transfer.
8. Whenever possible, it is ideal to have the mother and infant room-in 24 hours per day to enhance opportunities for breastfeeding and hence lactogenesis.<sup>5,65,23,40</sup>
9. Optimally, mothers need to express milk each time the baby receives a supplemental feeding, or about every 2 to 3 hours. Mothers should be encouraged to start expressing on the first day (within the first 24 hours) or as soon as possible. Maternal breast engorgement should be

**Table J-10** lists possible indications for the administration of such feedings. The physician must decide if the clinical benefits outweigh the potential negative consequences of such feedings.

- avoided as it will further compromise the milk supply and may lead to other complications.<sup>65,23</sup>
10. All infants must be formally evaluated for position, latch, and milk transfer prior to the provision of supplemental feedings.<sup>5,40</sup> Most babies who remain with their mothers and breastfeed adequately lose less than 7% of their birth weight. Weight loss in excess of 7% may be an indication of inadequate milk transfer or low milk production.<sup>59</sup> Although weight loss in the range of 8% to 10% may be within normal limits, if all else is going well and the physical exam is normal, it is an indication for careful assessment and possible breastfeeding assistance.
  11. The infant's physician should be notified if:
    - a. The infant exhibits other signs of illness in addition to poor feeding.
    - b. The mother-infant dyad meets the clinical criteria in **Table J-9**.
    - c. The infant's weight loss is greater than 7%.

## *Choice of Supplemental Feeding*

1. Expressed human milk is the first choice for supplemental feeding,<sup>5,29</sup> but sufficient colostrum in the first few days (0 to 72 hours) may not be available. The mother may need reassurance and education if such difficulties occur. Hand expression may elicit larger volumes than a pump in the first few days and may increase overall milk supply.<sup>55</sup> Breast massage along with expressing with a mechanical pump may also increase available milk.<sup>56</sup>
2. If the volume of the mother's own colostrum does not meet her infant's feeding requirements, pasteurized donor human milk is preferable to other supplements.<sup>29</sup>
3. Protein hydrolysate formulas are preferable to standard artificial milks as they avoid exposure to cow milk proteins, reduce bilirubin levels more rapidly,<sup>32</sup> and may convey the psychological message that the supplement is a temporary therapy, not a permanent inclusion of artificial feedings. Supplementation with glucose water is not appropriate.
4. The physician must weigh the potential risks and benefits of other supplemental fluids, such as standard formulas, soy formulas, or protein hydrolysate formula, with consideration given to available resources, the family's history for risk factors such as atopy, the infant's age, the amounts needed, and the potential impact on the establishment of breastfeeding.

## *Volume of Supplemental Feeding*

Several studies give us an idea of intakes at the breast over time. In one study the mean yield of colostrum (using infant test-weighing) for over the first 24 hours after birth was 37.1 g (range, 7 to 122.5 g) with an average intake of 6 g per feed and six feedings in the first 24 hours.<sup>74</sup> A similar study also using test-weighing revealed a mean intake of 13 g/kg/24 hours (range, 3 to 32 g/kg/24 hours) for the first 24 hours, increasing to a mean of 98 g/kg/24 hours (range, 50 to 163 g/kg/24 hours) on day 3 (by 72 hours).<sup>14</sup> Yet another study<sup>26</sup> noted breastmilk transfer of 6 mL/kg/24 hours for day 1 (24 hours), 25 mL/kg/24 hours for day 2 (48 hours), 66 mL/kg/24 hours for day 3 (72 hours), and 106 mL/kg/24 hours for day 4 (96 hours) in healthy, vaginally delivered infants allowed on-demand breastfeeding. Interestingly, the intake of infants delivered by cesarean section was significantly less during days 2 to 4 (within 48 to 96 hours).<sup>26</sup> In a study where there was no rooming in and infants were fed every 4 hours, the average intake was 9.6 mL/kg/24 hours on day 1 and 13 mL/kg/24 hours on day 2 (48 hours).<sup>24</sup> In most studies, the range of intake is wide, with formula-fed infants usually taking in larger volumes than breastfed infants.

1. Infants fed artificial milks ad libitum commonly have higher intakes than breastfed infants.<sup>24</sup> Acknowledging that ad libitum breastfeeding recapitulates evolutionary feeding and considering recent data on obesity in artificially fed infants, it can be concluded that such artificially fed infants may well be overfed.
2. As there is no definitive research available, the amount of supplement given should reflect the normal amounts of colostrum available, the size of the infant's stomach (which changes over time), and the age and size of the infant.
3. Based on the limited research available, suggested intakes for term healthy infants are given in **Table J-11**, although feeding should be by infant cue to satiation.

**TABLE J-11** Average Reported Intakes of Colostrum by Healthy Breastfed Infants<sup>74,14,26,24</sup>

Time	Intake (mL/feed)
1st 24 hours	2-10
24-48 hours	5-15
48-72 hours	15-30
72-96 hours	30-60

## Methods of Providing Supplementary Feedings

---

1. When supplementary feedings are needed there are many methods from which to choose: a supplemental nursing device at the breast, cup feeding, spoon or dropper feeding, finger feeding, syringe feeding, or bottle feeding.<sup>87</sup>
2. There is little evidence about the safety or efficacy of most alternative feeding methods and their effect on breastfeeding; however, when cleanliness is suboptimal, cup feeding is the recommended choice.<sup>29</sup> Cup feeding has been shown safe for both term and preterm infants and may help preserve breastfeeding duration among those who require multiple supplemental feedings.<sup>37,38,42,51,49,47</sup>
3. Supplemental nursing systems have the advantage of supplying appropriate supplement while simultaneously stimulating the breast to produce more milk and reinforcing the infant's feeding at the breast. Unfortunately, most systems are awkward to use, difficult to clean, expensive, and require moderately complex learning.<sup>87</sup> A simpler version, supplementing with a dropper or syringe while the infant is at breast, may be effective.
4. Bottle feeding is the most commonly used method of supplementation in more affluent regions of the world but is of concern because of distinct differences in tongue and jaw movements, differences in flow, and long-term developmental concerns.<sup>87</sup> Some experts have recommended a nipple with a wide base and slow flow to try to mimic breastfeeding, but no research has been done evaluating outcomes with different nipples.
5. An optimal supplemental feeding device has not yet been identified, and they may vary from one infant to another. No method is without potential risk or benefit.<sup>87,18</sup>
6. When selecting an alternative feeding method, clinicians should consider several criteria:
  - a. Cost and availability
  - b. Ease of use and cleaning
  - c. Stress to the infant
  - d. Whether adequate milk volume can be fed in 20 to 30 minutes
  - e. Whether anticipated use is short- or long-term
  - f. Maternal preference
  - g. Whether the method enhances development of breastfeeding skills.

## Research Needs

---

1. Research is necessary to establish evidence-based guidelines on appropriate supplementation

volumes for specific conditions and whether this varies for colostrum versus artificial milk. Other specific questions include: Should the volume be independent of infant weight or a per kg volume? Should supplementation make up for cumulative losses? Should feeding intervals be different for different supplements?

2. Research is also lacking on what is the optimal method of supplementation. Are some methods best for infants with certain conditions, ages, and available resources? Which methods interfere least with establishing direct breastfeeding?

## Notes

---

This protocol addresses the term healthy newborn. For information regarding appropriate feeding and supplementation for the late preterm infant (35 to 37 weeks), see "ABM Protocol #10: Breastfeeding the Near-Term Infant"<sup>1</sup> and "Care and Management of the Late Preterm Infant Toolkit."<sup>12</sup>

The World Health Organization is currently updating its annex to the Global Criteria for the Baby Friendly Hospital Initiative: "Acceptable Medical Reasons for Supplementation."<sup>6</sup> The annex has been broadened to acceptable reasons for use of breastmilk substitutes in all infants. The handout (#4.5) is available at: [http://www.who.int/nutrition/publications/infantfeeding/WHO\\_NMH\\_NHD\\_09.01/en/](http://www.who.int/nutrition/publications/infantfeeding/WHO_NMH_NHD_09.01/en/).

## Acknowledgments

---

This work was supported in part by a grant to the Academy of Breastfeeding Medicine from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

APPENDIX	Inappropriate Reasons for Supplementation, Responses, and Risks	
Concerns	Responses	Risks of Supplementation
There is no milk, or colostrum is insufficient, until the milk "comes in"	<ul style="list-style-type: none"> <li>Mother and family should be educated about the benefits of colostrum (e.g., liquid gold) including dispelling myths about the yellow substance. Small amounts of colostrum are normal, physiologic, and appropriate for the term healthy newborn.</li> </ul>	<ul style="list-style-type: none"> <li>Can alter infant bowel flora.<sup>9,68</sup></li> </ul>
Concern about weight loss and dehydration in the postpartum period	<ul style="list-style-type: none"> <li>A certain amount of weight loss is normal in the first week of life and is due to both a diuresis of extracellular fluid received from the placenta and passage of meconium.</li> <li>There is now evidence that too <i>little</i> weight loss in the newborn period is associated with an increased risk of obesity later in life.<sup>81</sup></li> </ul>	<ul style="list-style-type: none"> <li>Potentially sensitizes the infant to foreign proteins.<sup>70,71,83,36</sup></li> </ul>
Concern about infant becoming hypoglycemic	<ul style="list-style-type: none"> <li>Healthy, full-term infants do not develop symptomatic hypoglycemia simply as a result of suboptimal breastfeeding.<sup>90</sup></li> </ul>	<ul style="list-style-type: none"> <li>Increases the risk of diarrhea and other infections,<sup>16,39,41,63</sup> especially where hygiene is poor.<sup>23,81</sup></li> </ul>
Concern about jaundice	<ul style="list-style-type: none"> <li>The more frequent the breastfeeding, the lower the bilirubin level.<sup>4,93,22</sup></li> </ul>	<ul style="list-style-type: none"> <li>Potentially disrupts the "supply-demand" cycle, leading to inadequate milk supply and long-term supplementation.</li> </ul>
Concern about jaundice	<ul style="list-style-type: none"> <li>Bilirubin is a potent antioxidant.<sup>45</sup> The appropriately breastfed infant has <i>normal</i> levels of bilirubin unless affected by another pathologic process such as hemolysis (e.g., ABO or Rh incompatibility).</li> </ul>	<ul style="list-style-type: none"> <li>If the supplement is water or glucose water, the infant is at risk for increased bilirubin,<sup>44,21,61,62,85</sup> excess weight loss,<sup>30</sup> and potential water intoxication.<sup>76</sup></li> </ul>
Concern about jaundice	<ul style="list-style-type: none"> <li>Colostrum acts as a natural laxative, helping to eliminate the retained pool of bilirubin contained in meconium.</li> </ul>	<ul style="list-style-type: none"> <li>Risk for weight loss/dehydration.</li> </ul>
Not enough time to counsel mother about exclusive breastfeeding, mothers may request supplement	<ul style="list-style-type: none"> <li>Training all staff in how to assist mothers with breastfeeding is important.</li> </ul>	<ul style="list-style-type: none"> <li>Risk for weight loss/dehydration.</li> </ul>
Not enough time to counsel mother about exclusive breastfeeding, mothers may request supplement	<ul style="list-style-type: none"> <li>Mothers may also benefit from education about artificial feeds and/or how supplements may adversely affect subsequent breastfeeding.<sup>17,79</sup></li> </ul>	<ul style="list-style-type: none"> <li>If the supplement is artificial milk, which is slow to empty from the stomach<sup>15,84</sup> and often fed in larger amounts,<sup>24</sup> the infant will breastfeed less frequently.<sup>24</sup></li> </ul>
Not enough time to counsel mother about exclusive breastfeeding, mothers may request supplement	<ul style="list-style-type: none"> <li>Help health care professionals understand that time spent on passive activities and interactions such as listening to and talking with mothers is of critical importance as opposed to other more active interventions (which may be viewed more as "real work" to them).<sup>17,79</sup></li> </ul>	<ul style="list-style-type: none"> <li>Depending on the method of supplementation<sup>87,53</sup> or the number of supplements,<sup>38,87</sup> an infant may have difficulty returning to the breast.</li> </ul>
Not enough time to counsel mother about exclusive breastfeeding, mothers may request supplement	<ul style="list-style-type: none"> <li>Prelacteal feeds (as opposed to supplementation) are associated with delayed initiation of breastfeeding and negatively associated with exclusivity and duration of breastfeeding.<sup>38,27,10,64</sup></li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>
Medications that may be contraindicated with breastfeeding	<ul style="list-style-type: none"> <li>Accurate references are easily available to providers (e.g., Lactmed on Toxnet website,<sup>57</sup> AAP policy,<sup>3</sup> <i>Medications and Mothers' Milk</i><sup>33</sup>).</li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>
Mother too malnourished or sick to breastfeed	<ul style="list-style-type: none"> <li>Even malnourished mothers can breastfeed.</li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>
Mother too malnourished or sick to breastfeed	<ul style="list-style-type: none"> <li>Reasons for supplementation with maternal illness that are listed in text.</li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>
Need to quiet a fussy or unsettled baby	<ul style="list-style-type: none"> <li>Infants can be unsettled for many reasons. They may wish to "cluster feed" (several short feeds in a short period of time) or simply need additional skin-to-skin time or holding.<sup>87</sup></li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>
Need to quiet a fussy or unsettled baby	<ul style="list-style-type: none"> <li>Filling (and often <i>overfilling</i>) the stomach with artificial milk may make the infant sleep longer,<sup>84</sup> missing important opportunities to breastfeed, and demonstrating to the mother a short-term solution that may generate long-term health risks.</li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>
Need to quiet a fussy or unsettled baby	<ul style="list-style-type: none"> <li>Teaching other soothing techniques to new mothers such as breastfeeding, swaddling, swaying, side lying techniques, encouraging father or other relatives to assist. Again, caution should be taken to not ignore early feeding cues.<sup>11</sup></li> </ul>	<ul style="list-style-type: none"> <li>Risk for difficulty returning to the breast.</li> </ul>

Continued

APPENDIX	Inappropriate Reasons for Supplementation, Responses, and Risks—cont'd	
Concerns	Responses	Risks of Supplementation
Accommodate growth or appetite spurts or periods of cluster feeds	<ul style="list-style-type: none"> <li>Periods when infants demand to nurse more and/or excrete less stool are sometimes interpreted by mothers as insufficient milk. This may happen in later weeks but also in the second or third night (48–72 hours) at home, in the immediate postpartum period.</li> <li>Anticipatory guidance may be helpful.</li> </ul>	<ul style="list-style-type: none"> <li>Risk of decreasing breastfeeding duration or exclusivity.</li> </ul>
Mother needs to rest or sleep	<ul style="list-style-type: none"> <li>Postpartum mother has been shown to be restless when separated from her infant and actually gets less rest.<sup>17</sup></li> <li>Mothers lose the opportunity to learn their infant's normal behavior and early feeding cues.<sup>40</sup></li> <li>The highest risk time of day for an infant to receive a supplement is between 7 PM and 9 AM.<sup>2</sup></li> </ul>	<ul style="list-style-type: none"> <li>Risk of decreasing breastfeeding duration or exclusivity.</li> </ul>
Taking a break will help with sore nipples	<ul style="list-style-type: none"> <li>Sore nipples are a function of latch, positioning, and sometimes individual anatomic variation, like ankyloglossia, not length of time nursing.<sup>78</sup></li> <li>There is no evidence that limiting time at the breast will prevent sore nipples.</li> </ul>	<ul style="list-style-type: none"> <li>Problem with latch not addressed.</li> <li>Risk of shortening breastfeeding duration or cessation of breastfeeding.</li> </ul>

## Protocol 4: Mastitis

Lisa H. Amir and the Academy of Breastfeeding Medicine Protocol Committee

### *Introduction*

Mastitis is a common condition in lactating women; estimates from prospective studies range from 3% to 20%, depending on the definition and length of postpartum follow-up.<sup>31,10,15</sup> The majority of cases occur in the first 6 weeks, but mastitis can occur at any time during lactation. There have been few research trials in this area.

Quality of evidence (levels of evidence I, II-1, II-2, II-3, and III) for each recommendation as defined in the U.S. Preventive Services Task Force Appendix A Task Force Ratings<sup>16</sup> is noted in parentheses in this document.

### *Definition and Diagnosis*

The usual clinical definition of mastitis is a tender, hot, swollen, wedge-shaped area of breast associated with temperature of 38.5°C (101.3°F) or greater, chills, flu-like aching, and systemic illness.<sup>13</sup> However, mastitis literally means, and is defined herein, as an inflammation of the breast; this inflammation may or may not involve a bacterial infection.<sup>33,32</sup> Redness, pain, and heat may all be present when an area of the breast is engorged or "blocked"/"plugged," but an infection is not necessarily present. There appears to be a continuum from engorgement to noninfective mastitis to infective mastitis to breast abscess.<sup>32</sup> (II-2)

### *Predisposing Factors*

The following factors may predispose a lactating woman to the development of mastitis.<sup>32,1</sup> Other

than the fact that these are factors that result in milk stasis, the evidence for these associations is generally inconclusive (II-2):

- Damaged nipple, especially if colonized with *Staphylococcus aureus*
- Infrequent feedings or scheduled frequency or duration of feedings
- Missed feedings
- Poor attachment or weak or uncoordinated sucking leading to inefficient removal of milk
- Illness in mother or baby
- Oversupply of milk
- Rapid weaning
- Pressure on the breast (e.g., tight bra, car seatbelt)
- White spot on the nipple or a blocked nipple pore or duct: milk blister or "bleb" (a localized inflammatory response)<sup>28</sup>
- Maternal stress and fatigue

### *Investigations*

Laboratory investigations and other diagnostic procedures are not routinely needed or performed for mastitis. The World Health Organization publication on mastitis suggests that breastmilk culture and sensitivity testing "should be undertaken if

- there is no response to antibiotics within 2 days
- the mastitis recurs
- it is hospital-acquired mastitis
- the patient is allergic to usual therapeutic antibiotics or
- in severe or unusual cases."<sup>32</sup> (II-2)

Breastmilk culture may be obtained by collecting a hand-expressed midstream clean-catch sample into a sterile urine container (i.e., a small quantity of the

initially expressed milk is discarded to avoid contamination of the sample with skin flora, and subsequent milk is expressed into the sterile container, taking care not to touch the inside of the container). Cleansing the nipple prior to collection may further reduce skin contamination and minimize false-positive culture results. Greater symptomatology has been associated with higher bacterial counts and/or pathogenic bacteria.<sup>11</sup> (III)

## Management

### EFFECTIVE MILK REMOVAL

Because milk stasis is often the initiating factor in mastitis, the most important management step is frequent and effective milk removal:

- Mothers should be encouraged to breastfeed more frequently, starting on the affected breast.
- If pain interferes with the letdown, feeding may begin on the unaffected breast, switching to the affected breast as soon as letdown is achieved.
- Positioning the infant at the breast with the chin or nose pointing to the blockage will help drain the affected area.
- Massaging the breast during the feed with an edible oil or nontoxic lubricant on the fingers may also be helpful to facilitate milk removal. Massage, by the mother or a helper, should be directed from the blocked area moving toward the nipple.
- After the feeding, expressing milk by hand or pump may augment milk drainage and hasten resolution of the problem.<sup>20</sup> (III)

An alternate approach for a swollen breast is fluid mobilization, which aims to promote fluid drainage toward the axillary lymph nodes.<sup>29</sup> The mother reclines, and with gentle hand motions starts stroking the skin surface from the areola to the axilla.<sup>29</sup> (III)

There is no evidence of risk to the healthy term infant of continuing breastfeeding from a mother with mastitis.<sup>32</sup> Women who are unable to continue breastfeeding should express the milk from breast by hand or pump, as sudden cessation of breastfeeding leads to a greater risk of abscess development than continuing to feed.<sup>20</sup> (III)

### SUPPORTIVE MEASURES

Rest, adequate fluids, and nutrition are important measures. Practical help at home may be necessary for the mother to obtain adequate rest. Application of heat—for example, a shower or a hot pack—to the breast just prior to feeding may help with the letdown and milk flow. After a feeding or after milk

is expressed from the breasts, cold packs can be applied to the breast in order to reduce pain and edema.

Although most women with mastitis can be managed as outpatients, hospital admission should be considered for women who are ill, require intravenous antibiotics, and/or do not have supportive care at home. Rooming-in of the infant with the mother is mandatory so that breastfeeding can continue. In some hospitals, rooming-in may require hospital admission of the infant.

### PHARMACOLOGIC MANAGEMENT

Although lactating women are often reluctant to take medications, women with mastitis should be encouraged to take appropriate medications as indicated.

#### Analgesia

Analgesia may help with the letdown reflex and should be encouraged. An anti-inflammatory agent such as ibuprofen may be more effective in reducing the inflammatory symptoms than a simple analgesic like paracetamol/acetaminophen. Ibuprofen is not detected in breastmilk following doses up to 1.6 g/day and is regarded as compatible with breastfeeding.<sup>21</sup> (III)

#### Antibiotics

If symptoms of mastitis are mild and have been present for less than 24 hours, conservative management (effective milk removal and supportive measures) may be sufficient. If symptoms are not improving within 12 to 24 hours or if the woman is acutely ill, antibiotics should be started.<sup>32</sup> Worldwide, the most common pathogen in infective mastitis is penicillin-resistant *S. aureus*.<sup>17,19</sup> Less commonly, the organism is a *Streptococcus* or *Escherichia coli*.<sup>20</sup> The preferred antibiotics are usually penicillinase-resistant penicillins,<sup>13</sup> such as dicloxacillin or flucloxacillin 500 mg by mouth four times per day,<sup>27</sup> or as recommended by local antibiotic sensitivities. (III) First-generation cephalosporins are also generally acceptable as first-line treatment, but may be less preferred because of their broader spectrum of coverage. (III)

Cephalexin is usually safe in women with suspected penicillin allergy, but clindamycin is suggested for cases of severe penicillin hypersensitivity.<sup>27</sup> (III) Dicloxacillin appears to have a lower rate of adverse hepatic events than flucloxacillin.<sup>25</sup> Many authorities recommend a 10- to 14-day course of antibiotics<sup>14,8</sup>; however, this recommendation has not been subjected to controlled trials. (III)

*S. aureus* resistant to penicillinase-resistant penicillins (methicillin-resistant *S. aureus* [MRSA], also referred to as oxacillin-resistant *S. aureus*) has been increasingly isolated in cases of mastitis and breast abscesses.<sup>24,2,9,30</sup> (II-2) Clinicians should be aware of the likelihood of this occurring in their community and should order a breastmilk culture and assay of antibiotic sensitivities when mastitis is not improving 48 hours after starting first-line treatment. Local resistance patterns for MRSA should be considered when choosing an antibiotic for such unresponsive cases while culture results are pending. MRSA may be a community-acquired organism and has been reported to be a frequent pathogen in cases of breast abscess in some communities, particularly in the United States and Taiwan.<sup>2,6,30</sup> (I, II-2) At this time, MRSA occurrence is low in other countries, such as the United Kingdom.<sup>23</sup> (I) Most strains of methicillin-resistant staphylococci are susceptible to vancomycin or trimethoprim/sulfamethoxazole but may not be susceptible to rifampin.<sup>18</sup> Of note is that MRSA should be presumed to be resistant to treatment with macrolides and quinolones, regardless of susceptibility testing results.<sup>3</sup> (III)

As with other uses of antibiotics, repeated courses place women at increased risk for breast and vaginal *Candida* infections.<sup>26,12</sup>

## Follow-up

Clinical response to the above management is typically rapid and dramatic. If the symptoms of mastitis fail to resolve within several days of appropriate management, including antibiotics, a wider differential diagnosis should be considered. Further investigations may be required to confirm resistant bacteria, abscess formation, an underlying mass, or inflammatory or ductal carcinoma. More than two or three recurrences in the same location also warrant evaluation to rule out an underlying mass or other abnormality.

## Complications

### EARLY CESSATION OF BREASTFEEDING

Mastitis may produce overwhelming acute symptoms that prompt women to consider cessation of breastfeeding. Effective milk removal, however, is the most important part of treatment.<sup>32</sup> Acute cessation of breastfeeding may actually exacerbate the mastitis and increase the risk of abscess formation; therefore, effective treatment and support from health care providers and family are important at this time. Mothers may need reassurance that the antibiotics they are taking are safe to use during breastfeeding.

## ABSCESS

If a well-defined area of the breast remains hard, red, and tender despite appropriate management, then an abscess should be suspected. This occurs in about 3% of women with mastitis.<sup>5</sup> (II-2) The initial systemic symptoms and fever may have resolved. A diagnostic breast ultrasound will identify a collection of fluid. The collection can often be drained by needle aspiration, which itself can be diagnostic as well as therapeutic. Serial needle aspirations may be required.<sup>4,7,22</sup> (III) Ultrasound guidance for needle aspiration may be necessary in some cases. Fluid or pus aspirated should be sent for culture. Consideration of resistant organisms should also be given depending on the incidence of resistant organisms in that particular environment. Surgical drainage may be necessary if the abscess is very large or if there are multiple abscesses. After surgical drainage, breastfeeding on the affected breast should continue, even if a drain is present, with the proviso that the infant's mouth does not come into direct contact with purulent drainage or infected tissue. A course of antibiotics should follow drainage of the abscess. (III)

Photographs of breast abscesses and percutaneous aspiration can be found in a 2013 review by Kataria et al.<sup>34</sup>

## CANDIDA INFECTION

*Candida* infection has been associated with burning nipple pain or radiating breast pain symptoms.<sup>14</sup> Diagnosis is difficult, as the nipples and breasts may look normal on examination, and milk culture may not be reliable. Careful evaluation for other etiologies of breast pain should be undertaken with particular attention to proper latch and ruling out Raynaud's/vasospasm and local nipple trauma. When wound cultures are obtained from nipple fissions, they most commonly grow *S. aureus*. (I)

A recent investigation of women with these typical symptoms, using breastmilk cultures after cleansing the nipples, found that none of the 35 cultures from the control group of women grew *Candida*, whereas only 1 of 29 in the symptomatic group grew the organism. (I) There was also no significant difference in the measurement of a by-product of *Candida* growth [(1,3) $\beta$ -D-glucan] between groups. Yet, evidence is conflicting as another recent study on milk culture found that 30% of symptomatic mothers were positive for *Candida*, whereas 8% of women in the asymptomatic group grew the organism. (I)

Women with burning nipple and breast pain may also be more likely to test positive for *Candida* on nipple swab by polymerase chain reaction.

Using molecular techniques as well as standard culture, a large cohort study of women followed up for 8 weeks postpartum found that burning nipple pain with breast pain was associated with *Candida* species but not with *S. aureus*. (II-2)

Further research in this area is required. Until then, a trial of antifungal medications, either with or without culture, is the current expert consensus recommendation. (III)

## *Prevention (III)<sup>1</sup>*

### EFFECTIVE MANAGEMENT OF BREAST FULLNESS AND ENGORGEMENT

- Mothers should be helped to improve infants' attachment to the breast.
- Feeds should not be restricted.
- Mothers should be taught to hand-express when the breasts are too full for the infant to attach or the infant does not relieve breast fullness. A breast pump may also be used, if available, for these purposes, but all mothers should be able to manually express as the need for its use may arise unexpectedly.

### PROMPT ATTENTION TO ANY SIGNS OF MILK STASIS

- Mothers should be taught to check their breasts for lumps, pain, or redness.
- If the mother notices any signs of milk stasis, she needs to rest, increase the frequency of breastfeeding, apply heat to the breast prior to feedings, and massage any lumpy areas as described in the section "Effective milk removal."
- Mothers should contact their health care provider if symptoms are not improving within 24 hours.

### PROMPT ATTENTION TO OTHER DIFFICULTIES WITH BREASTFEEDING

Skilled help is needed for mothers with damaged nipples or an unsettled discontented infant or those who believe that they have an insufficient milk supply.

### REST

As fatigue is often a precursor to mastitis, health care providers should encourage breastfeeding mothers to obtain adequate rest. It may also be helpful for health care providers to remind family members that breastfeeding mothers may need more help and encourage mothers to ask for help as necessary.

### GOOD HYGIENE

Because *S. aureus* is a common commensal organism often present in hospitals and communities, the importance of good hand hygiene should not be overlooked.<sup>17</sup> It is important for hospital staff, new mothers, and their families to practice good hand hygiene. Breast pump equipment may also be a source of contamination and should be washed thoroughly with soap and hot water after use.

### Recommendations for Further Research

There are several aspects of prevention, diagnosis, and treatment of mastitis that require research. First, a consensus on a definition of mastitis is vital. We need to know when antibiotics are needed, which are the most appropriate antibiotics, and the optimal duration of treatment. The role of probiotics in prevention and treatment needs to be determined. Finally, the role of massage to prevent and treat breast engorgement and infection needs to be clarified.

### Acknowledgments

This work was supported in part by a grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

## APPENDIX J

# *Protocol 5: Peripartum Breastfeeding Management for the Healthy Mother and Infant at Term*

## *Background*

Hospital policies and routines greatly influence breastfeeding success.<sup>28,65,38,44,68,6,59,16,3,61</sup> The Baby-Friendly Hospital Initiative (BFHI) has defined the Ten Steps to Successful Breastfeeding, and 20 years of research has now verified that "the achievement of BFHI certification leads to substantially improved breastfeeding outcomes, especially increases in breastfeeding initiation and exclusivity."<sup>28</sup>

The peripartum hospital experience should include adequate support, instruction, and care to ensure the successful initiation of breastfeeding. Such management is part of a continuum of care and education that begins during the prenatal period, promotes breastfeeding as the optimal method of infant feeding, and includes information about maternal and infant benefits. The following principles and practices are recommended for care in the peripartum hospital setting.

## *Recommendations*

Quality of evidence (levels of evidence I, II-1, II-2, II-3, and III) for each recommendation as defined in the U.S. Preventive Services Task Force Appendix A Task Force Ratings<sup>8</sup> is noted in parentheses.

## *Prenatal*

1. All pregnant women must receive education about the benefits and management of breastfeeding to allow an informed decision about infant feeding.<sup>68,6,59,16,3,61</sup> An evidence-based review of practices that improve the duration or initiation of breastfeeding found that "prenatal combined with postnatal interventions are more effective than usual care in prolonging the duration of breastfeeding...."<sup>20</sup> Information and advice from a health professional early in pregnancy are also supported by the American College of Obstetricians and Gynecologists and the American Academy of Family Physicians in their policy statements, which read "Advice and encouragement of the obstetrician-gynecologist are critical in making the decision to breastfeed"<sup>6</sup> and "Family-centered care (the belief that health care staff and the family are partners, working together to best meet the needs of the patient) allows support of breastfeeding practices throughout the life-cycle to all family members."<sup>3</sup> (I, II-1, II-2, II-3, III)
2. Prenatal education should include information about the benefits to mother and baby of exclusive breastfeeding initiated in the first hour after birth.<sup>68</sup> Educational materials produced by formula manufacturers are inappropriate sources of information about infant feeding.<sup>30,2</sup> (I, III)

3. Maternity care includes an assessment of any medical or physical conditions that could affect a mother's ability to breastfeed her infant. In some cases, it may be helpful to obtain a prenatal consultation with the infant's physician or a lactation consultant or specialist and to develop a plan of follow-up to be instituted at the time of delivery.<sup>6,59,16</sup> Women will benefit from moderated group discussions, group prenatal visits, systematic case management, or referral to a lay support organization prior to delivery.<sup>6,59,16,20</sup> There is also good evidence that peer counseling promotes the initiation and maintenance of breastfeeding.<sup>17,62</sup> (I, II-3, III)

## *Labor and Delivery*

1. Women will benefit from the continuous presence of a close companion (e.g., doula, spouse/partner, or family member) throughout labor and delivery. The presence of a doula is known to enhance breastfeeding initiation and duration.<sup>37</sup> Many risk factors are associated with early cessation of breastfeeding, including the mean length of labor, the need for surgical intervention, and the use of pain-reducing interventions such as epidurals and other medications. These risks may be reduced by the presence of a doula.<sup>27,51,49</sup> (I, II-2, III)
2. Intrapartum analgesia may also have an impact on breastfeeding, and consideration needs to be given to the type and dose of analgesia.<sup>6,11,24,46</sup> Epidural analgesia, intramuscular opioids, exogenous oxytocin, and ergometrine have all been associated with lower rates of breastfeeding initiation.<sup>33</sup> (I, II-2, III)

## *Immediate Postpartum*

1. The healthy newborn should be given directly to the mother for skin-to-skin contact until after the first feeding. The infant may be dried and assigned Apgar scores, and the initial physical assessment may be performed as the infant is placed with the mother. Such physical contact provides the infant with optimal physiologic stability, warmth, and opportunities for the first feeding.<sup>61,19,43,45,47,13</sup> Extensive early skin-to-skin contact likely increases the duration of any and exclusive breastfeeding.<sup>45,47,13,15,31,22,42,63,50</sup> Delaying procedures such as weighing, measuring, administering eye prophylaxis as well as vitamin K, and the initial bath up to 6 hours after birth enhances early parent-infant interaction.<sup>61,55</sup> Infants are to be put close to the breast, as soon after birth

as is feasible for both mother and infant, to allow for a latch and feeding, ideally within an hour of birth.<sup>47,31,22,42,63,50</sup> This practice is to be initiated in the delivery, operating, or recovery room, and every mother should be instructed in proper breastfeeding technique.<sup>68,61,31,57,58,21,26,36</sup> (I, II-2, II-3, III)

2. Mother-baby rooming-in on a 24-hour basis enhances opportunities for bonding and for optimal breastfeeding initiation. Whenever possible, mothers and infants are to remain together during the hospital stay.<sup>61,15,50,35,66,9,53</sup> To avoid unnecessary separation, infant assessments in the immediate postpartum time period and thereafter are ideally performed in the mother's room. Evidence suggests that mothers get the same amount and quality of sleep whether infants room-in or are sent back to the nursery at night.<sup>35,66,9</sup> (II-1, II-2, II-3, III)
3. Education about the benefits of 24-hour rooming-in encourages parents to use it as the standard mode of hospital care for their families. At the same time, from a staffing standpoint, nursing personnel should arrange for time to be available to assess and document the status of the infant and infant feeding while the baby is in the family's room.<sup>68,61,36,53,56</sup> (I, II-3, III)
4. Women may need help from health care providers to ensure that they are able to position and attach their babies at the breast. Those delivered by cesarean section may need additional help from nursing staff to attain comfortable positioning. A trained observer should assess and document the effectiveness of breastfeeding at least once every 8 to 12 hours after delivery until mother and infant are discharged. In countries where the delivery hospital stay may last up to a week, then assessment should continue until breastfeeding is successfully established.<sup>28,61</sup> Peripartum care of the dyad should address and document infant positioning, latch, milk transfer, baby's weight, clinical jaundice, and any problems raised by the mother, such as nipple pain or the perception of an inadequate breastmilk supply. Formal inpatient lactation instruction programs need to be assessed carefully for effectiveness and best practices.<sup>58,21,26,36</sup> Some infants are sleepy in the first 24 hours after birth. By the second day, infants who are breastfeeding well will feed on demand. Feedings usually range from 8 to 12 times or more in 24 hours, with a minimum of eight feedings every 24 hours. Limiting the time that an infant is at the breast is not necessary and may even be harmful to the establishment of a good milk supply. Infants usually fall asleep or release the breast spontaneously when satiated. (I, II-2, II-3, III)

5. Supplemental feeding should not be given to breastfed infants unless there is a medical indication.<sup>61,30,14,12,54</sup> Supplementation can inhibit or delay the establishment of maternal milk supply and have adverse effects on breastfeeding (e.g., delayed lactogenesis, maternal engorgement). Supplements may alter infant bowel flora, sensitize the infant to allergens (depending on the content of the feeding and method used), interfere with maternal-infant bonding, and interfere with infant weight gain.<sup>2,14,12,54</sup> There is no role for the routine supplementation of nondehydrated infants with water or dextrose water; in fact, this practice could contribute to hyperbilirubinemia.<sup>5</sup> Before any supplementary feedings are begun, it is important that a formal evaluation of each mother-baby dyad, including a direct observation of breastfeeding, is completed by a provider trained in lactation.<sup>2</sup> (I, II-2, III)
6. Pacifiers in the neonatal period should be used with caution. Some earlier research showed that pacifier use in the neonatal period was detrimental to exclusive and overall breastfeeding,<sup>52,29</sup> while a recent Cochrane Review found that pacifier use in healthy term breastfeeding infants, started at birth or after lactation was established, did not significantly affect the prevalence or duration of exclusive and partial breastfeeding up to 4 months of age.<sup>32</sup> Other recent studies suggest that the relationship among pacifiers, breastfeeding, and supplementation is more complex than previously realized.<sup>34</sup> (I)
7. In general, acute infectious diseases, undiagnosed fever, and common postpartum infections in the mother are not a contraindication to breastfeeding, if such diseases can be readily controlled and treated. Infants should not be breastfed in the case of untreated active tuberculosis, or herpes simplex when there are breast lesions.<sup>69,40,41</sup> In the case of maternal human immunodeficiency virus the World Health Organization recommends that "national authorities in each country decide which infant feeding practice (i.e., breastfeeding with an anti-retroviral intervention to reduce transmission or avoidance of all breastfeeding) should be promoted and supported by their maternal and child health services."<sup>69</sup> Infectious peripartum varicella may require separation of the mother and newborn, limiting direct breastfeeding, but expressed milk can be used.<sup>10</sup> Beyond infectious diseases, the listing of all contraindications is beyond the scope of this document, but reliable sources of information are readily available and include information about medications and radioactive compounds.<sup>40,41,60,64,25,67,18,7</sup> (III)
8. All breastfed infants should be seen by a health-care provider at 3 to 5 days of life or within 48 to 72 hours of discharge to evaluate the infant's well-being and the successful establishment of breastfeeding.<sup>61,1,39,4</sup> Depending on the length of hospitalization or country of origin, these postpartum practices may vary. For example, in Japan and Australia the mother and infant stay for 4 to 5 days in the hospital, and in the United Kingdom mothers are home-visited by nurse midwives for about 10 days. (I, III) Peer-to-peer support should also be offered and has been proven to be helpful in promoting breastfeeding success.<sup>62,56</sup> (I, I-2)

## Problems and Complications

---

1. Mother-baby dyads at risk for breastfeeding problems benefit from early identification and assistance. Consultation with an expert in lactation management may be helpful in situations including but not limited to the following:
  - a. Maternal request/anxiety.
  - b. Previous negative breastfeeding experience.
  - c. Mother has flat/inverted nipples.
  - d. Mother has history of breast surgery.
  - e. Multiple births (twins, triplets, higher-order pregnancies).
  - f. Infant is early term (37 to 38 6/7 weeks of gestation) or premature (<37 weeks).
  - g. Infant has congenital anomaly, neurological impairment, or other medical condition that affects the infant's ability to breastfeed.
  - h. Maternal or infant medical condition for which breastfeeding must be temporarily postponed or for which milk expression is required.
  - i. Documentation, after the first few feedings, that there is difficulty in establishing breastfeeding (e.g., poor latch-on, sleepy baby, etc.).
  - j. Hyperbilirubinemia.
2. Discharge of mothers and babies from the hospital at less than 48 hours mandates that risks to successful breastfeeding be identified in a timely manner so that the time spent in the hospital is used to maximal benefit.<sup>1</sup> Recommendations for close follow-up are particularly important for dyads with early discharge.
3. If a neonate needs to be transferred to an intermediate or intensive care area, steps must be taken to maintain maternal lactation. When possible, transport of the mother to the intermediate or intensive care nursery to continue breastfeeding is optimal. If breastfeeding is not possible, arrangements should be made to

continue human milk feeding for the neonate. Mothers must be shown how to maintain lactation through both manual and mechanical expression.<sup>68,61</sup> There is evidence that there may be greater maternal milk production with the use of electric breast pumps compared with manual expression alone.<sup>10,23</sup> A combination of manual and mechanical expression (hands-on pumping)<sup>48</sup> may yield optimal milk production. (I, I-2, III)

4. If an infant is not feeding at the breast consistently and effectively at the time of hospital discharge, the mother must be shown how to maintain lactation through both manual and mechanical expression and demonstrate proficiency in emptying her breasts before she is released home.<sup>10,23</sup> The possible need for supplemental feedings for the infant must be addressed, with consideration given to the choice of supplement to be used and the method of feeding. Any and all breastmilk the mother can express should be used, and it should only be supplemented further if maternal supply is inadequate. Cup feeding may help preserve breastfeeding duration among those who require multiple supplemental feedings because of the concerns regarding nipple confusion or bottle preference.<sup>29</sup> The mother-infant dyad will need referral to a lactation professional for continued assistance and support.

## Recommendations for Future Research

1. Controversy remains as to the effects of labor medications on breastfeeding outcomes. More studies are needed to evaluate the effects of the various labor medications available on both short- and long-term breastfeeding outcomes.
2. Despite evidence that delaying postpartum interventions to the newborn is associated with improved breastfeeding outcomes, many hospital policies still dictate immediate weighing, measuring, administering eye prophylaxis and vitamin K, and an early initial bath, all of which interfere with early and continued skin-to-skin and breastfeeding initiation. Large implementation and/or multicenter trials may be needed to ultimately influence changes in hospital policies if these findings persist.
3. The relationship between pacifiers and breastfeeding is more complex than previously realized. More research is needed to assess the effect of pacifiers on short-term breastfeeding difficulties and long-term effect on breastfeeding duration.

4. As more hospitals adopt the Ten Steps and are certified as Baby-Friendly Hospitals, we need to continue to collect data concerning which specific peripartum practices are most important in achieving desirable breastfeeding outcomes.

## Acknowledgments

This work was supported in part by a grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

## APPENDIX J

# Protocol 6: Guideline on Co-Sleeping and Breastfeeding

---

## Introduction

---

The Academy of Breastfeeding Medicine is a worldwide organization of physicians dedicated to the promotion, protection, and support of breastfeeding and human lactation. One of the goals of the Academy of Breastfeeding Medicine is the facilitation of optimal breastfeeding practices. This clinical guideline addresses an aspect of parenting that has a significant impact on breastfeeding: infant sleep locations.

## Background

---

The terms *co-sleeping* and *bed sharing* are often used interchangeably. However, bed sharing is only one form of co-sleeping. Co-sleeping, in reality, refers to the diverse ways in which infants sleep in close social and/or physical contact with a caregiver (usually the mother).<sup>19</sup> This operational definition includes an infant sleeping alongside a parent on a different piece of furniture/object as well as clearly unsafe practices such as sharing a sofa or recliner. Around the world the practice of co-sleeping can be quite variable, and, as such, all forms of co-sleeping do not carry the same risks or benefits.<sup>3</sup> Some forms of parent-child co-sleeping provide physical protection for the infant against cold and extend the duration of breastfeeding, thus improving the chances of survival of the slowly developing human infant.<sup>19,14–16</sup> The human infant, relative to other mammals, develops more slowly, requires frequent feedings, and is born neurologically less mature.<sup>19,14–16</sup> In malaria

settings, co-sleeping is recommended as the most efficient use of available bed nets, and co-sleeping may be necessary in other geographic areas where available bedding or housing is inadequate. Bed sharing and co-sleeping have also long been promoted as a method to enhance parenting behavior or “attachment parenting” and also to facilitate breastfeeding.<sup>19,3,14–16,4,6,7,11,26,34,33,28</sup>

Bed sharing and some forms of co-sleeping have been rather controversial in the medical literature in recent years and have received considerable negative comment.<sup>4,6,7,11,26</sup> Some public health authorities have discouraged all parents from bed sharing.<sup>34,33</sup>

## Bed Sharing and Infant Mortality

---

The concerns regarding bed sharing and increased infant mortality have been centered around mechanical suffocation (asphyxiation) and sudden infant death syndrome (SIDS) risks.

### ASPHYXIATION RISK

Several studies using *unverified death certificate* diagnoses concluded that a significant number of infants were asphyxiated as they slept in unsafe sleep environments caused by either accidental entrapment in the sleep surface or overlying by a sleeping adult or older child.<sup>4,6,7,11,26</sup> The U.S. Consumer Product Safety Commission (USCPSC), using data from some of these studies, has made recommendations against the use of all types and forms of co-sleeping and advised parents against sleeping with their infants under any circumstances. The USCPSC is

concerned about the absence of infant safety standards for adult beds and the hazards that may result from an infant sleeping in an unsafe environment.<sup>34</sup> All of these studies lack data on the state of intoxication of the co-sleeping adult (drugs or alcohol) and fail to consider the sleep position of the baby at time of death, even though a prone sleep position appears to be one of the most significant risk factors for SIDS. The USCPSC also groups all bed sharing into one category, not separating known unsafe sleep environments such as sofas and couches, water-beds, and upholstered chairs from other, safer sleep surfaces. In these studies, there is no assurance of the quality of the data collection, no consistency in the criteria employed in using the term "overlay," and no validation of the conclusions. Bias by medical examiners and coroners may lead them to classify infant deaths that occur in an adult bed, couch, or chair in the presence of an adult as a rollover death even where there is no evidence that an actual overlay occurred. This is especially a problem in the absence of a death scene examination and detailed interviews of those present at the time of death. There is no autopsy method to differentiate between death caused by SIDS versus death from accidental or intentional causes such as infant homicide by pillow smothering. Thus infant deaths that occur in a crib are usually designated as SIDS, whereas deaths in a couch or adult bed are usually labeled as smothering. Further complicating analyses of infant deaths is the diversity of bed-sharing behaviors among different populations and even within the same families (i.e., bed sharing during the day vs. at night or when a baby is ill vs. when a baby is well), suggesting different levels of risk. A home visit study of families considered to be at high risk for SIDS because of socioeconomic status found that those who practiced bed sharing were more likely to place infants in the prone position and to use softer bed surfaces.<sup>8</sup> Similarly, a population-based retrospective review found that "Bed-sharing subjects who breastfed had a risk profile distinct from those who were not breastfed cases. Risk and situational profiles can be used to identify families in greater need of early guidance and to prepare educational content to promote safe sleep."<sup>27</sup>

## SIDS PREVENTION AND RISK

Several epidemiological studies and a meta-analysis have found a significant association between breastfeeding and a lowered SIDS risk, especially when breastfeeding was the exclusive form of feeding during the first 4 months of life.<sup>9,20</sup>

However, there is insufficient evidence at this time to show a causal link between breastfeeding and the prevention of SIDS. Several studies have consistently demonstrated an increased risk of

SIDS when infants bed share with mothers who smoke cigarettes.<sup>3,23,21,24,30,31,29,22</sup> Exposure to cigarette smoke as a fetus and in infancy appears to contribute to this risk and is independent of other known risk factors, including social class. This has led to the recommendation, which is well supported in the medical literature, that infants not bed share with parents who smoke. A large meta-analysis, after review of over 40 studies, concluded that, "Evidence consistently suggests that there may be an association between bed sharing and sudden infant death syndrome (SIDS) among smokers (however defined), but the evidence is not as consistent among nonsmokers. This does not mean that no association between bed sharing and SIDS exists among nonsmokers, but that existing data do not convincingly establish such an association."<sup>10</sup>

## Ethnic Diversity

The rates of SIDS deaths are low in Asian cultures in which co-sleeping is common. However, some argue that co-sleeping in these cultures is different from the bed sharing that occurs in the United States. As Blair and colleagues note in their study, "A baby sleeping at arm's length from the mother on a firm surface, as is often the case in Hong Kong, or a Pacific Island baby sleeping *on* the bed rather than *in* the bed is in a different environment from a baby sleeping in direct contact with the mother on a soft mattress and covered by a thick duvet."<sup>3</sup> Similarly, even within the United States there seems to be variation in bed-sharing practices based on ethnicity and race. A large, prospective study using multivariate analysis of bed sharing found that race or ethnicity appears to have the strongest association with bed sharing at all follow-up periods, with black, Asian, and Hispanic mothers four to six times more likely to bed share than white mothers.<sup>13</sup>

In a study in Alaska, where there is a high rate of co-sleeping among Alaska Native people, researchers found that almost all SIDS deaths associated with parental bed sharing occurred in conjunction with a history of parental drug use and occasionally in association with prone sleep position or sleeping on surfaces such as couches or waterbeds.<sup>12</sup> A study using the PRAMS (Pregnancy Risk Assessment Monitoring System) data set in Oregon found that "The women most likely to bed share are non-white, single, breastfeeding, and low-income. Non-economic factors are also important, particularly among blacks and Hispanics. Campaigns to decrease bed sharing by providing cribs may have limited effectiveness if mothers are bed sharing because of cultural norms."<sup>12</sup>

## Controlled Laboratory Studies

---

McKenna and colleagues have studied bed sharing in the greatest scientific detail in a laboratory setting and have found that infants who shared a bed with the mother had more sleep arousals and spent less time in Stage 3 and 4 sleep. This may be protective against SIDS as deep sleep and infrequent arousals have been considered as possible risk factors for SIDS.<sup>14,17,25</sup>

A similar study that was conducted in the natural physical environment of home instead of a sleep lab "compared the two different sleep practices of bed sharing and cot sleeping quantifying factors that have been identified as potential risks or benefits. Overnight video and physiologic data of bed-share infants and cot-sleep infants were recorded in the infants' own homes."<sup>1</sup> This study concluded that "Bed-share infants without known risk factors for sudden infant death syndrome (SIDS) experience increased maternal touching and looking, increased breastfeeding, and faster and more frequent maternal responses."<sup>1</sup> This increased interaction between mothers and babies may be protective.

## Parental Factors

---

The contribution of other parental factors to the risk of bed sharing is unclear. Blair and colleagues found in a multivariate analysis that maternal alcohol consumption of more than two drinks (one drink = 12 oz beer, 5 oz wine, or 1.5 oz distilled alcohol) and parental tiredness were associated with sudden infant death.<sup>3</sup> A study in New Zealand, however, did not show a clear link with alcohol consumption.<sup>30</sup> The role of obesity was examined in one study of SIDS cases. They found the mean pre-gravid weights of bed-sharing mothers to be greater than those of nonbed-sharing mothers.<sup>6</sup>

If overlying is thought to be the mechanism of infant suffocation, it would seem plausible that the psychological and physical states of those sharing the bed with an infant could be of importance.

Room sharing with parents (infants sharing the same room as their parents as opposed to being in a separate room) appears to be protective against SIDS.<sup>3,32,5</sup>

## Infant Factors

---

There is some evidence that bed sharing with younger babies <8 to 14 weeks may increase the risk of SIDS.<sup>3,32,5</sup>

## Breastfeeding and Bed Sharing

---

Research continues to show the strong relationship between breastfeeding and bed sharing/co-sleeping. A study of bed sharing and breastfeeding in the United States found that infants who routinely shared a bed with their mothers breastfed approximately three times longer during the night than infants who routinely slept separately. There was a twofold increase in the number of breastfeeding episodes, and the episodes were 39% longer.<sup>18</sup> Proximity to and sensory contact with the mother during sleep facilitates prompt responses to signs of the infant's readiness to breastfeed and provides psychological comfort and reassurance to the dependent infant as well as the parents. A large prospective study of more than 10,000 infants in the United States found that up to 22% of 1-month-old infants were bed sharing and that breastfeeding mothers were three times more likely to bed share than mothers who did not breastfeed. Ninety-five percent of infants who shared a bed did so with a parent.<sup>13</sup> Similarly, a study of parent-infant bed sharing in England found that "Breast feeding was strongly associated with bed-sharing, both at birth and at 3 months."<sup>2</sup>

Based on the above information and literature, the Academy of Breastfeeding Medicine has the following recommendations for health care providers.

## Recommendations

---

- A. Because breastfeeding is the best form of nutrition for infants, any recommendations for infant care that impede its initiation or duration need to be carefully weighed against the many known benefits to infants, their mothers, and society.
- B. It should not be assumed that all families are practicing only one sleeping arrangement all night every night and during the daytime as well. Health care providers should consider ethnic, socioeconomic, feeding, and other family circumstances when obtaining a history on infant sleep practices.<sup>3,8,27</sup>
- C. Parents need to be encouraged to express their views and to seek information and support from their health care providers. Sensitivity to cultural differences is necessary when obtaining sleep histories.
- D. There is currently not enough evidence to support routine recommendations against co-sleeping. Parents should be educated about risks and benefits of co-sleeping and unsafe co-sleeping practices and should be allowed to make their own informed decision.

Bed sharing/co-sleeping is a complex practice. Parental counseling about infant sleep environments should include the following information:

1. Some potentially unsafe practices related to bed sharing/co-sleeping have been identified either in the peer-reviewed literature or as a consensus of expert opinion:
  - Environmental smoke exposure and maternal smoking<sup>3,23,21,24,30,31,29,22,10</sup>
  - Sharing sofas, couches, or daybeds with infants<sup>3,7,11,26,34,33</sup>
  - Sharing waterbeds or the use of soft bedding materials<sup>4,7,11,26,34,33</sup>
  - Sharing beds with adjacent spaces that could trap an infant<sup>4,7,11,26,34,33</sup>
  - Placement of the infant in the adult bed in the prone or side position<sup>4,7,11,26,34,33</sup>
  - The use of alcohol or mind-altering drugs by the adult(s) who is bed sharing<sup>3</sup>
  - Infants bed sharing with other children<sup>10</sup>
  - Bed sharing with younger babies <8 to 14 weeks of age may be more strongly associated with SIDS.<sup>3,6,10,32,5</sup>
2. Families also should be given all the information that is known about safe sleep environments for their infants, including:
  - Place babies in the supine position for sleep.<sup>10</sup>
  - Use a firm, flat surface and avoid waterbeds, couches, sofas, pillows, soft materials, or loose bedding.<sup>4,7,11,26,34,33</sup>
  - If blankets are to be used, they should be tucked in around the mattress so that the infant's head is less likely to be covered.<sup>10</sup>
  - Ensure that the head will not be covered. In a cold room the infant could be kept in an infant sleeper to maintain warmth.<sup>4,7,11,26,34,33</sup>
  - Avoid the use of quilts, duvets, comforters, pillows, and stuffed animals in the infant's sleep environment.<sup>4,7,11,26,34,33</sup>
  - Never put an infant down to sleep on a pillow or adjacent to a pillow.<sup>4,7,11,26,34,33</sup>
  - Never leave an infant alone on an adult bed.<sup>4,7,11,26,34,33</sup>
  - Inform families that adult beds have potential risks and are not designed to meet federal safety standards for infants.<sup>4,7,11,26,34,33</sup>
  - Ensure that there are no spaces between the mattress and headboard, walls, and other surfaces, which may entrap the infant and lead to suffocation.<sup>4,7,11,26,34,33</sup>
  - Placement of a firm mattress directly on the floor away from walls may be a safe alternative. Another alternative to sharing an adult bed or sharing a mattress is the use of an infant bed that attaches to the side of the adult bed and provides proximity and access to the infant but a separate sleep surface. There are

currently no peer-reviewed studies on the safety or efficacy of such devices.

- Room sharing with parents appears to be protective against SIDS.<sup>3,10,32,5</sup>

## *Recommendations for Future Research*

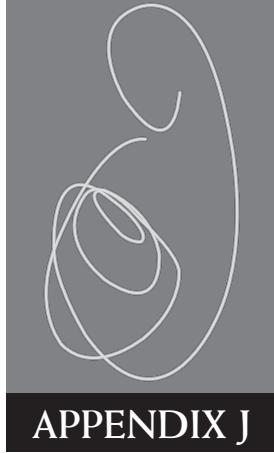

---

- A. The Academy of Breastfeeding Medicine urges that more research be undertaken so that the benefits and risks of co-sleeping and bed sharing and their association with breastfeeding can be better understood.
- B. Researchers should employ well-designed, impartial, prospective protocols with standardized, well-defined data collection methods. Control data for comparison are an essential part of such research. Studies should be population-based, so that actual risk of sudden infant death and overlying smothering due to bed sharing or co-sleeping can be computed. A denominator is needed for calculation of risk and for comparison with a population not practicing co-sleeping or bed sharing. In the final analysis, it is critical that dangerous, modifiable "factors" associated with bed sharing not be considered the same as bed sharing itself.
- C. The diversity of bed sharing/co-sleeping practices among the different ethnic groups in the United States and throughout the world needs to be carefully considered and documented as part of research protocols.
- D. Continuing study of the impact of co-sleeping on infant behavior, SIDS, and breastfeeding is essential.

## APPENDIX J

# Protocol 7: Model Breastfeeding Policy

---

### Purpose

The purpose of this protocol is to promote a philosophy of maternal infant care that advocates breastfeeding and supports the normal physiologic functions involved in the establishment of this maternal-infant process and to assist families choosing to breastfeed with initiating and developing a successful and satisfying experience.

This policy is based on recommendations from the most recent breastfeeding policy statements published by the Office on Women's Health of the U.S. Department of Health and Human Services,<sup>19</sup> the American Academy of Pediatrics,<sup>17</sup> the American College of Obstetricians and Gynecologists,<sup>3</sup> the American Academy of Family Physicians,<sup>18</sup> the World Health Organization,<sup>21</sup> the American Dietetic Association,<sup>11</sup> the Academy of Breastfeeding Medicine,<sup>1</sup> and the UNICEF/WHO evidence-based *Ten Steps to Successful Breastfeeding*.<sup>21,20,22</sup>

### Policy Statements

1. The "name of institution" staff will actively support breastfeeding as the preferred method of providing nutrition to infants. A multidisciplinary, culturally appropriate team comprising hospital administrators, physician and nursing staff, lactation consultants and specialists, nutrition staff, parents, and other appropriate staff shall be established and maintained to identify and eliminate institutional barriers to breastfeeding. On a yearly basis, this group will compile

and evaluate data relevant to breastfeeding support services and formulate a plan of action to implement needed changes.

2. A written breastfeeding policy will be developed and communicated to all health care staff. The "name of institution" breastfeeding policy will be reviewed and updated routinely (biannually) using current research as an evidence-based guide.
3. All pregnant women and their support people as appropriate will be provided with information on breastfeeding and counseled on the benefits of breastfeeding, contraindications to breastfeeding, and risk of formula feeding.
4. The woman's desire to breastfeed will be documented in her medical record.
5. Mothers will be encouraged to exclusively breastfeed unless medically contraindicated. The method of feeding will be documented in the medical record of every infant.
  - Exclusive breastfeeding is defined as providing breast milk as the sole source of nutrition. Exclusively breastfed babies receive no other liquids or solids.
6. At birth or soon thereafter all newborns, if baby and mother are stable, will be placed skin-to-skin with the mother. Skin-to-skin contact involves placing the naked baby prone on the mother's bare chest. Mother-infant couples will be given the opportunity to initiate breastfeeding within 1 hour of birth. Post-cesarean-birth babies will be encouraged to breastfeed as soon as possible. The administration of vitamin K and prophylactic antibiotics to prevent ophthalmia neonatorum should be delayed for

- the first hour after birth to allow uninterrupted mother-infant contact and breastfeeding.<sup>13</sup>
7. Breastfeeding mother-infant couples will be encouraged to remain together throughout their hospital stay, including at night (rooming-in). Skin-to-skin contact will be encouraged as much as possible.
  8. Breastfeeding assessment, teaching, and documentation will be done on each shift and whenever possible with each staff contact with the mother. After each feeding, staff will document information about the feeding in the infant's medical record. This documentation may include the latch, position, and any problems encountered. For feedings not directly observed, a maternal report may be used. Every shift, a direct observation of the baby's position and latch-on during feeding will be performed and documented.
  9. Mothers will be encouraged to utilize available breastfeeding resources, including classes, written materials, and video presentations, as appropriate. If clinically indicated, the clinician or nurse will make a referral to a lactation consultant or specialist.
  10. Breastfeeding mothers will be instructed about
    - a. proper positioning and latch-on;
    - b. nutritive suckling and swallowing;
    - c. milk production and release;
    - d. frequency of feeding/feeding cues;
    - e. expression of breastmilk and use of a pump if indicated;
    - f. how to assess if infant is adequately nourished; and
    - g. reasons for contacting the clinician.
 These skills will be taught to primiparous and multiparous women and reviewed before the mother goes home.
  11. Parents will be taught that breastfeeding infants, including cesarean-birth babies, should be put to breast at least 8 to 12 times each 24 hours. Infant feeding cues (e.g., increased alertness or activity, mouthing, or rooting) will be used as indicators of the baby's readiness for feeding. Breastfeeding babies will be breastfed at night.
  12. Time limits for breastfeeding on each side will be avoided. Infants can be offered both breasts at each feeding but may be interested in feeding only on one side at a feeding during the early days.
  13. No supplemental water, glucose water, or formula will be given unless specifically ordered by a physician or nurse practitioner or by the mother's documented and informed request. Prior to nonmedically indicated supplementation, mothers will be informed of the risks of supplementing. The supplement should be fed to the baby by cup if possible and will be no more than 10 to 15 mL in a term baby.<sup>7,6,9</sup> Alternative feeding methods such as syringe or spoon-feeding may also be used; however, these methods have not been shown to be effective in preserving breastfeeding. Bottles will not be placed in a breastfeeding infant's bassinet.
  14. This institution does not give group instruction in the use of formula. Those parents who, after appropriate counseling, choose to formula feed their infants will be provided individual instruction.
  15. Pacifiers will not be given to normal full-term breastfeeding infants. The pacifier guidelines at "*name of institution*" state that preterm infants in the Neonatal Intensive Care or Special Care Unit or infants with specific medical conditions may be given pacifiers for nonnutritive sucking. Newborns undergoing painful procedures (e.g., circumcision) may be given a pacifier as a method of pain management during the procedure. The infant will not return to the mother with the pacifier. "*Name of institution*" encourages "pain-free newborn care," which may include breastfeeding during the heel stick procedure for the newborn metabolic screening tests.
  16. Routine blood glucose monitoring of full-term, healthy, appropriate for gestational age (AGA) infants is not indicated. Assessment for clinical signs of hypoglycemia and dehydration will be ongoing.<sup>14</sup>
  17. Antilactation drugs will not be given to any postpartum mother.
  18. Routine use of nipple creams, ointments, or other topical preparations will be avoided unless such therapy has been indicated for a dermatologic problem. Mothers with sore nipples will be observed for latch-on techniques and will be instructed to apply expressed colostrum or breast milk to the areola after each feeding.
  19. Nipple shields or bottle nipples will not be routinely used to cover a mother's nipple to treat latch-on problems or prevent or manage sore or cracked nipples or when a mother has flat or inverted nipples. Nipple shields will be used only in conjunction with a lactation consultation.
  20. After 24 hours of life, if the infant has not latched on or fed effectively, the mother will be instructed to begin breast massage and hand expression of colostrum into the baby's mouth during feeding attempts. Skin-to-skin contact will be encouraged. (Parents will be instructed to watch closely for feeding cues and whenever these are observed to awaken and feed the infant.) If the baby continues to feed poorly,

pumping with skilled hand expression or a double set-up electric breast pump will be initiated and maintained approximately every 3 hours or a minimum of eight times per day. Any expressed colostrum or mother's milk will be fed to the baby by an alternative method. The mother will be reminded that she may not obtain much milk or even any milk the first few times she pumps her breasts. Until the mother's milk is available, a collaborative decision should be made among the mother, nurse, and clinician regarding the need to supplement the baby. Each day clinicians will be consulted regarding the volume and type of the supplement. Pacifiers will be avoided. In cases of problem feeding, the lactation consultant or specialist will be consulted.<sup>13</sup>

21. If the baby is still not latching on well or feeding well when going home, the feeding/pumping/supplementing plan will be reviewed in addition to routine breastfeeding instructions. A follow-up visit or contact will be scheduled within 24 hours. Depending on the clinical situation it may be appropriate to delay discharge of the couplet to provide further breastfeeding intervention, support, and education.
22. All babies should be seen for follow-up within the first few days postpartum. This visit should be with a pediatrician or other qualified health care practitioner for a formal evaluation of breastfeeding performance, a weight check, assessment of jaundice, and age-appropriate elimination:
  - For infants discharged at less than 2 days of age (<48 hours): Follow-up at 2 to 4 days of age.
  - For infants discharged at more than 2 days of age (>48 hours): Follow-up at 4 to 5 days of age.
  - All newborns should be seen by 1 month of age.
23. Mothers who are separated from their sick or premature infants will be
  - a. instructed on how to use skilled hand expression or the double set-up electric breast pump—instructions will include expression at least eight times per day or approximately every 3 hours for 15 minutes (or until milk flow stops, whichever is greater) around the clock and the importance of not missing a pumping session during the night;
  - b. encouraged to breastfeed on demand as soon as the infant's condition permits;
  - c. taught proper storage and labeling of human milk; and
24. Before leaving the hospital,<sup>15</sup> breastfeeding mothers should be able to
  - d. assisted in learning skilled hand expression or obtaining a double set-up electric breast pump prior to going home.

24. Before leaving the hospital,<sup>15</sup> breastfeeding mothers should be able to
  - a. position the baby correctly at the breast with no pain during the feeding;
  - b. latch the baby to breast properly;
  - c. state when the baby is swallowing milk;
  - d. state that the baby should be nursed approximately 8 to 12 times every 24 hours until satiety;
  - e. state age-appropriate elimination patterns (at least six urinations per day and three to four stools per day by the fourth day of life);
  - f. list indications for calling a clinician; and
  - g. manually express milk from their breasts.

## THE TEN STEPS TO SUCCESSFUL BREASTFEEDING

1. Have a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within 1 hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation, even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.<sup>1</sup>
7. Practice rooming-in—allow mothers and infants to remain together—24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.
25. Prior to going home, mothers will be given the names and telephone numbers of community resources to contact for help with breastfeeding, including (the support group or resource recommended by "name of institution").
26. "Name of institution" does not accept free formula or free breastmilk substitutes. Nursery or NICU discharge bags offered to all mothers

<sup>1</sup>A hospital must pay fair market price for all formula and infant feeding supplies that it uses and cannot accept free or heavily discounted formula and supplies.

- will not contain infant formula, coupons for formula, logos of formula companies, or literature with formula company logos.
27. "Name of institution" health professionals will attend educational sessions on lactation management and breastfeeding promotion to ensure that correct, current, and consistent information is provided to all mothers wishing to breastfeed.

## APPLICATION

All breastfeeding patients.

## EXCEPTIONS

Breastfeeding is contraindicated in the following situations:

- HIV-positive mother in developed countries (e.g., United States, Europe)
- Mother using illicit drugs (e.g., cocaine, heroin) unless specifically approved by the infant's health care provider on a case-by-case basis
- A mother taking certain medications. Although most prescribed and over-the-counter drugs are safe for the breastfeeding infant, some medications may make it necessary to interrupt breastfeeding. These include radioactive isotopes, antimetabolites, cancer chemotherapy, and a small number of other medications. The references used at "name of institution" are *Medications and Mothers' Milk* by Thomas Hale,<sup>5</sup> *Breastfeeding: A Guide for the Medical Profession* by R.A. Lawrence and R.M. Lawrence,<sup>8</sup> and the American Academy of Pediatrics Statement on the Transfer of Drugs into Human Milk.<sup>4</sup>
- Mother has active, untreated tuberculosis
- Infant has galactosemia
- Mother has active herpetic lesions on her breast(s)—breastfeeding can be recommended on the unaffected breast (The Infectious Disease Service will be consulted for problematic infectious disease issues.)
- Mother has varicella that is determined to be infectious to the infant
- Mother has HTLV1 (human T-cell leukemia virus type 1)

## APPENDIX J

# *Protocol 8: Human Milk Storage Information for Home Use for Healthy Full-Term Infants*

---

### *Storage Containers*

1. Hard-sided containers, such as hard plastic or glass, are the preferred containers for long-term human milk storage. These containers should have an airtight seal.<sup>3</sup>
2. Plastic bags specifically designed for human milk storage can be used for short-term (less than 72 hours) milk storage.<sup>3,11</sup> Use of plastic bags is not recommended for long-term storage as they may spill, leak, or become contaminated more easily than hard-sided containers, and some important milk components may adhere to the soft plastic and be lost.

### *General Guidelines*

1. Hands must be washed prior to expressing or pumping milk.
2. Use containers and pumping equipment that have been washed in hot, soapy water and rinsed. If available, cleaning in a dishwasher is acceptable; dishwashers that additionally heat the water may improve cleanliness. If a dishwasher is not available, boiling the containers after washing is recommended. Boiling is particularly important where the water supply may not be clean.
3. Store in small portions to minimize waste. Most breastfed babies take between 2 and 4 ounces (60

to 120 mL) of milk when beginning with an alternative feeding method. Storing in 2-ounce (60-mL) amounts and offering additional amounts if the baby is still hungry will prevent having to throw away unfinished milk.

4. Consider storing smaller size portions [1 to 2 ounces (30 to 60 mL) each] for unexpected situations. A small amount of milk can keep a baby happy until mom comes to nurse the baby.
5. Several expressions throughout a day may be combined to get the desired volume in a container. Chill the newly expressed milk for at least 1 hour in the main body of the refrigerator or in a cooler with ice or ice packs, and then add it to previously chilled milk expressed on the same day.
6. Do not add warm breast milk to frozen milk because it will partially thaw the frozen milk.
7. Keep milk from one day separate from other days.
8. Do not fill the container; leave some room at the top because breast milk expands as it freezes.
9. Label containers clearly with waterproof labels and ink, if possible.
10. Indicate the date that the milk was expressed and the child's name (for day care).
11. Expect that the milk will separate during storage because it is not homogenized. The cream will rise to the top of the milk and look thicker and whiter. Before feeding, gently swirling the container of milk will mix the cream

- back through again. Avoid vigorously shaking the milk.
12. The color of milk may vary from day to day, depending on maternal diet. It may look bluish, yellowish, or brownish. Frozen breast milk may also smell different from fresh breast milk.<sup>5</sup> There is no reason not to use the milk if the baby accepts it.
  6. Never use a microwave oven or stovetop to heat the milk, as these may cause scald spots and will also destroy antibodies.<sup>8,9</sup>
  7. Swirl the container of milk to mix the cream back in, and distribute the heat evenly. Do not stir the milk.
  8. Milk left in the feeding container after a feeding should be discarded and not used again.
  9. As with all foods, do not refreeze breast milk once it is thawed or partially thawed.

## MILK STORAGE GUIDELINES

1. Milk may be kept at room temperature (up to 77°F or 25°C) for 6 to 8 hours. Temperatures greater than 77°F (25°C) may not be safe for room temperature storage.<sup>4</sup> Containers should be covered and kept as cool as possible, covering the container with a cool towel may keep milk cooler.
2. Milk may be stored in an insulated cooler bag with ice packs for 24 hours.<sup>6</sup>
3. Milk may be safely refrigerated (39°F or 4°C) for up to 5 days.<sup>10</sup> Store milk in the back of the main body of the refrigerator, where the temperature is the coolest.<sup>7</sup>
4. The type of freezer in which the milk is kept determines timetables for frozen milk. Generally, store milk toward the back of the freezer, where the temperature is most constant.<sup>2</sup> Milk stored for the longer durations in the ranges listed below is safe, but there is some evidence that the lipids in the milk undergo degradation resulting in lower quality.<sup>1</sup>
  - Freezer compartment located inside the refrigerator (5°F or -15°C): 2 weeks
  - Refrigerator/freezer with separate doors (0°F or -18°C): 3 to 6 months
  - Chest or upright manual defrost deep freezer that is opened infrequently and maintains ideal temperature (-4°F or -20°C): 6 to 12 months
5. The above guidelines apply only to healthy term infants; guidelines are different for hospitalized, sick, or preterm infants.

## THAWING OR WARMING MILK

1. The oldest milk should be used first.
2. The baby may drink the milk cool, at room temperature, or warmed.
3. Thaw milk by placing it in the refrigerator the night before use or gently rewarm it by placing the container under warm running water or in a bowl of warm water.
4. Do not let the level of water in the bowl or from the tap touch the mouth of the container.
5. Milk may be kept in the refrigerator for 24 hours after it is thawed.

## APPENDIX J

# *Protocol 9: Use of Galactagogues in Initiating or Augmenting Maternal Milk Supply*

---

### *Background*

---

Galactagogues (or lactagogues) are medications or other substances believed to assist initiation, maintenance, or augmentation of maternal milk production. Because low milk supply is one of the most common reasons given for discontinuing breastfeeding,<sup>30</sup> both mothers and physicians have sought medicine to address this concern. Breast milk production is a complex physiologic process involving physical and emotional factors and the interaction of multiple hormones, the most important of which is believed to be prolactin. With parturition and expulsion of the placenta, progesterone falls and a full milk supply is initiated (Lactogenesis II).<sup>27</sup> Through interaction with the hypothalamus and anterior pituitary, dopamine agonists inhibit, and dopamine antagonists increase, prolactin secretion and thereby milk production (endocrine control). Thereafter, prolactin levels gradually decrease but milk supply is maintained or increased by local feedback mechanisms (autocrine control).<sup>20</sup> Therefore, an increase in prolactin levels is needed to increase, but not maintain, milk supply. If the breasts are not emptied regularly and thoroughly, milk production declines. Likewise, more frequent and thorough emptying of the breasts typically results in increased milk production. Use of galactagogues for faltering milk supply should generally be reserved for situations after both a thorough evaluation for treatable causes (e.g., maternal hypothyroidism or medication) and

increased frequency of breastfeeding or pumping or expression has not been successful.

### *Indications for Galactagogues*

---

Common indications for galactagogues are adoptive nursing (induction of lactation in a woman who was not pregnant with the current child), relactation (reestablishing milk supply after weaning), and increasing a faltering milk supply because of maternal or infant illness or separation. Mothers who are not directly breastfeeding but are expressing milk by hand or with a pump often experience a decline in milk production after several weeks. One of the most common indications for galactagogues is to augment a declining milk supply in mothers of preterm or ill infants in the neonatal intensive care unit.

### *Procedure*

---

1. Before using any substance to try to increase milk supply, a full evaluation of current maternal milk supply and effectiveness of milk transfer is imperative. Attention must be directed to the evaluation and augmentation of frequency and thoroughness of milk removal. This can be accomplished through increased frequency and duration of breastfeeding (if the infant has been shown to be effective at emptying the breasts) or

pumping. A full-size, automatic cycling breast pump, capable of draining both breasts ("hospital grade") at the same time is recommended, if available. Problems such as inappropriate timing and duration of feedings, inappropriate supplementation, mother-infant separation, ineffective latch, and inadequate milk transfer should be corrected.

2. Women should be informed of any data (or lack thereof) regarding the efficacy, safety, and timing of use of galactagogues. With the exception of adoptive nursing, where galactagogues are started *before* the birth of the baby, there is no research to suggest that starting galactagogues within the first week postpartum is efficacious.
3. Mothers should be screened for contraindications to the chosen medication or substance and informed as to possible side effects. Although a lactation consultant may recommend the medication or herb, it is the physician's responsibility to prescribe medications and follow the mother and infant.
4. The physician who prescribes the medication is obligated to follow, or to ensure appropriate follow-up, of both mother and infant regarding milk supply and any side effects. In practice, many times it is the nurse practitioner, pediatrician, or neonatologist who is asked to prescribe a galactagogue and not the obstetrician-gynecologist. As is commonly found when dealing with lactation, family physicians are ideally situated to manage this issue.
5. Although short-term use (1 to 3 weeks) has been evaluated for some of these substances, long-term use has not been studied. Anecdotal reports suggest no increase in side effects with the most commonly used medications (metoclopramide, domperidone, and fenugreek), but long-term effects on both mother and infant are unknown.

## Specific Galactagogues

Many medications, foods, and herbal therapies have been recommended as galactagogues. The medications used often exert their effects through antagonism of dopamine receptors, resulting in increased prolactin. In many cases, the mechanism(s) of action are unknown.

### METOCLOPRAMIDE

Metoclopramide (Reglan) is the most well studied and most commonly used medication for inducing or augmenting lactation in the United States. It promotes lactation by antagonizing the release of dopamine in the central nervous system, thereby

increasing prolactin levels.<sup>26</sup> It is an antiemetic and also commonly used for gastroesophageal reflux in infants. Although levels found in breastmilk have been measured higher than maternal serum levels, levels in infants have been undetectable or well below infant therapeutic levels with no reported side effects.<sup>17</sup> Metoclopramide does not appear to alter milk composition significantly.<sup>9,8</sup> Many studies have shown its efficacy in the induction and augmentation of milk production.<sup>31,12,21,33,18,19,8,16,11,10,23,2</sup> However, there is one controlled trial that failed to show efficacy.<sup>22</sup>

Maternal restlessness, drowsiness, fatigue, and diarrhea may occur but usually do not require stopping the medication.<sup>26,16</sup> The drug should be discontinued if any of the rare extrapyramidal side effects of sleeplessness, headache, confusion, dizziness, mental depression, or feelings of anxiety or agitation occur. Acute dystonic reactions are very rare (<0.05%) and may require diphenhydramine (Benadryl) treatment. Metoclopramide should not be used if patients have epilepsy or are on antiseizure medications, have a history of significant depression or are on antidepressant drugs, have a pheochromocytoma or uncontrolled hypertension, have intestinal bleeding or obstruction, or have a known allergy or prior reaction to metoclopramide.<sup>26</sup> Metoclopramide does transfer into the milk, but research has demonstrated no side effects in the infants of mothers taking metoclopramide.<sup>31,12,21,33,18,19,8,16,11,10,23,2,13</sup>

The usual dose is 30 to 45 mg/day in three or four divided doses, with a dose-response effect up to 45 mg daily.<sup>18</sup> It is usually given for 7 to 14 days at full dose with a taper off over 5 to 7 days. Longer periods of use may be associated with an increased incidence of depression. Occasionally a mother's milk supply will falter as the dose is reduced, and the lowest effective dose has been continued for longer periods successfully. Some experts also advise a gradual increase when beginning the dosage.

### DOMPERIDONE (MOTILIUM)

Domperidone is also a dopamine antagonist that is available outside the United States for the treatment of gastroesophageal reflux and emesis.<sup>15</sup> Because of its drug characteristics it is less likely to cross the maternal blood-brain barrier, resulting in fewer extrapyramidal side effects than metoclopramide. Domperidone is also less likely than metoclopramide to cross into the breastmilk.<sup>33</sup> Administration of domperidone results in significant increases in mean serum prolactin levels in normal women.<sup>7,28</sup> Domperidone is the only galactagogue evaluated in a randomized controlled trial

and shown to be safe and effective in increasing breastmilk production.<sup>7</sup>

Side effects are very uncommon and include dry mouth, headache (resolved with decreased dosage), and abdominal cramps.<sup>15</sup> Chronic high-dose treatment with domperidone in rodents has been associated with increased numbers of breast tumors. This has not been reported in humans. Domperidone is contraindicated in patients with known sensitivity to the drug and in situations in which gastrointestinal stimulation might be dangerous (e.g., gastrointestinal hemorrhage, mechanical obstruction, or perforation). Despite the fact that domperidone is approved for use in most of the developed world and has been used for many years with an excellent safety record, the U.S. Food and Drug Administration (FDA) issued a warning against its use in the United States based on safety concerns with IV use and risks associated with drug importation.<sup>34a</sup> There is no evidence that oral administration is associated with toxicity in either mother or infant.<sup>34a</sup> The usual dosage is 10 to 20 mg three to four times per day taken for 3 to 8 weeks. Most women respond within 3 to 4 days, but some women respond in 24 hours, and some require 2 to 3 weeks to get maximum effect.<sup>28</sup>

### SULPIRIDE (EGONYL) AND CHLORPROMAZINE (THORAZINE)

Sulpiride is an antipsychotic (neuroleptic) medication not available in the United States that acts as a galactogogue by increasing prolactin-releasing hormone from the hypothalamus. Two studies have shown an increase in milk supply over placebo. Maternal side effects may include the extrapyramidal effects listed above for metoclopramide and possibly weight gain. The suggested dosage is 50 mg two or three times daily.<sup>1,35,36</sup>

Psychiatric practitioners have long noted galactorrhea in both males and females taking chlorpromazine (also a neuroleptic). A dose of 25 mg orally three times daily for 1 week has been shown in case reports to increase milk supply.

As both sulpiride and chlorpromazine increases prolactin levels by blocking dopamine receptors (and therefore the prolactin-inhibiting action of dopamine), extrapyramidal side effects are again possible.<sup>1</sup>

### HUMAN GROWTH HORMONE

One randomized, double-blind, placebo-controlled trial of human growth hormone in a dose of 0.1 international unit/kg/day subcutaneously noted a significant increase in milk volume by day 7 in 16 healthy lactating women. There were no

documented changes in milk composition or side effects reported in the mothers. The usefulness of this expensive, injectable galactogogue appears limited.<sup>13,4</sup>

### THYROTROPIN-RELEASING HORMONE

Thyrotropin-releasing hormone (TRH) is used in the United States to assess thyroid function. It causes the release of both thyroid-stimulating hormone and prolactin from the pituitary. The most recent study suggests short-term use is both safe and effective, but long-term use has not been evaluated. Dosage was one spray (1 mg TRH) four times daily.<sup>5</sup> Other studies used IV (200 mcg) or oral (5 mg) forms.<sup>34</sup> TRH is not commonly used.

### HERBAL/NATURAL GALACTOGOGUES

Throughout world history women have used certain herbs or foods to enhance their milk supply. Most of these substances have not been scientifically evaluated, but traditional use suggests safety and some efficacy. The mechanisms of action for all are unknown. Herbs commonly mentioned as galactagogues include fenugreek, goat's rue, milk thistle, anise, basil, blessed thistle, fennel seeds, marshmallow, and others. Beer is commonly used in some cultures, but alcohol may actually reduce milk production, and there is no evidence to support that the yeasts in beer are effective galactagogues.

It is of note that herbs and dietary supplements were removed by the Federal 1994 Dietary Supplement Act from undergoing the rigorous evaluation by the U.S. Food and Drug Administration that is required for drugs. The composition of herbal and dietary supplements is unknown, and they have been known to contain toxic substances. This is especially true for herbs from mainland China. There is no standard dosing, preparation, or composition, and fraudulent preparations may be a risk.

Fenugreek (*Trigonella foenum-graecum*) is the most commonly recommended herbal galactogogue, treasured as a spice and medicine throughout India and the Middle East for thousands of years. It is a member of the pea family listed as GRAS (generally regarded as safe) by the U.S. Food and Drug Administration. Usual dose is one to four capsules (580 to 610 mg) three to four times per day, although as with most herbal remedies there is no standard dosing. The higher of these doses may be required in relactating or adoptive mothers. Alternatively, it can be taken as one cup of strained tea three times per day (1/4 tsp seeds steeped in 8 oz water for 10 minutes).<sup>24</sup> Huggins<sup>14</sup> reported the anecdotal use of fenugreek in at least 1200

women with increased milk supply within 24 to 72 hours. Reported side effects are rare: maple-like odor to sweat, milk, and urine; diarrhea; and increased asthmatic symptoms. Use during pregnancy is not recommended because of its uterine stimulant effects. Fenugreek is known to lower blood glucose, so caution is advised. Two recent preliminary reports suggest effectiveness.<sup>32,6</sup>

Goat's rue (*Gallica officinalis*) is a traditional galactagogue, widely recommended in Europe, based on observations of increased milk supply when fed to cows in the 1900s. No controlled human trials have been done, and no adverse effects have been reported with the following possible exception: Maternal ingestion of a lactation tea containing extracts of licorice (*Glycyrrhiza glabra*), fennel, anise, and goat's rue was linked to drowsiness, hypotonia, lethargy, emesis, and poor suckling in two breastfed neonates. An infection work-up was negative, and symptoms and signs resolved on discontinuation of the tea and a 2-day break from breastfeeding.<sup>29</sup> The tea was not tested for contaminants or adulterants, and there have been no other adverse events reported in Europe or South America, where the herb is also used as a hypoglycemic agent. It is usually used as a tea (1 tsp dried leaves steeped in 8 oz water for 10 minutes) with 1 cup taken three times a day.<sup>24</sup>

Milk thistle (*Silybum Marianum*) has been used historically throughout Europe, but there are no randomized controlled trials to validate its use. The plant is still commonly known as St. Mary's thistle in honor of the Virgin Mary. Early Christians believed that the white colored veins in the leaves were symbolic of her breast milk. The American Herbal Products Association gives it a rating of 1, meaning that the herb may be safely consumed when used appropriately and does not contraindicate its use during lactation.<sup>25</sup> It is used as a strained tea (simmer 1 tsp crushed seeds in 8 oz water for 10 minutes) taking two to three cups per day.<sup>24</sup>

## Conclusions

Of the substances used to induce, maintain, or augment milk production, domperidone and metoclopramide appear to be the most clinically useful. Prior to the use of any galactagogue, evaluation and correction of any modifiable factors such as frequency and thoroughness of breast emptying should be addressed. Medication should never replace evaluation and counseling on modifiable factors or reassurance when appropriate. As with any medication given to lactating women, close follow-up of both mother and baby is essential.

## APPENDIX J

# *Protocol 10: Breastfeeding the Near-Term Infant (35 to 37 Weeks' Gestation)*

---

### *Goals*

---

1. Promote, support, and sustain breastfeeding in the near-term infant.
2. Maintain optimal health of infant and mother.

### *Purpose*

---

1. Allow infants born at 35 to 37 weeks of gestation to breastfeed and/or breastmilk feed to the greatest extent possible.
2. Heighten awareness of difficulties near-term infants and their mothers may experience with breastfeeding.
3. Offer strategies to anticipate, identify promptly, and manage breastfeeding problems that the near-term infant and mother may experience in the inpatient and outpatient setting.
4. Prevent medical problems such as dehydration, hypoglycemia, hyperbilirubinemia, and failure to thrive in the near-term infant.
5. Maintain awareness of mothers' needs.

### *Definition*

---

"Near-term infant" refers to infants born between 35 0/7 and 36 6/7 weeks of gestation. Many problems of the near-term infant are also found in the larger 34- to 35-week preterm infant and the borderline term infant of 37 0/7 to 37 6/7 weeks'

gestation, and, therefore, the following guidelines may be applicable to these infants as well.

### *Background*

---

The advantages of breastmilk feeding for premature infants appear to be even greater than those for term infants. Establishing breastfeeding in the near-term infant, however, is frequently more problematic than in the full-term infant. Because of their immaturity, near-term infants may be sleepier and have less stamina; more difficulty with latch, suck, and swallow; more difficulty maintaining body temperature; increased vulnerability to infection; greater delays in bilirubin excretion; and more respiratory instability than the full-term infant. The sleepiness and inability to suck vigorously is often misinterpreted as sepsis, leading to unnecessary separation and treatment. Alternatively, the near-term infant may appear deceptively vigorous at first glance. Physically large newborns are often mistaken for being more developmentally mature than their actual gestational age. (Remember the 3.84-kg baby born at 40 weeks was 3.0 kg at 36 weeks of gestation.) Near-term infants are more likely to be separated from their mother as a result of the infant being ill or requiring a screening procedure such as evaluation for sepsis, IV placement for antibiotics, and phototherapy.

Mothers who deliver near, but not at, term are more likely to deliver multiples or have a medical

condition such as diabetes, pregnancy-induced hypertension, prolonged rupture of membranes, chorioamnionitis, Pitocin induction, or a C-section delivery that may affect the success of breastfeeding. Any one or a combination of these conditions places these mothers and infants at risk for difficulty in establishing successful lactation or for breastfeeding failure.

The potential maternal and infant problems listed above place the near-term breastfeeding infant at increased risk for hypothermia, hypoglycemia, excessive weight loss, dehydration, slow weight gain, failure to thrive, prolonged artificial milk supplementation, exaggerated jaundice, kernicterus, dehydration, fever secondary to dehydration, rehospitalization, and breastfeeding failure. In places where early discharge is the norm, these infants will be sent home soon after delivery. Discussion and parental education become crucial in the proper management of breastfeeding.

Near-term infants have a greater chance of exclusive breastfeeding in hospitals that adhere to the Ten Steps to Successful Breastfeeding. To this end, practitioners should become knowledgeable in the Ten Steps and work with the administration in their maternity hospitals to endorse the guidelines set forth in the Ten Steps (see Protocol #7).

Most of the acute problems encountered in the newborn are managed on the postpartum floor in the first few hours and days after parturition; however, there are times that an infant's condition deteriorates in the interval between discharge and the first office visit. Therefore, timely evaluation of the near-term infant after discharge is critical. Just as many hospitals are becoming breastfeeding friendly, the outpatient office or clinic needs to be not only supportive of the breastfeeding mother, but also able to assist mothers with uncomplicated problems or questions related to breastfeeding. In addition, it is essential to be able to refer mothers and infants in a timely manner to a trained lactation professional for more complicated breastfeeding problems. A lactation referral should be viewed with the same medical urgency as any other acute medical referral.

## *Principles of Care*

---

1. Optimal communication
  - a. Pathway and order set for breastfeeding the near-term infant.
  - b. Written feeding plan to follow on hospital discharge.
  - c. Facilitate communication among physician, nurses, and lactation consultants in the inpatient and outpatient settings.

- d. Avoid conflicting advice to mother and family of the near-term infant.
2. Assessment/reassessment
  - a. Objective assessment of gestational age and associated risk factors.
  - b. Daily assessment of breastfeeding on the postpartum floor or special care nursery.
  - c. Careful assessment of breastfeeding issues in the outpatient setting.
3. Timely lactation support in the inpatient and outpatient setting
4. Avoid separation of mother and infant
  - a. Immediate postpartum period.
  - b. In cases in which either mother or infant is hospitalized for medical reasons.
5. Prevent frequently encountered problems in breastfed near-term infant
  - a. Hypoglycemia.
  - b. Hypothermia.
  - c. Hyperbilirubinemia.
  - d. Dehydration or excessive weight loss.
6. Education
  - a. Ongoing education of staff and care providers of issues specific to breastfeeding the near-term infant in the inpatient and outpatient settings.
  - b. Have one (or two) outpatient office support person (RN or lactation educator) trained in breastfeeding support, assessment, basic breastfeeding problem solving, and near-term breastfeeding issues.
  - c. Educate parents about breastfeeding the near-term infant.
7. Discharge/follow-up
  - a. Develop criteria for discharge readiness.
  - b. Establish a feeding plan to follow after discharge.
  - c. Facilitate timely and frequent outpatient follow-up to assure effective breastfeeding after discharge.
  - d. Careful outpatient monitoring of mother and near-term infant.

## **INPATIENT: IMPLEMENTATION OF PRINCIPLES OF CARE**

1. Initial steps
  - a. Communicate the feeding plan through a prewritten order set that can be easily modified.
  - b. Encourage immediate and extended skin-to-skin contact to improve postpartum stabilization of heart rate, respiratory effort, temperature control, metabolic stability, and early breastfeeding.

- c. Assessment of gestational age by obstetrical estimate and Dubowitz scoring. Observe infant closely for 12 to 24 hours to assure physiologic stability (e.g., temperature, apnea, tachypnea, hypoglycemia).
  - d. Encourage rooming-in 24 hours a day. If the infant is physiologically stable and healthy, allow the infant to remain with the mother while receiving IV antibiotics or phototherapy. Depending on the individual situation, use of the biliblanket during breastfeeds, as well as limiting time outside more intense phototherapy, may be necessary.
  - e. Allow free access to the breast, encouraging initiation of breastfeeding within 1 hour after birth. Encourage continuous skin-to-skin contact as much as possible.
  - f. Breastfeeding ad libitum (on demand) should be encouraged. It is very important that the infant be breastfed (or breastmilk fed) *at least* eight times per 24-hour period. Sometimes it may be necessary to wake the baby if he or she does not indicate hunger. A mother may need to express her milk and give it to the baby using a cup or other alternative feeding method. Mothers should be warned that use of bottles at this stage might prevent breastfeeding in some babies.
2. Ongoing care
- a. Communicate daily changes in feeding plan either directly or with use of a written bedside tool such as a crib card.
  - b. Formal evaluation from a lactation consultant or other certified health professional with expertise in lactation management should be completed within 24 hours of delivery.
  - c. Assess and document breastfeeding at least three times per day by at least two different providers with use of a standardized tool (e.g., LATCH Score,<sup>5</sup> IBFAT,<sup>7</sup> Mother/Baby Assessment Tool<sup>10</sup>).
  - d. Educate the mother about breastfeeding her infant (e.g., position, latch, duration, early feeding cues, etc.).
  - e. Monitor vital signs, weight change, stool and urine output, and milk transfer. Pre/post feeding weights where available, may be helpful, especially once lactogenesis II has occurred. Monitor for frequently occurring problems (e.g., obtain bilirubin if jaundiced before discharge, glucose screen before feeds for the first three feeds or until stable if hypoglycemia has occurred [see Protocol #1]). It is recommended to routinely screen for hyperbilirubinemia in near-term infants and to use standardized nomograms to assess risk of hyperbilirubinemia as well as plan for follow-up testing.
  - f. Avoid excessive weight loss or dehydration. Losses greater than 3% of birth weight by day 1 or greater than 7% by day 3, ineffective milk transfer, or exaggerated jaundice are considered excessive and merit further evaluation and monitoring.
    - i. The infant may need to be supplemented after breastfeeding with small quantities (5 to 10 mL per feeding on day 1, 10 to 30 mL per feeding thereafter) of expressed breast milk or formula. Mothers may supplement using a supplemental nursing device at the breast, cup feeds, finger feeds, syringe feeds, or bottle depending on clinical situation and mother's preference. Cup feedings have demonstrated safety in both preterm<sup>6</sup> and term infants.<sup>3</sup> Cup feeding may also preserve breastfeeding duration among both preterm<sup>2</sup> and term<sup>4</sup> infants who require multiple supplemental feeds. However, there is little evidence about the safety or efficacy of other alternative feeding methods or their effect on breastfeeding. When cleanliness is suboptimal, cup feeding may be the best choice.<sup>12</sup>
    - ii. If supplementing, the mother should pump or express milk regularly (use of a hospital-grade electric pump is recommended when feasible) during the day (e.g., every 3 hours) until the baby is breastfeeding well or if the mother and infant are separated and unable to breastfeed.
    - iii. Consider use of an ultrathin silicone nipple shield if there is difficulty with latch or evidence of ineffective milk transfer.<sup>8</sup> The use of nipple shields is controversial and generally requires close supervision of a trained lactation consultant or knowledgeable health care professional. Inappropriate or prolonged nipple shield use can decrease milk supply, and in some situations, nipple shields decrease, rather than increase, milk transfer.
    - g. Avoid thermal stress by using skin-to-skin (e.g., kangaroo) care or by double wrapping if necessary and by dressing the baby in a shirt and hat. Consider intermittent use of an incubator to maintain temperature. Where it is culturally acceptable, mothers can sleep with their babies to provide warmth.

3. Discharge planning.
  - a. Assess readiness for discharge, including physiologic stability and adequate intake exclusively at breast or with supplements. May use 24-hour test weights, with a scale designed with adequate precision for such weights, for infants with >7% weight loss.<sup>9</sup>
  - b. Develop discharge-feeding plan. Consider diet, milk intake (mL/kg/day), and method of feeding (breast, bottle, supplemental device, etc.). If supplementing, determine method most acceptable to mother for use after discharge.
  - c. Make an appointment for follow-up within 48 hours of discharge to recheck weight, feeding adequacy, jaundice.
  - d. Communicate discharge-feeding plan to pediatric outpatient provider. Written communication is preferred.

## OUTPATIENT: IMPLEMENTATION OF PRINCIPLES OF CARE

1. Initial visit.
  - a. The first outpatient office or home health visit should be when the infant is 3 to 5 days of life or 1 or 2 days after discharge.
  - b. Review the inpatient maternal and infant records including prenatal, perinatal, infant, and feeding history (e.g., need for supplement in the hospital, problems with latch, need for phototherapy, etc.). Gestational age, birth weight, and weight at discharge should be recorded in the outpatient chart.
  - c. Physician review of breastfeeding since discharge needs to be very specific regarding frequency, approximate duration of feedings, and how baby is being fed (e.g., at breast, expressed breast milk with supplemental device such as supplemental nursing system, finger feeds, or bottle with artificial nipple). Information about stool and urine output, color of stools, baby's state (e.g., crying, not satisfied after a feed, sleepy and difficult to keep awake at the breast during a feed, etc.) should be obtained. If parents have a written feeding record, it should be reviewed.
  - d. Examination of the infant must include an accurate weight without clothes and calculation of change in weight from birth and discharge, state of alertness, and hydration. Assess for jaundice with cutaneous bilirubin screen and/or serum bilirubin determination if indicated.
  - e. Assess the mother's breast for nipple shape, pain and trauma, engorgement, and mastitis.

The mother's emotional status and degree of fatigue should be considered, especially when considering supplemental feeding routines. Observe the baby feeding at the breast, looking at the latch, suck, and swallow.

2. Problem solving.
  - a. Poor weight gain (<20 g/day) is most likely the result of inadequate intake. Median daily weight gain of a healthy newborn is 26 to 31 grams per day.<sup>11</sup> The care provider must determine whether the problem is insufficient breastmilk production, inability of the infant to transfer enough milk, or a combination of both. The infant who is getting enough breastmilk should have six to eight voids and yellow seedy stools daily by day 4, have lost no more than 8% of birth weight, and be satisfied after 20 to 30 minutes of nursing. Consider feeding more frequently or supplementing (preferably with expressed breast milk) after suckling if the mother is not already doing so or increasing the amount of supplement. Consider instituting or increasing frequency of pumping or manual expression. Consider referral to a lactation specialist.
  - b. For infants with latch difficulties, the baby's mouth should be examined for anatomical abnormalities [e.g., ankyloglossia (tongue-tied),<sup>1</sup> cleft palate], and a digital suck exam performed. A referral to a trained professional lactation specialist or in the case of ankyloglossia a referral to someone trained in frenotomy may be indicated.
  - c. The jaundiced near-term infant poses more of a problem when considering management of hyperbilirubinemia. Keep in mind all risk factors should be determined, and if the principal factor is lack of milk the primary treatment is to provide milk (preferably through improved breastfeeding or expressed breastmilk) to the baby. Institution of phototherapy for breastfeeding jaundice either in the home or in the hospital may actually interfere with the primary treatment of getting increased quantities of milk to the baby.
  - d. Consider the use of a galactogogue (a medicine or herb that increases breast milk supply) in mothers who have a documented low breastmilk supply (see Protocol #9).
  - e. The mother's ability to cope and manage the feeding plan needs to be evaluated. If the mother is not coping well, work with her to find help, and/or modify the feeding plan to something that is more manageable.

3. Follow-up: The near-term infant should have weekly weight checks until 40 weeks' postconceptual age or until it is demonstrated that he or she is thriving with no supplements.
  - a. Babies who are not gaining well and for whom adjustments are being made to the feeding plan may need a visit 2 to 4 days after each adjustment. A home health provider, preferably trained in medical evaluation of the newborn and in lactation support, who reports the weight to the primary care provider could make this visit.
  - b. Near-term infants have less vitamin D stored at birth, increasing their risk for later deficiency. Depending on sunlight exposure and skin color, vitamin D supplements (200 IU/day) may be indicated if the infant is exclusively breastfed. Strong consideration should be given to starting these supplements earlier than the 2 months of age recommended for term infants in the United States. Consideration should also be given to supplementing the near-term exclusively breastfed infant with iron, as iron stores in these infants are not those of the full-term infant. The American Academy of Pediatrics Committee on Nutrition recommends 2 mg/kg/day of elemental iron for preterm breastfed infants in the form of iron drops from 1 to 12 months of age.
  - c. After the first week, infants should be monitored for adequate growth and evidence of normal biochemical indices (see Table P-4 from Protocol #12). Weight gain should average more than 20 g/day, and length and head circumference should each increase by an average of more than 0.5 cm/week.

APPENDIX	Baby Friendly Hospital Initiative Steps for Successful Breastfeeding
1. Have a written breastfeeding policy.	
2. Train all health care staff in the skills necessary to implement the policy.	
3. Inform all mothers of the benefits of breastfeeding.	
4. Help mothers initiate breastfeeding within 1 hour of birth.	
5. Show mothers how to breastfeed and how to maintain lactation, even if they are to be separated from their infant.	
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.	
7. Practice rooming-in—allow mothers and infants to remain together—24 hours a day if medically stable.	
8. Encourage breastfeeding on demand.	
9. Give no artificial teats or pacifiers to breastfeeding infants.	
10. Foster the establishment of breastfeeding support groups and refer mothers to them, on discharge from the hospital or clinic.

## APPENDIX J

# *Protocol 11: Guidelines for the Evaluation and Management of Neonatal Ankyloglossia and Its Complications in the Breastfeeding Dyad*

## *Definition*

*Ankyloglossia, partial:* The presence of a sublingual frenulum that changes the appearance or function of the infant's tongue because of its decreased length, lack of elasticity, or attachment too distal beneath the tongue or too close to or onto the gingival ridge. In this document we will refer to partial ankyloglossia as simply "ankyloglossia." "True" or "complete ankyloglossia," extensive fusion of the tongue to the floor of the mouth, is extremely rare and is not within the scope of this discussion.

## *Background*

At birth, the infant's tongue is normally able to extend over and past the mandibular gum pad. Significant ankyloglossia prevents an infant from anteriorly extending and elevating the tongue, and many breastfeeding experts believe that these limitations alter the normal peristaltic motion of the tongue during feeding, resulting in the potential for nipple trauma and problems with effective milk transfer and infant weight gain.

Ankyloglossia, commonly known as tongue-tie, occurs in approximately 3.2% to 4.8% of consecutive term infants at birth<sup>14,1</sup> and in 12.8% of infants with breastfeeding problems.<sup>1</sup> The condition has been associated with an increased incidence of breastfeeding difficulties: 25% in affected versus 3% in unaffected infants.<sup>14</sup>

Various methods have been suggested to diagnose and evaluate the severity of ankyloglossia<sup>7,11</sup> and to determine the criteria for intervention.<sup>13,21</sup> Short- and long-term consequences of ankyloglossia may include feeding and speech difficulties,<sup>5,15</sup> as well as orthodontic and mandibular abnormalities<sup>23,22,24,6</sup> and psychological problems.<sup>10</sup>

In the 1990s a number of case reports and observational studies were published that documented an association between ankyloglossia and breastfeeding problems.<sup>8,18,2,12,17</sup> There is considerable controversy regarding the significance of ankyloglossia and its management, both within and among medical specialty groups.<sup>3,16</sup> Both the diagnosis of ankyloglossia and the use of frenotomy, an incision or "snipping" of the frenulum, to treat ankyloglossia vary widely. The frenotomy procedure, carefully performed, has recently been shown to decrease maternal nipple pain to improve infant latch<sup>1</sup> and

to improve milk transfer (personal communication, J. Ballard, July 27, 2004). There is a growing tendency among breastfeeding medicine specialists to favor releasing the tongue of the infant to facilitate breastfeeding and to protect the breastfeeding experience. To date, no randomized trials exist to demonstrate frenotomy for ankyloglossia is effective in treating infant or maternal breastfeeding problems.

## Assessment of Ankyloglossia

All newborn infants, whether healthy or ill, should have a thorough examination of the oral cavity that assesses function as well as anatomy. This examination should include palpation of the hard and soft palate, gingivae, and sublingual areas in addition to the movements of the tongue, and the length, elasticity, and points of insertion of the sublingual frenulum.

When breastfeeding difficulties are encountered and a short or tight sublingual frenulum is noted, the appearance and function of the tongue may be semi-quantified using a scoring system such as the Hazelbaker<sup>7</sup> (Table J-12). The Hazelbaker scale has been tested for interrater reliability (personal communication, J. Ballard, July 27, 2004) and validated in a sample of term neonates.<sup>1</sup> Hazelbaker scores consistent with significant ankyloglossia have been shown to be highly correlated with difficulty with latching the infant onto the breast and maternal complaints of sore nipples.<sup>1</sup> Alternatively, ankyloglossia may be qualified as mild, moderate, or severe by the appearance of the tongue and of the frenulum.

## Assessment of the Breastfeeding Dyad

Breastfeeding complications caused by ankyloglossia can generally be placed into broad categories of those caused by maternal nipple trauma or failure of the infant to breastfeed effectively. Specific complaints include difficulty latching or sustaining a latch, infant becoming frustrated or falling asleep at breast, prolonged feedings, a dissatisfied baby, gumming or chewing at the breast, poor weight gain, or failure to thrive. Maternal complaints include traumatized nipples, severe unrelenting pain with feeding, inability to let down because of pain, incomplete breast drainage, breast infections, and plugged ducts.

The physician should interview the mother to ascertain her degree of confidence and comfort while breastfeeding. This can be done semiquantitatively by using a scoring system such as the

**TABLE J-12** Hazelbaker Assessment Tool for Lingual Frenulum Function\*

Appearance Items	Function Items
Appearance of tongue when lifted	Lateralization
2: Round or square	2: Complete
1: Slight cleft in tip apparent	1: Body of tongue but not tongue tip
0: Heart- or V-shaped	0: None
Elasticity of frenulum	Lift of tongue
2: Very elastic	2: Tip to mid-mouth
1: Moderately elastic	1: Only edges to mid-mouth
0: Little or no elasticity	0: Tip stays at lower alveolar ridge or rises mid-mouth only with jaw closure
Length of lingual frenulum when tongue lifted	Extension of tongue
2: >1 cm	2: Tip over lower lip
1: 1 cm	1: Tip over lower gum only
0: <1 cm	0: Neither of the above, or anterior or mid-tongue humps
Attachment of lingual frenulum to tongue	Spread of anterior tongue
2: Posterior to tip	2: Complete
1: At tip	1: Moderate or partial
0: Notched tip	0: Little or none
Attachment of lingual frenulum to inferior	Cupping alveolar ridge
2: Entire edge, firm cup	2: Attached to floor of mouth or well below ridge
1: Side edges only, moderate cup	1: Attached just below ridge
0: Poor or no cup	0: Attached at ridge Peristalsis
	2: Complete, anterior to posterior
	1: Partial, originating posterior to tip
	0: None or reverse motion
	Snapback
	2: None
	1: Periodic
	0: Frequent or with each suck

\*The infant's tongue is assessed using the five appearance items and the seven function items. Significant ankyloglossia is diagnosed when the appearance score total is 8 or less and/or the function score total is 11 or less.<sup>1,7</sup>  
Modified with permission from Hazelbaker AK: *The assessment tool for lingual frenulum function (ATLFF): use in a lactation consultant private practice*. Master's Thesis, 1993, Pacific Oaks College.

LATCH score or a similar tool.<sup>9</sup> The LATCH score has been shown to correlate with breastfeeding duration, but only due to subscores for breast comfort.<sup>20</sup>

If the mother describes nipple pain, the physician may wish to use a pain scale in order to semi-quantify her perception of the degree of her pain. This serves to follow trends in the severity of pain, which may help in determining the effectiveness of an intervention.

The infant should be weighed, and the rate of weight gain since birth should be assessed. The physician should observe the mother and infant while breastfeeding to assess the effectiveness of the feeding and provide assistance as appropriate. Problems including an inadequate or nonsustained latch, and ineffective feedings should be noted. Test weights may be useful in assessing milk transfer. The infant should be weighed prior to and after breastfeeding without a change in clothing or diaper; the difference between the weights in grams indicates the amount of breastmilk consumed in milliliters.

The mother's nipples should be examined carefully for creases, bruises, blisters, cracks, or bleeding. Areolar edema and erythema should be noted as possible signs of nipple infection. A family history of bleeding diatheses should be elicited.

## Recommendations

Conservative management of tongue-tie may be sufficient, requiring no intervention beyond breastfeeding assistance, parental education, and reassurance.<sup>3</sup> For partial ankyloglossia, if a tongue-tie release is deemed appropriate, the procedure should be performed by a physician or pedodontist experienced with the procedure; otherwise a referral should be made to an ear, nose, and throat specialist or oral surgeon. Release of the tongue-tie appears to be a minor procedure, but it may be ineffective in solving the immediate clinical problem and may cause complications such as infant pain and distress and postoperative bleeding, infection, or injury to the Wharton duct.<sup>3</sup> Complications are rare, however.<sup>14,1,13,23</sup>

Frenotomy, or simple incision or "snipping," of a tongue-tie is the most common procedure performed for partial ankyloglossia. It should be recognized that postoperative scarring may further limit tongue movement.<sup>3</sup> Excision with lengthening of the ventral surface of the tongue or a z-plasty release is a procedure with less postoperative scarring, but it carries the additional risks of general anesthesia.<sup>3</sup>

## The Frenotomy Procedure

**Instruments:** Iris scissors and grooved retractor.

**Supplies:** Clean gloves and gauze; gelatin foam.

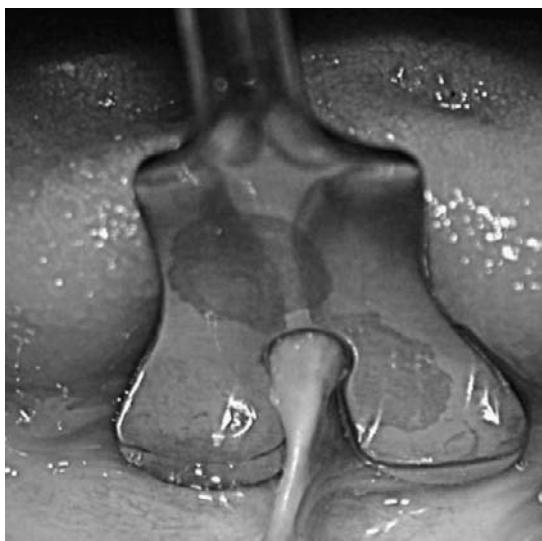

**Method:** Parents should be counseled about risks, benefits, and alternatives of the procedure, and informed consent should be obtained. This counseling should include a discussion of the possibility that the clinical breastfeeding problem will not improve.

The frenulum may be transilluminated to check for translucency and lack of vasculature. The frenulum is usually a thin, translucent hypovascular membrane, where a simple frenotomy results in an almost bloodless procedure. Rarely, it may be thick and fibrous or muscular and relatively vascular. Thicker frenula are best incised by an otolaryngologist or oral surgeon under controlled conditions.

The frenulum is almost devoid of sensory innervation. Infants under 4 months of age can usually tolerate the frenotomy very well without any local anesthesia. Alternatively, topical anesthetic (e.g., benzocaine gel or paste) may be applied with cotton applicators to both sides of the frenulum in the area to be incised. This, however, may have the undesirable effect of numbing the mouth, such that the baby may not be able to suck effectively after the frenotomy is completed.

The infant is placed supine on the examining table or mother's lap. An assistant holds the baby's elbows firmly against the ears and stabilizes the chin with one index finger. Alternatively, the infant may be swaddled with a receiving blanket to immobilize the arms while the assistant stabilizes the head. Slight extension of the infant's neck allows better visualization of the tongue and frenulum. Using the grooved retractor or physician's fingers, the physician lifts the tongue to expose the frenulum. With the tips of the iris scissors an incision is made in the thinnest portion of the frenulum, close to the retractor and parallel to the tongue. Care is taken not to incise the tongue, the genioglossus muscle, or the gingival tissue. The incision should extend into the sulcus between the tongue and the genioglossus muscle, just beyond the level of the muscle, carefully avoiding the floor of the mouth. This ensures complete detachment of the tongue from the gingiva, without causing damage to the sublingual mucosa or to the salivary duct (Figure J-1).

The site beneath the tongue is blotted with gauze until little or no blood is seen. In the event of unexpected bleeding beyond 2 to 3 minutes, a strip of gelatin foam may be used to achieve rapid hemostasis. The infant may be returned to the mother immediately to be breastfed. Infant latch and maternal nipple pain should be reassessed at this time. There is no specific aftercare required except for breastfeeding. A small white patch or eschar is seen in some infants for 1 or 2 weeks during the healing process. Infection of the site is exceedingly rare if clean technique is used as described.

**Figure J-1.** Using a Lorenz tongue elevator, the lingual frenum is exposed. Pulling upward on the tongue stretches and allows visualization of the frenum and the floor of the mouth. In this infant an 8-mm incision was needed to allow sufficient movement of the tongue for effective breastfeeding to occur. Courtesy Dr. Larry Kotlow.

Medical equipment used in this procedure should be sterilized or disinfected in accordance with the guidelines of the Centers for Disease Control and Prevention.<sup>4</sup>

## Management of Maternal and Infant Complications of Ankyloglossia

If nipple damage or infection is present, a problem-specific treatment program should be instituted. Mastitis and yeast infections should be treated according to established guidelines.<sup>19</sup>

Some mothers may need nipple rest for one to several days to allow healing to occur before reinstituting feedings at the breast. These mothers should be encouraged to express their breastmilk to maintain their milk supply and to feed their milk to the baby by an alternate method.

Suppressed lactation should be addressed and every attempt made to reestablish the mother's milk supply. Infants who have been gaining weight slowly or failing to thrive may need to receive supplements of expressed breastmilk or formula temporarily.

Follow-up for resolution of maternal and infant complications of ankyloglossia should take place by the mother's or infant's primary health care provider within 3 or 4 days of the frenotomy.

## Further Research

This protocol was developed by the Academy of Breastfeeding Medicine to provide clinicians with guidance about the assessment and treatment of ankyloglossia and associated breastfeeding problems. More definitive recommendations await future research in this area. The Academy of Breastfeeding Medicine urges that more research be undertaken so that the benefits and risks of frenotomy for ankyloglossia and its effectiveness in treating breastfeeding concerns can be better understood. We specifically recognize that the Hazelbaker and LATCH instruments cited in this document require further interrater and intrarater reliability and validity testing. We recognize that a critical need exists for clinical tools to assess breastfeeding performance as well as the degree of ankyloglossia and function of the tongue. In addition, a randomized investigator-blinded clinical trial is needed to assess the effectiveness of frenotomy in treating infant and maternal breastfeeding problems associated with ankyloglossia.

## APPENDIX J

# *Protocol 12: Transitioning the Breastfeeding/Breast-Milk-Fed Premature Infant from the Neonatal Intensive Care Unit to Home*

---

### *Introduction and Background*

The practice of breastfeeding or providing expressed mother's milk to premature infants is promoted because of the considerable benefits to their health and well-being.<sup>15,1</sup> Exclusive breastfeeding has been shown to result in adequate postdischarge weight gain even in very-low-birth-weight infants.<sup>18</sup> The following guidelines include recommendations for monitoring and optimizing nutritional support of premature infants after they are discharged from the hospital. These guidelines represent expert opinions and have not been validated experimentally.

This protocol addresses the care of premature infants less than 37 weeks' gestation and less than 2500 g at birth, who are being transitioned from the hospital to home. Depending on the unit, these infants often weigh 1750 to 2000 g at discharge or less if a kangaroo mother care (also known as skin-to-skin) program is practiced, which may allow for more rapid development of feeding skills. Many of the infants weighing 2000 to 2500 g are not admitted to NICU; they may be either in a transitional nursery or in the postnatal ward with their mothers. (Please also refer to Protocol #10.) The plan does not

distinguish in utero appropriately grown (AGA) from growth-restricted (SGA) infants but bases decisions on current nutritional status and body weight.

For infants less than 1500 g at birth, it is recommended that they be fed their mothers' milk fortified with nutrients and calories. Infants 1500 g or more may breastfeed ad libitum as they are able, provided they are supplemented with multivitamins and iron. Near the time of discharge, a decision must be made as to the feeding in the postdischarge period (to 1 year corrected age). Many of these infants do well after discharge with full or partial breastfeeding, or receiving mother's milk by bottle, cup,<sup>10,4</sup> syringe, nasogastric tube, or supplemental nursing (feeding tube) device. Growth faltering, however, has been observed in some premature infants in the postdischarge period if they receive exclusive human milk feedings without nutrient and caloric fortification.<sup>8,2,16,3,5,9</sup>

Most slow growth in these babies, with the exception of the extremely low-birth-weight infant (ELBW is defined as less than 1000 g at birth), is a function of absolute intake rather than milk composition such that every effort to ensure optimal milk volume should be exhausted prior to switching feedings to formula.

## Predischarge: Discharge Planning

- A. The clinician should work with the mother to devise a feeding plan well before the actual date of discharge. Rooming-in by the mother for a few days prior to discharge during this transition period is strongly recommended. The baby will preferably be on exclusive breastmilk, either suckling straight from the breast or by use of expressed breastmilk. Less often, the plan may include a combination of breastmilk (directly from the breast or expressed) and formula.
- B. The following aspects of the current feeding plan should be assessed when making post-discharge plans.
1. "Type" of feeding: Unfortified human milk, fortified human milk, formula, or a combination.
  2. "Amount" of feeding: Milk intake (mL/kg/day). This includes either measuring the mothers' pumped milk volume or performing daily test weights<sup>13</sup> for infants who feed at the breast. If the baby is already growing adequately, it is not typically necessary to perform test weights.
  3. "Method" of feeding: Oral (breast, bottle, cup, supplemental nursing device, other, or a combination of methods) versus, or in combination with, tube-feeding (nasal or orogastric) or use of a feeding device (e.g., gastrostomy tube).
  4. "Adequacy of growth": In-hospital growth noted as daily rate of weight gain and weekly rate of length gain calculated or plotted on appropriate growth charts ([Table J-13](#)).

TABLE J-13	Biochemical* and Growth Monitoring for Premature Infants in the Postdischarge Period
Parameter	Action Values
<b>Growth</b>	
Weight gain	<20 g/day
Length increase	<0.5 cm/wk
Head circumference increase	<0.5 cm/wk
<b>Biochemical markers</b>	
Phosphorus	<4.5 mg/dL
Alkaline phosphatase	>450 international units/L
Blood urea nitrogen	<5 mg/dL

\*It is recognized that biochemical monitoring is not feasible in all settings; presence or absence of clinical rickets then becomes a substitute parameter.

Modified from Hall RA: Nutritional follow-up of the breastfeeding premature infant after hospital discharge, *Pediatr Clin North Am* 48:453, 2001; Schanler RJ: Nutrition support of the low birth weight infant. In Walker WA, Watkins JB, Duggan CP, editors: *Nutrition in pediatrics*, ed 3, Hamilton, ON, Canada, 2003, BC Decker Inc., pp. 392-412.

5. "Adequacy of nutrition": In-hospital biochemical nutritional status, when feasible ([Table J-13](#)).

(NOTE: It is recognized that biochemical monitoring is not feasible in all settings. In such situations, dietary adequacy is based on optimal growth and absence of clinical rickets.)

6. Summary of current nutritional assessment: optimal versus suboptimal.
  - a. Optimal status (includes *all* of the following).
    - i. Infant can achieve entire intake orally, by breastfeeding or alternate methods.
    - ii. Volume of intake is approximately 180 mL/kg/day or more. (Rarely, lower volumes will be adequate if both of the following criteria are met.)
      - iii. Growth (weight and length) is within normal limits or improving.
      - iv. Biochemical indices (phosphorus, alkaline phosphatase, blood urea nitrogen) are within normal limits ([Table J-5](#)) or improving.
  - b. Suboptimal (includes *any* one or more of the following).
    - i. Infant's intake is less than 160 mL/kg/day (with rare exceptions).
    - ii. Infant cannot consume all feedings orally.
    - iii. Growth is less than adequate (weight gain less than 20 g/day and/or length gain less than 0.5 cm/week).
    - iv. Biochemical indices are abnormal and are not improving.

- C. Transition to postdischarge nutrition for infants with "optimal assessment":

1. If the infant has been receiving fortified human milk with or without preterm formula, the diet may be changed to unfortified human milk ad libitum, by breastfeeding or alternative feeding methods, at least 1 week before anticipated discharge.
  - a. Prior to this transition it is necessary to assure that mother's milk supply is appropriate for a trial of breastmilk without fortification. This can be done by reviewing the mother's pumping record. Ideally, the mother has been pumping or expressing breastmilk regularly. It is recommended that the mother continue pumping or expressing milk at least three times per day to have an "oversupply" to facilitate adequate volume consumption by the premature infant at the breast. For some mothers, pumping after each feeding ensures optimal drainage of the breast, optimal milk production, and expression of the highest fat content (hindmilk) for

supplemental feedings. This technique of breastfeeding, then feeding previously pumped breastmilk, and then pumping any residual volume from the breast is termed "triple feeding."

(NOTE: In many areas manual expression is the norm or only available method for milk expression. Preliminary evidence suggests that greater volumes may be obtained with electric, hospital-grade pumps.<sup>14</sup> Therefore, whenever possible, use of the latter is recommended.)

- b. For infants receiving formula supplements, a trial without formula is appropriate while increasing human milk intake to approximately 180 mL/kg/day, if possible. Use of hindmilk to increase caloric intake for some feedings may be appropriate.
  - c. Add iron, 2 mg/kg/day. If enriched post-discharge formula is used, a decrease in the quantity of iron and multivitamin supplementation is indicated. Generally, if formula constitutes about 50% of the diet, the dose for iron is 1 mg/kg/day and multivitamin preparation is half the doses listed below.
  - d. Add a complete multivitamin preparation. (Dosed to receive at least the following amounts of vitamin A [1500 IU/day], C [20 to 70 mg/day], and D [400 IU/day]; vitamin C requirements of preterm infants are poorly studied. B vitamins are also necessary for the former preemie receiving unfortified human milk. Typically, appropriate amounts of all vitamins will be provided by infant multivitamin [MVI] preparations at 1 mL/day.) See note under iron above C1 (c) if providing enriched post-discharge formula supplements.
  - e. Monitor milk intake and growth (weight and length) during this week. Volumes of pumped or expressed milk and daily test weights (for infants fed at the breast) should be recorded during this period.<sup>13</sup>
  - f. If intake and growth are adequate, continue this diet after discharge.
  - g. If intake and growth are suboptimal, follow D (d) below.
  2. If the infant has been receiving unfortified human milk:
    - a. Continue iron (2 mg/kg/day).
    - b. Continue multivitamin preparation [see dosing above, C1 (c)].
    - c. Continue this diet after discharge.
  - D. Transition to postdischarge nutrition for infants with "suboptimal assessment":
    1. If the infant has been receiving fortified human milk:
      - a. Change the diet to unfortified human milk, with or without preterm formula, ad libitum (by breastfeeding and/or alternative feeding methods) plus a minimum of two to three feedings of enriched post-discharge formula prepared per manufacturer instructions ( $\approx$ 22 kcal/oz) at least 1 week before anticipated discharge.
- (NOTE: Many neonatologists and institutions add powdered discharge premature formula to expressed breastmilk to provide enriched feeds while still providing the advantages of breastmilk. There is no evidence to recommend for or against this practice. This use of powdered premature formula is off-label and the potential for error is great, so be advised to be extremely cautious if using this approach.)
- b. Recommend that the mother continue pumping or expressing milk at least three times/per day [see C,1 (a) above].
  - c. Monitor milk intake and growth during this week.
  - d. Assess adequacy of breastfeeding and address problems or potential problems.
    - i. Latch.
    - ii. Milk transfer/milk volume. If lactation has been suppressed or the baby is not adequately draining the breast, it may be necessary to intervene to increase volume (i.e., increased pumping after feeds or pumping at some feeds and feeding the expressed milk in lieu of or in addition to feeding at the breast.) (Please also see Protocol #9.)
    - iii. Maternal milk content. Consider the use of hindmilk for some feedings to increase caloric content. This must be considered in conjunction with milk transfer and volume as it may be particularly important if the baby is getting only foremilk and leaving hindmilk.
    - iv. Frequency of feeds at breast (please note that with "sleepy preemies" subtle feeding cues may be missed).
    - v. Optimize milk transfer. Suggested techniques may include pumping or expressing to let down before putting baby to breast or using breast compression during feedings.
    - vi. Maternal satisfaction. Mothers may have preferences regarding timing of feeds, feeding devices, and so on that fit best with the family's needs and can be accommodated without compromising the infant's nutrition.

- vii. Consider use of a feeding device.
  - (A) Nipple shield to improve milk transfer.<sup>6</sup>  
 (NOTE: Any mother who is discharged using a nipple shield must be closely monitored by a competent lactation professional to watch for potential associated complications.)
  - (B) Supplemental nursing (feeding tube) device while at breast.
  - (C) May be able to use nipple shield and supplemental nursing device together effectively (e.g., by placing tube inside nipple shield so when baby suckles, the volume of milk available for transfer is increased).
  - (D) Test weighing.<sup>13</sup>
    - (I) Monitor milk intake and growth (weight and length) during this week. Record volumes of pumped or expressed milk and daily test weights (for infants fed at the breast) during this period.<sup>13</sup>
    - (II) If intake and growth are adequate during this week after switching:
      - (a) Add iron (1 to 2 mg/kg/day), depending on how much formula is fed.
      - (b) Add multivitamin preparation (half to full dose described above C,1 [c]), depending upon how much formula is fed.
    - (III) Continue this diet after discharge.
- 2. If the infant has been receiving unfortified human milk, assess the adequacy of breastfeeding and address problems or potential problems as above, D,1 (d).
  - a. If addressing any existing breastfeeding problems does not result in "optimal assessment," add two to three feedings of enriched postdischarge formula prepared per manufacturer instructions ( $\approx 22$  kcal/oz) [see note under D,1 (a) above]. Ensure that the mother is expressing milk to maintain and optimize her milk production. Anticipate at least 1 more week of continued hospitalization before discharge.
    - i. Monitor milk intake and growth during this week.

- ii. Continue iron and multivitamin supplement.
- iii. If the feeding assessment continues to be suboptimal after 1 week, increase the number of feedings of enriched postdischarge formula or increase the concentration of enriched formula to 24 to 30 kcal/oz.

## Postdischarge Assessment

---

- A. Nutrition monitoring 1 week after discharge.
  - 1. Assess intake.
    - a. History.
    - b. Observation of feeding.
    - c. Consider test weighing if concerns persist.<sup>13</sup>
  - 2. Growth—weight and length (Table J-13).
  - 3. Biochemical indices of nutritional status (Table J-13).
  - 4. Reassess nutritional status as "Optimal" versus "Suboptimal."
    - a. Infants with an "Optimal" assessment may be reevaluated at 1 month after discharge (see III,B, below).
    - b. For infants with a "Suboptimal assessment":
      - i. Assess adequacy of breastfeeding.
        - (A) Latch.
        - (B) Milk transfer/volume.
        - (C) Maternal satisfaction.
        - (D) Milk content—consider hindmilk.
        - (E) Consider use of feeding devices.
          - (I) Nipple shield to improve milk transfer.<sup>12</sup>
          - (II) Test weighing<sup>13</sup> to evaluate milk volume.
      - ii. If addressing any existing breastfeeding problems does not result in an "optimal assessment," add additional feedings of enriched postdischarge formula, prepared as below, per clinical judgment according to the individual infant's assessment.
        - (A) Prepared per manufacturer instructions ( $\approx 22$  kcal/oz).
        - (B) Concentrated to 24 to 30 kcal/oz.
        - (C) Ensure that the mother is expressing milk to maintain and optimize her milk production.
      - iii. Frequent follow-up visits for ongoing nutritional monitoring.

- B. Nutrition monitoring 1 month after discharge.
    - 1. Assess intake.
      - a. History.
      - b. Observation of feeding.
      - c. Consider test weighing if concerns persist.<sup>13</sup>
    - 2. Growth—weight and length ([Table J-13](#)).
    - 3. Biochemical indices of nutritional status ([Table J-13](#)).
    - 4. Reassess nutritional status as "Optimal" versus "Suboptimal."
      - a. Infants with an "Optimal" assessment may be reevaluated at every 2 months to 1 year corrected age.
      - b. For infants with a "Suboptimal assessment":
        - i. Ensure optimal milk production, breastfeeding.
        - ii. Add additional feedings of enriched postdischarge formula, individualizing preparation either prepared per manufacturer instructions ( $\approx 22 \text{ kcal/oz}$ ) or concentrated to 24 to 30 kcal/oz.
        - iii. Frequent follow-up visits for ongoing nutritional monitoring.
  - C. Once nutrition has been optimized, nutritional monitoring can occur every 2 months until 1 year corrected age.
  - D. With regard to enriched formula, a few studies have demonstrated a positive effect on growth using enriched formulas for 6 to 9 months. Until more definitive data are available for breastfed former preemies, we recommend continuing an enriched postdischarge formula for a minimum of 6 months.
- See [Figure J-2](#) for an algorithm for care of premature infants postdischarge.

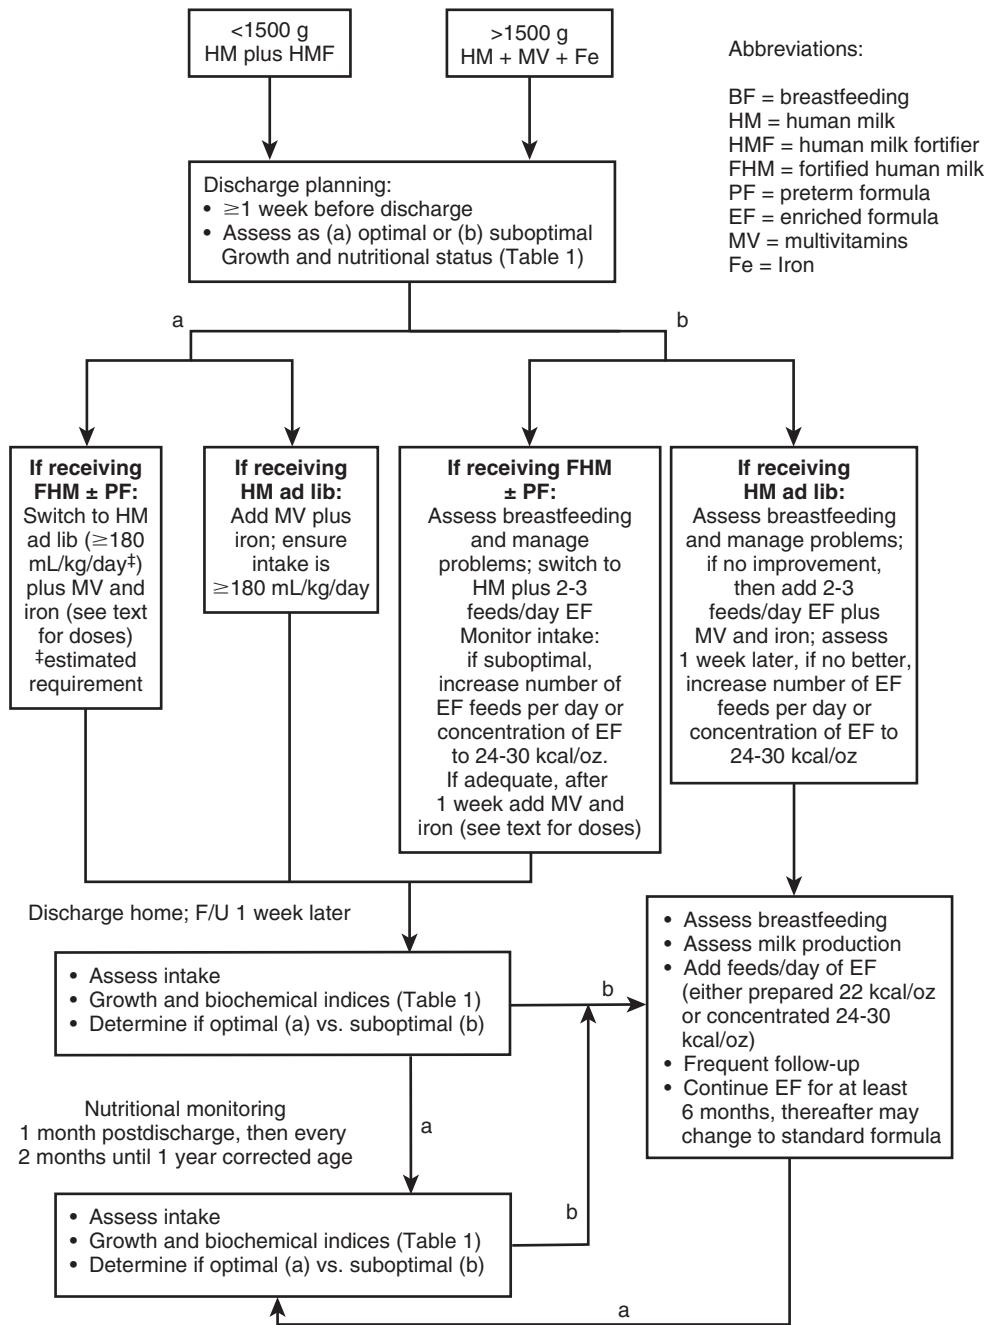

## *General Strategies*

- A. Enriched postdischarge formula is used because it provides greater nutrient intake than term infant formula. Human milk fortifier usually is not recommended postdischarge because its nutrient content is too great for the infant at the time of discharge and it is expensive and very difficult to prepare according to specifications.
- B. Hindmilk, if used, provides extra calories (estimated at 22 to 24 cal/oz) but no increase in the intake of minerals or protein. (Hindmilk is the fat-rich milk that occurs at the end of the feeding.)
- C. It is imperative that the hospital physician communicate with the physician who will provide follow-up care to ensure that the desired plan

is carried out and to convey any unique concerns about growth, diet, feeding patterns, and biochemical monitoring.

## *Support for Breastfeeding Mothers of Premature Infants*

- A. Support mothers to initiate kangaroo (skin-to-skin) care as early as possible in-hospital.<sup>15,6</sup>
- B. Encourage mothers to express their milk soon after delivery and approximately every 3 hours on an ongoing basis. Aim for at least eight pumping sessions in 24 hours, so that if pumping does not occur exactly every 3 hours, sessions will not be missed. Instruct mothers on the use of effective breast pumping methods, either electric rental-grade or effective manual pumps or manual expression. Whenever possible, electric rental-grade pumps should be used for maximal stimulation, particularly for the establishment of milk supply. Skin-to-skin contact, simultaneous milk expression, and nonnutritive suckling at the breast may facilitate the establishment of the milk supply.
- C. Educate mothers that early feeding behaviors emerge during skin-to-skin holding and that mothers can follow the infant's cues for early feeding attempts. Mothers should understand that early feeding attempts are gradual and not expected to result in a full feeding for the infant.
- D. Sustained suckling with swallowing for 5 minutes is one indicator that the infant may be ready to transition from nasogastric tube to breastfeeding.<sup>7,19</sup> Other studies suggest that early introduction of oral feeding hastens the development of oral motor skills.<sup>17</sup> Nursing supplementers may provide additional volume.<sup>11</sup>
- E. Have trained personnel evaluate breastfeeding (position and latch) on a regular basis. A correct latch is critical for efficient milk removal.
- F. Monitor mothers for nipple soreness. If present, this may be an indication of shallow latch. Temporary use of silicone nipple shields is a helpful adjunct for milk transfer and more efficient latch-on for premature infants with shallow latch.<sup>6</sup>
- G. If the infant is achieving partial intake directly at the breast, consider "triple feeding"—put the baby to breast, supplement with expressed breastmilk or formula (at breast with the supplemental nursing [tube feeding] device or after the breastfeeding), and then pump or express milk afterward to maintain the milk supply.

**Figure J-2.** Algorithm for care of prematures postdischarge by weight (<1500 g or >1500 g).

- H. If the baby is discharged with partial feedings at the breast, consider a scale sensitive enough to distinguish milk intake for home use to help with the transition to total feedings at the breast.
- I. Refer and coordinate supportive care services such as community support, visiting nurse, lactation consultant visits, social services, and WIC.

#### Abbreviations:

BF = breastfeeding  
 HM = human milk  
 HMF = human milk fortifier  
 FHM = fortified human milk  
 PF = preterm formula  
 EF = enriched formula  
 MV = multivitamins  
 Fe = Iron

## APPENDIX J

# *Protocol 13: Contraception During Breastfeeding*

Pamela Berens, Miriam Labbok, and the Academy of Breastfeeding Medicine

### *Purpose*

The purpose of this protocol is to outline considerations in assisting breastfeeding families to achieve optimal birth spacing by selecting a contraceptive method that is effective, unlikely to disrupt lactation, and satisfactory for the mother and her partner. The protocol covers the use of contraceptive methods during breastfeeding and provides guidance on the lactational amenorrhea method (LAM).

This protocol assumes that the practitioner is well versed in the risks and benefits of different types of contraception, including all pharmaceutical, permanent, and periodic abstinence/natural family planning methods.

### *Issues in Counseling and Selection of Contraceptives During Breastfeeding*

#### **CONSIDERATIONS FOR CLINICIAN COUNSELING AND METHOD USE**

Postpartum contraception, like breastfeeding, should be discussed with women during their own obstetric prenatal and postpartum visits and the infant's pediatric well-baby visits. A woman's contraceptive choice depends on many factors such as previous experience with contraceptives, future childbearing plans,

husband or partner's attitude, level of user attention required for use, medical considerations, return of menses, and the woman's lactation status. If a woman is not comfortable with a method, she may not use it effectively.

#### **ADVANTAGES AND DISADVANTAGES OF AVAILABLE OPTIONS**

Contraceptive counseling during breastfeeding extends beyond issues of efficacy, because the selected method must be appropriate for a woman's breastfeeding expectations. [Table J-14](#) provides useful information for counseling the breastfeeding mother. Considerations include the potential for hormonal methods to either disrupt milk synthesis or expose the infant to synthetic hormones. Because a falling progesterone level after birth is necessary for onset of milk production, initiation of hormonal contraception before lactation is established is of particular concern. Published evidence is insufficient to exclude these risks. At the same time, long-acting reversible hormonal methods have high contraceptive efficacy. Health care providers should discuss the limitations of the available data within the context of a mother's desire to breastfeed, her risk of low milk production, and her risk of unplanned pregnancy, so that she can make an autonomous and informed decision.

<b>TABLE J-14</b>	General Principles for Counseling Breastfeeding Women Concerning Contraceptive Selection and Birth Spacing
<b>Issues</b>	<b>Considerations</b>
1. Breastfeeding patterns, status, and plans	<ul style="list-style-type: none"> <li>Consider both short- and long-term breastfeeding intent as well as well birth spacing plans. There is the potential for hormonal methods to have an impact depending on when they are started</li> <li>Mothers may plan to exclusively breastfeed; some may do so to use LAM, others may use LAM because they are already fully breastfeeding. LAM users should be counseled to have another method in hand for when menses return or breastfeeding patterns change. Effectiveness of LAM in exclusively breastmilk pumping mothers may not be equivalent to direct breastfeeding</li> <li>Many women who intend to breastfeed exclusively are not able to achieve their goals</li> </ul>
2. Child's age/time postpartum	<ul style="list-style-type: none"> <li>Many methods should not be introduced until breastfeeding is well established (i.e., at 4-6 weeks), as there may be potential for hormonal methods to directly impact lactogenesis and/or to impact the infant</li> </ul>
3. Maternal age and future childbearing plans	<ul style="list-style-type: none"> <li>Choices depend on desire to space births or desire to limit family size. Globally recommended interpregnancy intervals are at least 18 months to 2+ years for maternal health, depending on the setting, and about 3-5 years for child health outcomes</li> </ul>
4. Previous contraceptive experience	<ul style="list-style-type: none"> <li>Discussion of previous contraceptive experience, including compliance, satisfaction, side effects, and social issues, is essential. These issues can influence compliance and satisfaction, particularly as they pertain to prior lactation experiences</li> </ul>
5. Partners/interactions	<ul style="list-style-type: none"> <li>Partner's experiences and opinions may impact compliance, particularly for barrier methods, LAM, and natural family planning</li> <li>The woman's social and behavioral considerations, such as number of partners and sexual activity, should be explored. A woman's history of unplanned pregnancy and short interpregnancy interval should be reviewed and discussed</li> </ul>
6. Previous lactation experience/medical conditions	<ul style="list-style-type: none"> <li>Prior insufficient milk supply or inadequate infant growth</li> <li>Prior breastfeeding experience did NOT meet goals (either exclusivity or duration), AND supply was a potential reason</li> <li>Physical examination suggestive of insufficient glandular tissue</li> <li>Prior breast surgery</li> <li>Medical conditions potentially adversely affecting supply (polycystic ovary syndrome, infertility, obesity)</li> <li>Multiple gestation</li> <li>Preterm infant(s)</li> </ul>

LAM, Lactational amenorrhea method.

## *LAM for Contraception in the Early Postpartum Period and for the Introduction of Other Methods*

### **BACKGROUND**

Data published in the 1970s showed that women who breastfed were less likely to ovulate early postpartum and that if breastfeeding were more intensive, they were less likely than partial or non-breastfeeders to experience a normal ovulation prior to the first menstrual-like bleed.<sup>33</sup> In 1988, at a Bellagio Conference, a group of expert scientists proposed three criteria as sufficient to predict fertility return. This three-criteria approach described in further detail below as the "Lactational Amenorrhea Method" was subsequently tested.<sup>32,27</sup> Studies of the acceptability and contraceptive efficacy of active LAM use continue to confirm the original findings, demonstrating that LAM is acceptable, learnable, user-friendly, and as effective as many other alternatives.<sup>43,42,25,34,17,22</sup> (II-2) (Quality of evidence [levels of evidence I, II-1, II-

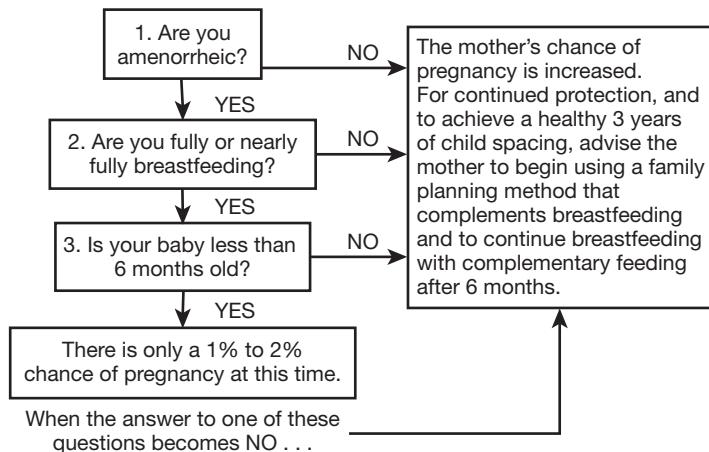

2, II-3, and III] is based on the U.S. Preventive Services Task Force Appendix A Task Force Ratings<sup>1</sup> and is noted throughout this protocol in parentheses.)

### **METHOD: WHAT IS LAM?**

LAM is presented as an algorithm (Figure J-3) and includes three criteria for defining the period of lowest pregnancy risk. If one of these criteria is not met, women should immediately initiate another method. Clinically, the mother is asked these three questions:

- "Are you amenorrheic?" meaning that you have not had a menstrual bleed or any bleed of >2 days in duration (discounting any bleed in the first 2 months).
- "Are you fully or nearly fully breastfeeding?" This includes not giving your baby any supplementary foods or fluids in addition to breastfeeding (greater than once or twice a week)?
- "Is your infant less than 6 months of age?"

Ask the mother, or advise her to ask herself, these three questions:

**Figure J-3.** The lactational amenorrhea method (LAM).

If she answers "yes" to all three questions, she meets the requirements for LAM. If any of the above three questions is answered "no," then her chance of pregnancy is increased, and she should be advised to initiate another form of contraception to prevent pregnancy. If the mother is interested in and qualifies for LAM, she should review these three questions regularly. Clinicians should ensure that she has chosen her next method of contraception and either has it on hand or knows how to obtain it if it is an implant or intrauterine device (IUD).

## DEFINITIONS FOR LAM USE

To use LAM correctly, it is important that the patient understand each of the three criteria, which can be remembered using the letters "LAM" to indicate Lactation, Amenorrhea, and the number of Months:

1. Lactation. Full or nearly full breastfeeding includes exclusive, nearly exclusive, and some irregularly provided supplements, as long as they do not disrupt the frequency of feeds.<sup>26</sup>
2. Amenorrhea. For the purposes of LAM use, menses return is defined as any bleeding that occurs after 56 days postpartum that is perceived by the patient as a menses or any two consecutive days of bleeding.
3. Months. The "6 months" criterion is added primarily because this is the time that complementary feeding should begin. If breastfeeding continues at the same frequency and complementary foods are offered after the breastfeed, efficacy apparently remains high as long as amenorrhea continues. In Rwanda, the method was used up to 9 months, by maintaining the breastfeeding frequency experienced during

month 6.<sup>9</sup> This was achieved by feeding before each complementary feeding. Another study in Pakistan found a continued high efficacy under these conditions for up to 12 months.<sup>21</sup> (II-2)

## EFFICACY

A Cochrane Review<sup>47</sup> (and assessed as up-to-date in 2008) concluded that fertility rates are low among fully breastfeeding, amenorrheic women. In controlled studies of LAM, pregnancy rates for 6 months ranged from 0.45% to 2.45%. In six uncontrolled studies of LAM users, pregnancy ranged from 0% to 7.5%. The World Health Organization (WHO) carried out a prospective trial on lactational amenorrhea and fertility return; although this was not a study of women selecting and using LAM, the findings confirmed the physiological potential for high efficacy as seen in the LAM trials.<sup>43,42</sup> Subsequently, studies of method use have consistently found a 6-month pregnancy rate averaging 2%<sup>15</sup> (I, II-2)

## LAM MANAGEMENT ISSUES

Suggested behaviors contributing to method success and duration include:

1. Number of feedings. One controlled study found exclusively breastfeeding women using LAM are more likely to be amenorrheic at 6 months than exclusively breastfeeding controls (84% vs. 69.7%, respectively).<sup>28</sup> Women using LAM had a higher feeding frequency and a shorter interfeeding interval than other exclusively breastfeeding women.
2. LAM can be used beyond the sixth month. The two studies mentioned above in Rwanda<sup>9</sup> and

- Pakistan<sup>21</sup> have indicated that the efficacy of LAM can be maintained during the 6- to 12-month period, provided the mother continues to breastfeed before giving complementary foods at less than 4-hour intervals during the day and 6-hour intervals at night while remaining amenorrheic. (II-2)
3. LAM effectiveness has not as yet been adequately tested to offer the method with confidence to women who are giving supplemental feedings daily or expressing milk by hand or pump instead of breastfeeding.<sup>46</sup> (II-2) Women who are expressing milk more than a few times per week should be counseled to initiate an additional contraceptive method. (III)

## TRANSITION TO OTHER METHODS

LAM may also be used as an introductory method to inform the user when it is time to initiate use of

another method. Of note is that fully breastfeeding women are very unlikely to conceive in the first 56 days postpartum so secondary methods can be delayed until at least 8 weeks postpartum. When LAM criteria no longer apply or whenever a breastfeeding woman wishes to use an alternate family planning method, she should have an alternative method readily available. Alternative methods are discussed in terms of advantages and disadvantages and special issues related to breastfeeding.

## *Additional Comments on Individual Methods*

**Table J-15** provides additional specific information for many individual methods, including advantages, disadvantages, and potential issues related to breastfeeding for each.

<b>TABLE J-15</b> Use of Contraceptive Methods During Lactation: Advantages, Disadvantages, and Impact on Lactation			
Method	Advantages	Disadvantages	Effects Related to Breastfeeding
<b>Lactational amenorrheic method</b>			
<b>Natural family planning</b>			
• Billings ovulation • Creighton model • Marquette • Symptothermal	<ul style="list-style-type: none"> <li>No side effects</li> <li>Effectiveness rates comparable with other user-directed methods of birth control (i.e., pills or barriers)</li> <li>Low cost for most methods</li> </ul>	<ul style="list-style-type: none"> <li>Requires special instruction for use during breastfeeding</li> <li>ClearBlue fertility monitor expense with Marquette</li> <li>May require long periods of abstinence</li> </ul>	<ul style="list-style-type: none"> <li>None</li> </ul>
<b>Barrier methods</b>			
• Diaphragm/cap • Spermicide • Condoms	<ul style="list-style-type: none"> <li>Few side effects</li> <li>Effective with diligent and appropriate use</li> <li>Easily accessible as “back-up”</li> <li>Low cost</li> <li>Also provide protection from sexually transmitted infection</li> </ul>	<ul style="list-style-type: none"> <li>Potential for user error</li> <li>Allergy possible</li> <li>May be inconvenient and limit spontaneity</li> <li>Cervical cap and diaphragm require fitting</li> </ul>	<ul style="list-style-type: none"> <li>None</li> <li>Use of lubricant may be beneficial with condoms in setting of vaginal atrophy</li> </ul>
<b>Other contraceptive options</b>			
<b>IUDs</b>			
• Copper IUD (ParaGard T380A), 10 years • Levonorgestrel IUD (Mirena), 5 years • Levonorgestrel IUD (Skyla), 3 years	<ul style="list-style-type: none"> <li>Highly effective</li> <li>Reversible</li> <li>Long-term contraceptives</li> <li>Little user attention required (typical use and perfect use are similar)</li> </ul>	<ul style="list-style-type: none"> <li>Small risk of infection, perforation, expulsion</li> <li>Requires provider insertion and removal</li> <li>Copper contraindicated with Wilson's disease and copper allergy</li> <li>Short-term use costly; long-term use cost-effective</li> </ul>	<ul style="list-style-type: none"> <li>Copper IUD: no known impact on lactation</li> <li>Possible risk of perforation at insertion requiring surgical removal, which may necessitate short interruption in breastfeeding</li> <li>Levonorgestrel IUD (Mirena) placed immediately postpartum may be associated with shorter duration of breastfeeding. No adverse effect on breastfeeding reported when placed 6 weeks postpartum or later</li> </ul>

*Continued*

**TABLE J-15** Use of Contraceptive Methods During Lactation: Advantages, Disadvantages, and Impact on Lactation—cont'd

Method	Advantages	Disadvantages	Effects Related to Breastfeeding
<b>Sterilization</b>			
• Male (vasectomy) • Female: postpartum; laparoscopic; hysteroscopic	• Highly effective • Male vasectomy and female hysteroscopic occlusion may be performed on an outpatient basis	• Permanent; risk of regret • Surgical procedural risks • Cost related to surgery • Requires surgeon • Risk of ectopic pregnancy with female procedures	• Male sterilization: none • Female sterilization: postpartum procedure separates mother and infant and may require use of maternal narcotics (ideally avoid procedures in first 1-2 hours to allow skin-to-skin, initial breastfeeding, etc.)
<b>Progestin-only hormonal options<sup>a</sup></b>			
• Injectable (DMPA) every 3 months • Oral daily pills (norethindrone) • Progestin-releasing IUD (see above): LNG IUD (Mirena), 5 years; LNG IUD (Skyla), 3 years • Progestin vaginal rings • Implants: etonogestrel (Implanon/ Nexplanon), 3 years (Jadelle), 5 years	• Long-term options highly reliable	• Common side effect of irregular bleeding may be less problematic in breastfeeding mothers • Potential for user failure with daily pills • Other progestin side effects: headache, acne, weight gain, bloating, depressed mood • DMPA may have delayed return to fertility • Implant and IUDs require provider insertion and removal	• Theoretical potential to adversely impact milk supply when started in the early postpartum period prior to establishing a milk supply. Insufficient data to determine risk at this time • If milk supply decreases with DMPA, cannot be discontinued or removed • LNG IUD (Mirena) placed immediately postpartum may be associated with shorter duration of breastfeeding (single study). No adverse effect on breastfeeding reported when placed 6 weeks postpartum or later
<b>Estrogen-containing combined hormonal options</b>			
• COC pills, daily • Estrogen-containing vaginal ring (NuvaRing), monthly • Estrogen-containing transdermal patch (Ortho-Evra), weekly	• Options can be self-administered • Regular menstrual cycles (extended cycle options have more breakthrough bleeding) • Noncontraceptive benefits: decreased bleeding, less anemia, improved acne, improved dysmenorrhea	• Potential for user failure (especially with COCs) • Increased risk of blood clots • Potential for drug interactions • Multiple medical contraindications	• Ideally avoid until lactation/ milk supply well established • Potential for adverse effect on milk supply. Risk appears more pronounced with higher estrogen levels than used in contemporary products • If used by a breastfeeding mother, begin lowest possible dose as late as possible into well-established breastfeeding
<b>Emergency contraceptives</b>			
• Combined estrogen/progestin pills (Preven, Yuzpe method) • Progestin-only pills—LNG (Plan B) • Mifepristone • Ulipristal • Copper IUD	• Most effective within 72 hours of exposure • LNG options appear to have superior efficacy to COC with fewer side effects • Copper IUD most effective and provides continued contraception • Mifepristone similar or superior to LNG in efficacy	• Estrogen-containing options cause nausea/vomiting and often require use of antiemetics • No data for ulipristal in lactation currently available • Limited data on mifepristone in lactation	• LNG preferred over estrogen-containing options in breastfeeding mothers owing to previously described concerns related to estrogen and milk supply

COC, Combined oral contraceptive; DMPA, depo-medroxyprogesterone acetate; IUD, intrauterine device; LNG, levonorgestrel.

<sup>a</sup>Conclusive research regarding the clinical implications of progestin contraceptive administration in the early postpartum period is contradictory and insufficient.

## Natural Family Planning

Four methods of "fertility awareness" natural family planning include the Billings ovulation method (OM), the Creighton model system, the symptothermal method, and the Marquette method. Each of these methods can be used even when a woman's menses has not yet returned because of breastfeeding. These methods rely on observation of various combinations of cervical mucus, temperature, and/or hormonal monitoring, and then couples abstain during fertile periods. All of these methods have specific protocols for women to use during the postpartum period so they may plan accordingly if they wish to delay another pregnancy. The Marquette model has a recent peer-reviewed study to show the efficacy of its postpartum protocol.<sup>3</sup>

These methods may require significant periods of abstinence. Research on the use of the Billings OM during the postpartum period found that those who were using OM and were breastfeeding had a lower pregnancy rate than those using OM but not breastfeeding. The rate of unplanned pregnancy was less than 1% during the first 6 months of lactational amenorrhea. However, OM-associated pregnancy rates were elevated among breastfeeders after menses returned (36% vs. 13% for nonlactating women) and when infant feeding supplementation was started. This increase in unplanned pregnancies was not directly attributable to OM nonadherence. Special emphasis on both the need for improved breastfeeding support to delay menses return and the increased potential for method failure among new users during this period of time should be incorporated into OM training and support programs.<sup>29</sup>

## HORMONAL CONTRACEPTIVE METHOD: GENERAL COMMENTS

Controversy exists in the literature regarding hormonal contraceptive effects on milk supply. Although Koetsawang<sup>24</sup> reported an increase, Tankeyoon et al.<sup>40</sup> noted a 12% decline in milk supply with progestin-only contraception compared with placebo. Other studies have not found an effect. A recent study quantified the effect of hormonal contraception on infant's milk ingestion between days 42 and 63 using deuterium as a marker.<sup>2</sup> Forty women who had previously breastfed began contraception at 42 days postpartum with an estrogen-containing pill (150 mcg of levonorgestrel [LNG] and 30 mcg of ethinyl estradiol), the LNG-IUD (Mirena, Bayer Pharmaceuticals, Leverkusen, Germany), the etonogestrel implant (Implanon; Merck & Co., Whitehouse

Station, NJ), or the copper-containing IUD (ParaGard; Teva Women's Health Inc., North Wales, PA). No difference in the infants' milk intake was noted among groups in this study. A Cochrane Review indicated that evidence from randomized controlled trials on the effect of hormonal contraceptives during lactation is limited and of poor quality: "The evidence is inadequate to make evidence-based recommendations regarding hormonal contraceptive use for lactating women."<sup>45</sup> Until better evidence exists, it is prudent to advise women that hormonal contraceptive methods may decrease milk supply especially in the early postpartum period. Hormonal methods should be discouraged in some circumstances (III):

1. Existing low milk supply or history of lactation failure
2. History of breast surgery
3. Multiple birth (twins, triplets)
4. Preterm birth
5. Compromised health of mother and/or baby

## HORMONAL CONTRACEPTIVE METHOD: PROGESTIN-ONLY OPTIONS

There is theoretical concern related to milk supply when progesterone options are initiated in the initial 48 hours after delivery<sup>23</sup> as a drop in progesterone levels after birth is necessary for secretory differentiation/lactogenesis II to occur. Progestin-containing contraceptives include the progestogen-only pill ("minipill") as well as contraceptive implants such as Nexplanon (Merck & Co.), DepoProvera (depot medroxyprogesterone acetate [DMPA]; Pfizer, New York, NY), and the Mirena intrauterine system. A 2010 systematic review of the effects of progestin-only contraceptive options when initiated after the initial postpartum period found five randomized controlled trials and 38 observational trials addressing the topic.<sup>20</sup> No adverse effects on breastfeeding through 12 months of age, infant immunoglobulins, or infant sex hormones were noted. Research regarding the clinical implications of progestin contraceptive administration in the early postpartum period is contradictory.

Particularly controversial in clinical practice is the effect of DMPA. Prior studies of DMPA did not account for infant weight, milk supply, and the amount of supplement used. A systematic review of prospective studies on the effects of early postpartum DMPA use in lactating mothers by Brownell et al.<sup>5</sup> found all studies to be of low quality with inadequate control of confounders. Another study of low-income new mothers found that of the 31.3% who received DMPA, 62.6% received it prior to hospital discharge,<sup>10</sup> indicating that early

postpartum use is common in some settings. This study team quantified the association between postpartum DMPA and early breastfeeding cessation among 183 women and concluded that if there is a causal effect of DMPA on breastfeeding duration, it is minimal. A prospective case control study of 150 women receiving DMPA after initiation of lactation but prior to hospital discharge (days 2 to 10) compared with 100 women not receiving hormonal contraception followed up for 6 months found no difference in satisfaction with their breastfeeding experience or infant growth, although it is unclear how the breastfeeding patterns compared.<sup>39</sup>

A study by Brito et al.<sup>4</sup> compared either insertion of an etonogestrel-releasing implant within 1 to 2 days after delivery or DMPA given at 6 weeks postpartum. Forty women were then followed up through 12 weeks postpartum. Newborns of those in the implant group had a trend toward more weight gain in the first 6 weeks, but the overall duration of exclusive breastfeeding was not statistically different. Gurtcheff et al.<sup>30</sup> similarly studied early (1 to 3 days) versus delayed (4 to 8 weeks) insertion of the contraceptive implant. This noninferiority study found no difference in breastfeeding failure rates with early insertion compared with the delayed group.

## ESTROGEN-CONTAINING COMBINED HORMONAL OPTIONS

Estrogen-containing options include combination oral contraceptive (COC) pills (taken daily using monthly cyclic, extended cyclic, or continuous options), transdermal patch (weekly), or combined contraceptive vaginal rings (monthly). Estrogen-containing options are not ideal for early postpartum breastfeeding mothers because of the potential adverse impact on milk supply. The potential for estrogen to cause milk suppression is exemplified by the historical use of large estrogen doses immediately postpartum for lactation suppression prior to our understanding of the elevated thrombogenic risk during that time period. A Cochrane Review on methods of lactation suppression noted seven trials using four different estrogen preparations and found a significant reduction in lactation within 7 days postpartum; of note is that the doses and estrogen preparations used differ from those currently used in hormonal contraceptives.<sup>31</sup>

A 2010 systematic review on COCs and breastfeeding found only three randomized controlled trials and four observational studies; the three randomized controlled trials found a decreased mean breastfeeding duration in COC users and an

increased use of supplement.<sup>19</sup> No other documented adverse effects on infant health were noted.

If an estrogen-containing contraceptive is chosen, it is prudent to start the lowest estrogen-containing options as late as possible and after milk supply and lactation are well established. (III) Additionally, estrogen-containing options should not be initiated in the first few weeks postpartum because of the elevated risk of deep venous thrombosis and pulmonary embolism. Absolute and relative contraindications are otherwise the same for lactating women as for nonlactating women.

Contemporary COCs have estrogen doses ranging from 10 to 35 mcg daily. No significant difference in contraceptive efficacy has been found in a Cochrane Review of COCs containing <20 mcg of estrogen compared with those with >20 mcg.<sup>13</sup> This information should provide reassurance regarding anticipated efficacy when choosing lower estrogen dose options in a breastfeeding mother to minimize potential adverse effects.

## DIRECT COMPARISON OF PROGESTIN-ONLY PILLS AND COCs

A WHO task force study done in the 1980s found a 41.9% decrease in milk supply in women using COCs within 6 weeks of initiation.<sup>40</sup> However, a recent randomized controlled trial compared 63 women using a 35-mcg progestin-only pill (POP) with 64 women using a COC containing 35 mcg of ethynodiol diacetate from 2 through 8 weeks postpartum; the authors found no difference in continued breastfeeding at 8 weeks (63.5% POP vs. 64.1% COC).<sup>11</sup> Forty-four percent of those in the POP group stopped breastfeeding because of perceived insufficient milk supply compared with 55% in the COC group. Twenty-three percent of women who stopped their pills in the POP group and 21% in the COC groups reported that they did so because of a perceived negative impact on milk supply.

## EMERGENCY CONTRACEPTION

Emergency contraception is most effective when initiated within 72 hours after unprotected sexual intercourse, although it is still useful up to 120 hours. Postcoital copper IUD placement, mifepristone, COC, and progesterone options (LNG) are potentially available choices. Postcoital copper IUD placement would be unlikely to impact lactation (see section on IUDs) and has the advantage of providing continued contraception. LNG options are slightly more effective than the COC and also are less likely to cause significant nausea and vomiting.<sup>7</sup> Furthermore, in theory, LNG options would be less

likely to impact lactation. A pharmacologic study of 12 breastfeeding mothers found the estimated infant exposure to the maternal treatment of 1.5 mg of LNG was 1.6 mcg on the day of therapy.<sup>12</sup> A single observational study comparing progestin-only with estrogen-containing options for postcoital contraception found that an adverse effect on breastfeeding was uncommon and similar in both groups.<sup>35</sup> Based on similar efficacy, less propensity to nausea, and the absence of exposure to estrogen, it appears that the use of LNG is likely the preferred option over a COC in a breastfeeding mother. There are limited data on mifepristone and ulipristal in lactation. The use of postcoital mifepristone (an antiprogestrone) is similar to or superior in efficacy to LNG depending on dosage. Based on a small study, mifepristone transfers into milk in low levels (relative infant doses 1.5%) and would not be anticipated to have adverse effects on the breastfeeding infant.<sup>38</sup> Ulipristal is a selective progesterone receptor modulator. There are currently no data available on its use in breastfeeding mothers.

Postcoital contraception has also been evaluated as a backup to lactational amenorrhea. Although this may not be a practical option, one study found a lower pregnancy rate for the group that was provided with a postcoital contraceptive during counseling regarding lactational amenorrhea at the postpartum visit.<sup>37</sup>

## BARRIER METHODS

There are no known adverse effects on lactation with the use of barrier methods of contraception. Patients should be counseled regarding the reduced efficacy of these methods compared with other hormonal, intrauterine, or permanent options.

## IUDS

The IUD is one of the most frequently used contraceptives in the world. Prevalence rates range from 6% in the United States and in other countries up to 80% of contraceptive users.<sup>18,41</sup> Hormonal and nonhormonal IUDs are available and have different side effect profiles.

Progestin-releasing IUDs are associated with reduced menstrual blood flow, although around the time of insertion, women frequently experience irregular bleeding. This side effect is most pronounced during the initial 6 months and typically improves with time. Other progestin-related side effects are also possible. The copper IUD is associated with increased dysmenorrhea and menorrhagia.

In a study comparing breastfeeding outcomes in women randomized to receive a copper or progestin IUD at 6 to 8 weeks postpartum, the authors found

no difference in full breastfeeding duration, infant growth, or development through 1 year postpartum.<sup>38</sup> However, in a secondary analysis of a randomized controlled trial comparing women who had an LNG-IUD placed immediately postpartum versus 6 to 8 weeks postpartum, early LNG-IUD placement was associated with lower breastfeeding rates;<sup>6</sup> in the delayed placement group, four women received DMPA prior to their 6-week visit. Studies of the copper-containing IUD have found no change in milk or serum copper levels.<sup>36</sup>

Complications related to the device itself include uterine perforation, failure (pregnancy), inability to visualize strings, vaginal discharge, infection, pain, the partner feeling the strings, malpositioning (which may require a surgical procedure to remove the IUD), and expulsion (2% to 10% within the first year). Data do suggest that there is an increased risk of perforation when either IUD is inserted in breastfeeding women.<sup>16</sup> A recent systematic review suggested that IUDs remain a long-acting reversible contraceptive option for breastfeeding women with cesarean birth.<sup>14</sup>

## IRREVERSIBLE OPTIONS (STERILIZATION)

Multiple methods of surgical sterilization are available, including male vasectomy, postpartum tubal ligation, laparoscopic tubal ligation, and hysteroscopic tubal occlusion. These procedures involve different technologies, surgical techniques, anesthesia, and procedural settings.

Important considerations for breastfeeding dyads include the potential to impact early maternal-infant interaction. Ideally, procedures should not be performed during the initial hours postpartum to allow skin-to-skin contact between the mother and infant and initiation of breastfeeding. Early maternal-infant contact should not, however, prevent breastfeeding mothers from undergoing postpartum tubal ligation. To minimize disruption, the infant should be kept skin-to-skin with the mother in the preoperative area and be reunited with her as soon as the mother is awake and alert in the recovery room. This interruption should be managed in a breastfeeding-supportive way, and the provider should remain cognizant of the implications of anesthesia and analgesia on the breastfeeding dyad.<sup>30</sup>

Unfortunately, women who do not have the postpartum tubal sterilization procedure performed during their maternity stay are at risk for ultimately not having the procedure performed and subsequent pregnancy.<sup>8,48,44</sup> This risk should be considered. Such considerations may warrant early maternal-infant separation for the procedure to be completed prior to discharge.

## The Medical Eligibility Criteria

Criteria provide guidance on the level of safety of contraception in relation to specific medical conditions and other demographic variables. Risks are divided into four categories as outlined in **Table J-16**, although the categories are sometimes divided into two categories: generally use and generally do not use. The current recommendations from WHO and the Centers for Disease Control and Prevention (CDC) differ. **Table J-17** shows

TABLE J-16 Medical Eligibility Criteria		
WHO Category	With Clinical Judgment	With Limited Clinical Judgment
1	Use the method in any circumstances	Use the method
2	Generally use the method	Use the method
3	Use of the method not usually recommended unless other, more appropriate methods are not available or acceptable	Do not use the method
4	Method not to be used	Do not use the method

Where a doctor or nurse is not available to make clinical judgments, the four categories can be simplified into a two-category system (third column) by combining World Health Organization (WHO) Categories 1 with 2 and 3 with 4.

TABLE J-17 World Health Organization and Centers for Disease Control and Prevention Medical Eligibility Categories		WHO		CDC	
		Timing Postpartum	MEC Level	Timing Postpartum	MEC Level
Combined oral contraceptive	0-6 weeks	4	<1 month	3	
	6 weeks to 6 months	3	≥1 month	2	
	>6 months	2			
Progestin-only contraceptive (oral and implants)	0-6 weeks	3	<1 month	2	
	6 weeks to 6 months	1	≥1 month	1	
	>6 months	1			
LNG-IUD	<48 h	3	<10 min	2	
	48 h to 4 weeks	3	10 min to <4 weeks	2	
	>4 weeks	1	≥4 weeks	1	
Cu-IUD	<48 h	1	<10 minutes	1	
	48 h to 4 weeks	3	10 min to <4 weeks	2	
	>4 weeks	1	≥4 weeks	1	

IUD, Intrauterine device; LNG, levonorgestrel.

Adapted from the World Health Organization (WHO) Medical Eligibility Criteria (MEC) and the Centers for Disease Control and Prevention (CDC) Summary Chart of U.S. Medical Eligibility Criteria for Contraceptive Use Updated June 2012 ([www.cdc.gov/reproductivehealth/unintendedpregnancy/USMEC.htm](http://www.cdc.gov/reproductivehealth/unintendedpregnancy/USMEC.htm)). See Table 3 for MEC categories.

the categories for the use of several methods during lactation as presented by WHO and revised by CDC. CDC recently revised recommendations to include reducing the postpartum period from 6 weeks to 4 weeks and no longer contraindicating immediate postpartum use of progestin-only contraception.

There are limited data from well-conducted scientific studies that adequately take into consideration the effect on the infant of exclusive breastfeeding, especially in the immediate postpartum period when the establishment of lactation and adequate milk production is essential. (III) Moreover, exclusively breastfeeding women are very unlikely to become pregnant in the first 6 weeks after birth as described above. In this setting, hormonal contraception has minimal benefit, and early initiation may derail a woman's exclusive breastfeeding intentions. Unless the risk of unplanned pregnancy or loss to follow-up is high, early initiation of hormonal contraception in breastfeeding women is not recommended.

## Future Research

There is need for more detailed prospective research regarding the impact of all hormonal contraception on breastfeeding and on the potential long-term impact on the infant due to exposure to exogenous hormones. Such information will enable women to make informed decisions regarding the risk of unplanned pregnancy versus the risks of disrupted breastfeeding. Prior research has often

not adequately accounted for maternal breastfeeding goals, the importance of breastfeeding exclusivity, and amount of supplement used. Until research has addressed these concerns and focused on women's intentions to exclusively breastfeed, it is not possible to exclude adverse potential effects on milk supply, on long-term breastfeeding success, or on the infant, especially if any of these is a rare occurrence. This is particularly true when initiating hormonal contraception in the initial postpartum period. Research is needed to evaluate the impact of contemporary contraceptive options, which include lower estrogen doses and progestin-only agents, on both breastfeeding in the short term and on the infant in the long term. Further research is also needed on the effectiveness of LAM given the widespread availability of breast pumps and the growing number of mothers who are choosing to exclusively express and feed their infants expressed breastmilk. In sum, rare or long-term adverse outcomes are often not detected, and method efficacy has not been evaluated under a wide variety of conditions. Both of these issues demand study of large populations over time. For the individual breastfeeding family, this lack of sufficient data regarding the impact of hormonal contraception may have significant negative consequences.

## Conclusions

Every woman should be offered full information and support about contraception options so she can make an optimal decision for her individual situation. Physicians and other health care providers should not "pre-decide" which method is most appropriate; rather, in discussion with the patient, clinicians should discuss the risks, benefits, availability, and affordability of all methods. This discussion should address contraceptive efficacy and possible impact on breastfeeding outcomes, within the context of each woman's desire to breastfeed, risk of breastfeeding difficulties, and risk of unplanned pregnancy.

## APPENDIX J

# *Protocol 14: Breastfeeding-Friendly Physician's Office, Part 1: Optimizing Care for Infants and Children*

---

## *Definitions*

---

*Breastfeeding-friendly physician's office:* A physician's practice that enthusiastically promotes, supports, and protects breastfeeding through a warm office environment and education of health care professionals and families.

*Breastmilk substitutes:* Infant formula, glucose water.

## *Background*

---

Prenatal intention to breastfeed is influenced to a great extent by health care providers' opinion and support.<sup>4,17</sup> Ongoing parental support through in-person visits and phone contacts with health care providers results in increased breastfeeding duration.<sup>24</sup> Pediatric health care providers are in a unique position to contribute to the initial and ongoing support of the breastfeeding dyad.<sup>21,5</sup> Practices that employ a health care professional trained in lactation have significantly higher breastfeeding initiation and maintenance rates, with mothers experiencing fewer problems related to breastfeeding.<sup>16,15</sup> The World Health Organization's Baby Friendly Hospital Initiative describes Ten Steps for Successful Breastfeeding.<sup>23</sup> These 10 steps are based on scientific evidence and the experience of respected authorities. The scientific

basis of many of these recommendations can be extended to outpatient pediatric practices.<sup>5,20</sup> Initiating incremental changes to improving breastfeeding support is of value because there is a dose-response relationship between the number of steps achieved and breastfeeding outcomes.<sup>6</sup>

## *Recommendations*

---

1. Establish a written breastfeeding-friendly office policy.<sup>23</sup> Collaborate with colleagues and office staff during development. Inform all new staff about policy. Provide copies of your practice's policy to hospitals and physicians covering for you.
2. Encourage breastfeeding mothers to feed newborns only breastmilk and avoid offering supplemental formula or glucose water unless medically indicated.<sup>2</sup> Instruct mother to not offer bottles or a pacifier until breastfeeding is well established.<sup>13</sup>
3. Offer culturally and ethnically competent care.<sup>2</sup> Understand that families may follow cultural practices regarding infant colostrum consumption and maternal diet during lactation. Provide access to a multilingual staff, translators, and ethnically diverse educational material.

4. Offer a prenatal visit and show your commitment to breastfeeding during this visit.<sup>19</sup> If providing antenatal care to the mother, broach the subject of infant feeding in the first trimester and continue to express your support of breastfeeding throughout the course of the pregnancy. Inquire about a feeding plan and previous breastfeeding experience. Provide educational material that highlights the many ways in which breastfeeding is superior to formula feeding. Direct education and educational material to all family members involved in child care (father, grandparents, etc.).<sup>4,2,14</sup> Encourage attendance of both parents at prenatal breastfeeding classes before parents decide about the feeding plan. Identify patients with lactation risk factors (e.g., flat or inverted nipples, history of breast surgery, no increase in breast size during pregnancy, previous unsuccessful breastfeeding experience).
5. Collaborate with local hospitals and maternity care professionals in the community.<sup>2</sup> Convey to delivery rooms and newborn units your office policies on breastfeeding initiation. Leave orders in the hospital not to give formula/sterile water/glucose water to the baby without orders and not to dispense commercial discharge bags containing infant formula and/or feeding bottles to mothers.<sup>7,22</sup> Show support for breastfeeding during hospital rounds. Facilitate breastfeeding within 1 hour of an infant's birth. Help mothers initiate and continue breastfeeding. Counsel mothers to follow the infant's hunger and satiety cues and ensure that the infant breastfeeds 8 to 12 times in 24 hours. Encourage rooming-in and breastfeeding on demand.
6. Schedule a first follow-up visit for the infant 48 to 72 hours after hospital discharge<sup>1</sup> or earlier if there are breastfeeding-related problems, such as excessive weight loss (>7%) or jaundice present at the time of hospital discharge.<sup>2,19,1</sup> Ensure access to a lactation consultant/educator or other health care professional trained to address breastfeeding questions or concerns during this visit. Provide comfortable seating and a nursing pillow for the breastfeeding dyad to facilitate adequate evaluation. Assess latch and successful and adequate breastfeeding at the early follow-up visit. Identify lactation risk factors and assess the infant's weight, hydration, jaundice, feeding activity, and output. Provide medical help for women with sore nipples or other maternal health problems that impact breastfeeding. Begin by asking parents open-ended questions and then focus on their concerns. Take the time to address the many questions that a mother may have, especially if it is her first nursing experience. Provide close follow-up until the infant is doing well with adequate weight gain and parents feel confident.
7. Ensure availability of appropriate educational resources for parents. Educational material should not be commercial and not advertise breastmilk substitutes, bottles, or nipples.<sup>12</sup> Educational resources may be in the form of handouts, visual aids, books, and videos. Recommended topics for educational material are growth patterns, feeding, and sleep patterns of breastfed babies; management of growth spurts; recognition of hunger and satiety cues; latch-on and positioning; management of sore nipples; mastitis; low supply; blocked ducts; engorgement; reflux; normal stooling and voiding patterns; maintaining lactation when separated from the infant (e.g., during illness, prematurity, return to work); postpartum depression; maternal medication use; and maternal illness during breastfeeding.
8. Do not interrupt or discourage breastfeeding in the office. Allow and encourage breastfeeding in the waiting room. Display signs in the waiting area encouraging mothers to breastfeed. Provide a comfortable private area to breastfeed for those mothers who prefer privacy.<sup>19</sup>
9. Ensure an office environment that demonstrates breastfeeding promotion and support. Eliminate the practice of distribution of free formula and baby items from formula companies to parents.<sup>12</sup> Store formula supplies out of view of parents. Display posters, pamphlets, pictures, and photographs of breastfeeding mothers in your office.<sup>19</sup> Do not display images of infants bottle feeding. Do not accept gifts (including writing pads, pens, or calendars) or personal samples from companies manufacturing infant formula, feeding bottles, or pacifiers. Specifically target material to populations with low breastfeeding rates.
10. Develop and follow telephone triage protocols to address breastfeeding concerns and problems.<sup>19</sup> Conduct follow-up phone calls to assist breastfeeding mothers. Provide readily accessible resources such as books and protocols to triage nurses.
11. Commend breastfeeding mothers during each visit for choosing and continuing breastfeeding. Provide breastfeeding anticipatory guidance in routine periodic health maintenance

<sup>1</sup>In cultures or medical situations in which the dyad has remained hospitalized for long enough that weight gain and parental confidence are established prior to hospital discharge, follow-up may be deferred until the initial well child care visit at 1 to 2 weeks of age if otherwise appropriate.

- visits. Encourage fathers of infants to accompany mother and baby to office visits.<sup>14,25</sup>
12. Encourage mothers to exclusively breastfeed for 6 months and continue breastfeeding with complementary foods until at least 24 months and thereafter as long as mutually desired.<sup>26</sup> Discuss introduction of solid food at 6 months of age, emphasizing the need for high-iron solids, and assess the need for vitamin D supplementation.<sup>2</sup>
  13. Set an example for your patients and community. Have a written breastfeeding policy and provide a lactation room with supplies for your employees who breastfeed or express breast-milk at work.
  14. Acquire or maintain a list of community resources (e.g., breast pump rental locations) and be knowledgeable about referral procedures. Refer expectant and new parents to community support and resource groups. Identify local breastfeeding specialists, know their background and training, and develop working relationships for additional assistance. Support local breastfeeding support groups.<sup>9</sup>
  15. Work with insurance companies to encourage coverage of breast pump costs and lactation support services.<sup>2</sup> Bill lactation support codes.<sup>3</sup>
  16. Encourage community employers and day care providers to support breastfeeding.<sup>2,18</sup>
- The following website provides material to help motivate and guide employers in providing lactation support in the workplace<sup>10</sup>: [http://www.hmhbwa.org/forprof/materials/BCW\\_packet.htm](http://www.hmhbwa.org/forprof/materials/BCW_packet.htm).
17. All clinical physicians should receive education regarding breastfeeding.<sup>19,8</sup> Areas of suggested education include the benefits of breastfeeding, physiology of lactation, management of common breastfeeding problems, and medical contraindications to breastfeeding. Make educational resources available for quick reference by health care professionals in your practice (books, protocols, etc.). Staff education and training should be provided to the front office staff, nurses, and medical assistants. Identify one or more breastfeeding resource personnel on staff. Consider employing a lactation consultant or nurse trained in lactation.<sup>16,15</sup>
  18. Volunteer to let medical students and residents rotate in your practice. Participate in medical student and resident physician education.<sup>8,11</sup> Encourage establishment of formal training programs in lactation for future and current health care providers.<sup>2</sup>
  19. Track breastfeeding initiation and duration rates in your practice and learn about breastfeeding rates in your community.

## Recommendations for Future Research

---

1. There are currently no studies demonstrating the effectiveness of specific educational interventions related to breastfeeding (e.g., distribution of handouts, counseling by the primary care provider, group counseling, counseling by nurse) during pediatric preventative care visits.
2. More studies are needed about specific office practices and their effects on breastfeeding initiation, exclusivity, and maintenance.
3. More studies on the short- and long-term effectiveness of educational programs for physicians would be helpful.
4. Research on specific challenges to providing support in the outpatient setting is needed.
5. Studies regarding the cost-effectiveness of steps related to making an outpatient practice breastfeeding-friendly are needed.

## Acknowledgment

---

This work was supported in part by a grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

## APPENDIX J

# *Protocol 15: Analgesia and Anesthesia for the Breastfeeding Mother*

Anne Montgomery, Thomas W. Hale, and the Academy of Breastfeeding Medicine Protocol Committee

### *Purpose*

Labor, birth, and breastfeeding initiation comprise a normal, continuous process. Oxytocin, endorphins, and adrenaline produced in response to the normal pain of labor may play significant roles in maternal and neonatal response to birth and early breastfeeding.<sup>23</sup> Use of pharmacologic agents for pain relief in labor and postpartum may improve outcomes by relieving suffering during labor and allowing mothers to recover from birth, especially cesarean birth, with minimal interference from pain. However, these methods also may affect the course of labor and the neurobehavioral state of the neonate and have adverse effects on breastfeeding initiation. Unfortunately, the literature in this area has not addressed the whole integrated process. Very few studies directly address breastfeeding outcomes of various approaches to labor pain management. Randomized controlled trials are rare and subject to a great deal of crossover, which confounds results. The technology of epidural analgesia in particular is evolving quickly, so studies that are even a few years old may not reflect current practices. This protocol examines the evidence currently available and makes recommendations for prudent practice.

There is even less information in the scientific literature about anesthesia for other surgery in breastfeeding mothers. Recommendations in this

area focus on pharmacologic properties of anesthetic agents and limited studies of milk levels and infant effects.

### *Analgesia and Anesthesia for Labor*

Maternity care providers should initiate an informed consent discussion for pain management in labor during the prenatal period before the onset of labor. Risk discussion should include what is known about the effects of various modalities on the progress of labor, risk of instrumented and cesarean delivery, effect on the newborn, and possible breastfeeding effects.

Unmedicated, spontaneous vaginal birth with immediate, uninterrupted skin-to-skin contact leads to the highest likelihood of baby-led breastfeeding initiation.<sup>35</sup> Longer labors, instrumented deliveries, cesarean section, and separation of mother and baby after birth may lead to higher risks of difficulty with breastfeeding initiation.<sup>32,41,31</sup> Labor pain management strategies may affect these labor outcomes and secondarily affect breastfeeding initiation in addition to any direct effects of the medications themselves.<sup>19</sup>

Women have differing levels of pain tolerance. Pain that exceeds a woman's ability to cope, or pain magnified by fear and anxiety, may produce

suffering in labor. Suffering in labor may lead to dysfunctional labors, poorer psychologic outcomes, and increased risk of postpartum depression, all of which may have a negative effect on breastfeeding.<sup>9</sup>

Continuous support in labor, ideally by a trained doula, reduces the need for pharmacologic pain management in labor, decreases instrumented delivery and cesarean section, and leads to improved breastfeeding outcomes both in the immediate postpartum period and several weeks after birth.<sup>18</sup>

Nonpharmacologic methods for pain management in labor such as hypnosis, psychoprophylaxis (e.g., Lamaze), intradermal or subcutaneous water injections for back pain, and so on, appear to be safe, have no known adverse neonatal effects, and may reduce the need for pharmacologic pain management. More study of breastfeeding outcomes is needed for these modalities.<sup>38,39</sup>

Evidence suggests that breastfeeding success is affected by the behavior of the newborn. Depressed or delayed suckling, which can be caused by medications given to mothers, can lead to delayed or suppressed lactogenesis and risk of excess infant weight loss.<sup>29,6</sup>

Intravenous opiates for labor may block the newborn's normal reflexes to seek the breast, root, and suckle within the first hour after birth.<sup>33,30</sup>

1. Shorter-acting opiates such as fentanyl are preferred. Remifentanil is potent and has rapid onset and offset but can be associated with a high incidence of maternal apnea, requiring increased monitoring. Its transfer in utero to the fetus is minimal.
2. Meperidine/pethidine generally should not be used except in small doses less than 1 hour before anticipated delivery because of greater incidence and duration of neonatal depression, cyanosis, and bradycardia.
3. Nalbuphine, butorphanol, and pentazocine may be used for patients with certain opioid allergies or at increased risk of difficult airway management or respiratory depression. However, these medications may interfere with fetal heart rate monitoring interpretation. Observe the mother and infant for psychotomimetic reactions (3%).
4. Multiple doses of intravenous analgesic and their timing of administration may lead to greater neonatal effects. For example, fentanyl administration within 1 hour of delivery or meperidine administration between 1 and 4 hours before delivery is associated with more profound neonatal effects.
5. When a mother has received intravenous narcotics for labor, mother and baby should be given more skin-to-skin time to encourage early breastfeeding.<sup>30</sup>

There is little evidence regarding the effects of epidural analgesia on breastfeeding and the available data are inconclusive. Early studies of epidural analgesia for labor showed neonatal neurobehavioral effects and labor effects that may have had a significant impact on breastfeeding. The few studies that have looked directly at breastfeeding outcomes have suggested poorer outcomes in women who had epidural analgesia.<sup>43,45,15,2</sup> These results must be interpreted with caution, however, as most of these studies have been problematic with poor control groups and much crossover between study groups. Furthermore, it is difficult to ascertain whether the effects were caused by the epidural per se, or epidural use was a marker for abnormal labor with adverse effects not directly attributable to the epidural. Epidural analgesia also may affect labor outcomes, for example, increasing instrumented delivery, which may secondarily affect breastfeeding outcomes.<sup>41,31</sup> One study has suggested that when epidural analgesia is commonplace in a hospital supportive of breastfeeding, longer-term breastfeeding outcomes are not adversely affected by epidural analgesia.<sup>13</sup> A recent randomized, double-blind study showed that epidural analgesia with fentanyl in low to moderate doses, along with bupivacaine, did not have any effect on breastfeeding outcomes compared to epidural analgesia using bupivacaine alone. Higher doses of fentanyl (>150 mg total dose) may have had a small negative effect on maternal perception of breastfeeding at 24 hours and breastfeeding continuation at 6 weeks.<sup>3</sup>

1. If epidural anesthesia is chosen, methods that minimize the dose of medication and minimize motor block should be used. Longer durations of epidural analgesia should be avoided if possible,<sup>36</sup> and administration should be delayed until necessary to minimize the effect on labor outcomes that may secondarily affect breastfeeding. Combined spinal-epidural analgesia and patient-controlled epidural analgesia may be preferable.
2. Infants lose more weight in the first postpartum days when labor medications are used.<sup>6</sup> Some of this weight loss may be a result of mothers receiving an intravenous (IV) fluid load for epidural analgesia. One report notes babies are slightly heavier on average and lose more weight in the first days postpartum when epidural analgesia is used.<sup>28</sup> In addition, the use of large volumes of intrapartum IV fluids has been associated with a decrease in plasma oncotic pressure,<sup>4</sup> which may then increase breast engorgement and interfere with subsequent milk production and/or transfer. Conservative use of fluids may mitigate this effect. Definitive studies of these

- interrelationships are needed to better assess first-week weight loss in individual newborns.
3. When epidural analgesia has been used for labor, particular care to provide mothers with good breastfeeding support and close follow-up after postpartum hospitalization should be taken.

There are minimal data concerning the pediatric effects of other labor anesthesia, including inhaled nitrous oxide, paracervical block, pudendal block, and local perineal anesthesia.<sup>27,40</sup> These modalities do not usually expose the infant to significant quantities of medication. In some situations, these may serve as alternatives to intravenous narcotics or epidural analgesia for labor. However, their use is limited by several factors, including lack of efficacy, technical difficulties, and a high rate of complications.

## Anesthesia for Cesarean Section

Regional anesthesia (epidural or intrathecal/spinal) is preferred over general anesthesia.<sup>22,21</sup> Separation of the mother and baby should be minimized and breastfeeding initiated as soon as feasible. In fact, the baby may go to the breast in the operating room during abdominal closure with assistance to support the infant on the mother's chest. If breastfeeding is initiated in the recovery room, there is the added advantage that the incision is often still under the influence of the anesthetic.

A mother may breastfeed postoperatively as soon as she is alert enough to hold the baby.

## Postpartum Anesthesia

### NONOPIOID ANALGESICS

Nonopioid analgesics generally should be the first choice for pain management in breastfeeding postpartum women as they do not impact maternal or infant alertness.

1. Acetaminophen and ibuprofen are safe and effective for analgesia in postpartum mothers.
2. Parenteral ketorolac may be used in mothers not subject to hemorrhage and with no history of gastritis, aspirin allergy, or renal insufficiency.
3. Diclofenac suppositories are available in some countries and commonly used for postpartum analgesia. Milk levels are extremely low.
4. COX-2 inhibitors such as celecoxib may have some theoretic advantages if maternal bleeding is a concern. This must be balanced with higher cost and possible cardiovascular risks, which should be minimal with short-term use in healthy young women.

Both pain and opioid analgesia can have a negative impact on breastfeeding outcomes; thus mothers should be encouraged to control their pain with the lowest medication dose that is fully effective. Opioid analgesia postpartum may affect babies' alertness and suckling vigor. However, when maternal pain is adequately treated, breastfeeding outcomes improve.<sup>16</sup> Especially after cesarean birth or severe perineal trauma requiring repair, mothers should be encouraged to adequately control their pain.

### INTRAVENOUS MEDICATIONS

1. Meperidine should be avoided because of reported neonatal sedation when given to breastfeeding mothers postpartum,<sup>48</sup> in addition to the concerns of cyanosis, bradycardia, and risk of apnea, which have been noted with intrapartum administration.<sup>14,17</sup>
2. The administration of moderate to low doses of IV or IM morphine is preferred as its passage to milk and oral bioavailability in the infant are least with this agent.<sup>48,8</sup>
3. When patient-controlled IV analgesia (PCA) is chosen after cesarean section, morphine or fentanyl is preferred to meperidine.<sup>47</sup>
4. Although there are no data on the transfer of nalbuphine, butorphanol, and pentazocine into milk, there have been numerous anecdotal reports of a psychotomimetic effect when these agents are used in labor. They may be suitable in individuals with certain opioid allergies or other conditions described in the preceding section on labor.<sup>47</sup>
5. Hydromorphone (approximately 7 to 11 times as potent as morphine), is sometimes used for extreme pain in a PCA, IM, IV, or orally. Following a 2-mg intranasal dose, levels in milk were quite low, with a relative infant dose of about 0.67%.<sup>7</sup> This correlates with about 2.2 mg/day via milk. This dose is probably too low to affect a breastfeeding infant, but this is a strong opioid and some caution is recommended.

### ORAL MEDICATIONS

1. Hydrocodone and codeine have been used worldwide in millions of breastfeeding mothers. This suggests they are suitable choices even though there are no data reporting their transfer into milk. Higher doses (10 mg hydrocodone) and frequent use may lead to some sedation in the infant.

## EPIDURAL/SPINAL MEDICATIONS

- Single-dose opioid medications (e.g., neuraxial morphine) should have minimal effects on breastfeeding because of the negligible maternal plasma levels achieved. Extremely low doses of morphine are effective.
- Continuous postcesarean epidural infusion may be an effective form of pain relief that minimizes opioid exposure. A randomized study that compared spinal anesthesia for elective cesarean with or without the use of postoperative extradural continuous bupivacaine found that the continuous group had lower pain scores and a higher volume of milk fed to their infants.<sup>16</sup>

## Anesthesia for Surgery in Breastfeeding Mothers

The implications of drugs used in anesthesia in postpartum mothers depends on numerous factors, including the age of the infant, stability of the infant, stage of lactation (early or late stage), and ability of the infant to handle the clearance of small quantities of anesthetic medications.<sup>11</sup> Anesthetic agents will have little or no effect on older infants but could cause problems in newborn infants, particularly those who are premature or suffer from apnea.

The ability of the infant to clear small amounts of these medications is of primary concern before returning to breastfeeding. Infants subject to apnea, hypotension, or weakness probably should be protected by a few more hours of interruption from breastfeeding before resuming (12 to 24 hours) nursing.

Mothers with normal term or older infants generally can resume breastfeeding as soon as they are awake, stable, and alert. Resumption of normal mentation is a hallmark that these medications have left the plasma compartment (and thus the milk compartment) and entered adipose and muscle tissue where they are slowly released. A single pumping and discarding of the mother's milk following surgery will significantly eliminate any drug retained in milk fat, although this is seldom necessary and not generally recommended. For women who undergo postpartum tubal ligation, breastfeeding interruption is not indicated, as the volume of colostrum is small.<sup>34</sup> In addition, the levels of medication in the maternal plasma and milk are low once mothers resume normal mentation. Regional anesthesia is recommended for this procedure in preference to general anesthetic for maternal safety.

Mothers who have undergone dental extractions or other procedures requiring the use of single doses of medication for sedation and analgesia can breastfeed as soon as they are awake and stable. Although shorter-acting agents such as fentanyl and midazolam may be preferred, single doses of meperidine or diazepam are unlikely to affect the breastfeeding infant.<sup>11</sup>

Mothers who have undergone plastic surgery, such as liposuction, in which large doses of local anesthetics (lidocaine) have been used probably should pump and discard their milk for 12 hours before resuming breastfeeding.

## Specific Agents Used for Anesthesia and Analgesia

### ANESTHETICS

Drugs used for induction such as propofol, midazolam, etomidate, or thiopental enter the milk compartment only minimally, as they have extraordinarily brief plasma distribution phases (only minutes) and hence their transport to milk is low to nil.<sup>1,26,5,37</sup>

Little or nothing has been reported about the use of anesthetic gases in breastfeeding mothers. However, they too have brief plasma distribution phases and milk levels are likely nil.

The use of ketamine in breastfeeding mothers is unreported. Because of its high rate of psychotomimetic effect, including hallucinations and dissociative anesthesia (catalepsy, nystagmus), ketamine is probably not an ideal anesthetic agent for breastfeeding mothers.

### ANALGESICS/OPIOID ANALGESICS

- Morphine is still considered an ideal analgesic for breastfeeding mothers because of its limited transport to milk and poor oral bioavailability in infants.<sup>48,47</sup>
- The transfer of meperidine into breast milk is documented, although it is somewhat low (1.7% to 3.5% of maternal dose). However, the administration of meperidine and its metabolite (normeperidine) is consistently associated with neonatal sedation, which is dose related. Transfer into milk and neonatal sedation have been documented for up to 36 hours after the dose.<sup>48</sup> Meperidine should be avoided during labor and in postpartum analgesia (except, perhaps, within 1 hour before delivery). Infants of mothers who have been exposed to repeated doses of meperidine should be closely monitored for sedation, cyanosis, bradycardia, and possibly seizures.

3. Although there are no published data on remifentanil, this esterase-metabolized opioid has a brief half-life even in infants ( $\leq 10$  minutes) and has been documented to produce no fetal sedation even in utero. Although its duration of action is limited, it could be used safely, and indeed may be ideal in breastfeeding mothers for short painful procedures.
4. Fentanyl levels in breast milk have been studied and are extremely low to below the limit of detection.<sup>24,25</sup>
5. Sufentanil transfer into milk has not been published, but it should be similar to fentanyl.
6. Nalbuphine, butorphanol, and pentazocine levels in breast milk have not been published. At this time they would only be indicated in the specific situations mentioned previously.<sup>47</sup> If these agents are used, observe the mother and infant for psychotomimetic reactions (3%).
7. Hydrocodone and codeine have been used in millions of breastfeeding mothers. Occasional cases of neonatal sedation have been documented, but these are rare and generally dose related. Doses in breastfeeding mothers should be kept at the minimum necessary to control pain. Routine, consistent dosing throughout the day may lead to sedative effects in the breastfed infant.

## NSAID ANALGESICS

1. Ibuprofen is considered an ideal, moderately effective analgesic. Its transfer to milk is low to nil.<sup>42,44</sup>
2. Ketorolac is considered an ideal and potent analgesic in breastfeeding mothers. The transfer of ketorolac into milk is extremely low.<sup>46</sup> However, its use in patients with hemorrhage is risky as it inhibits platelet function. Other contraindications are noted in the preceding section on postpartum anesthesia.<sup>47</sup>
3. Celecoxib transfer into milk is extraordinarily low ( $\leq 0.3\%$  of the maternal dose).<sup>12</sup> Its short-term use is safe.
4. Naproxen transfer into milk is low, but gastrointestinal disturbances have been reported in some infants after prolonged therapy. Short-term use (1 week) probably is safe.<sup>10,20</sup>

## Recommendations for Future Research

Studies of labor analgesia and labor anesthesia should specifically study breastfeeding outcomes.

Specific data are needed about the use of intravenous fluid loading during labor, such as for

epidural anesthesia, and its effects on infant birth weight, breast engorgement, milk supply, and neonatal weight loss to more appropriately assess early infant feeding and weight loss in these babies.

More study is required of the special needs of premature and unstable babies, including how their ability to clear maternal anesthetic and analgesic drugs may differ from healthy term babies.

## Acknowledgment

This work was supported in part by a grant from the Maternal and Child Health Bureau, U.S. Department of Health and Human Services.

## APPENDIX J

# *Protocol 16: Breastfeeding the Hypotonic Infant*

### *Goal*

To promote, support, and sustain breastfeeding in children with hypotonia.

### *Definition*

Hypotonia, a condition of diminished muscle tone, is also referred to as "floppy infant syndrome" and may occur with or without muscle weakness. There are diverse etiologies including abnormalities of the central or peripheral nervous system, neuromuscular junction, or muscle; metabolic, endocrine, or nutritional disorders; connective tissue diseases; and chromosomal abnormalities. Perinatal hypoxia, hypotonic cerebral palsy, and nonspecific mental deficiency may all result in central hypotonia. There is also a condition referred to as benign congenital hypotonia, which is a diagnosis of exclusion, and improves or disappears entirely with age.<sup>33</sup> Preterm infants as well will have age-appropriate hypotonia. Hypotonic babies often have feeding problems that result from abnormal or underdeveloped control of the oropharyngeal structures, contributing to an uncoordinated and/or weak suck.

### *Background*

One of the more common causes of hypotonia, which we shall use as an example, is Down syndrome. Down syndrome is a genetic disorder caused by a trisomy of chromosome 21 resulting

in hypotonia in more than 90% of cases. Associated oral abnormalities characteristically include malocclusion and a small mouth with a relatively large, protruding tongue, which when coupled to the hypotonia, result in significant associated feeding difficulties in some, but not all, of these children.<sup>4</sup>

The Academy of Breastfeeding Medicine, American Academy of Pediatrics, World Health Organization, and other international organizations have recommended that all children should be breastfed, unless there is a medical contraindication.<sup>1</sup> It is particularly important that Down syndrome and other hypotonic children be breastfed to minimize the risk of morbidities associated with artificial feedings, many of which they are at increased risk from by virtue of their condition. For example, in addition to the oral abnormalities and malocclusion, children with Down syndrome have developmental delay; are more susceptible to ear, respiratory, and other infections; and have an increased incidence of other congenital anomalies such as heart and gastrointestinal malformations. In looking at the effects of breastfeeding on these problems in a healthy population, approximately 44% of dental malocclusion can be attributed to lack of or short duration of breastfeeding,<sup>17</sup> suggesting that breastfeeding promotes oral motor strength, a potential benefit to those children with Down syndrome and other causes of hypotonia.<sup>4</sup> Breastfeeding helps with normal mouth and tongue coordination. Breastfeeding has also been shown to be protective against the development of ear and respiratory infections.<sup>17,34,29,28,8</sup> Studies indicate that there is a positive neurocognitive advantage of breastfeeding,<sup>3,2,12,14</sup> which is most pronounced in

low birth weight and small for gestational age children<sup>38,27,32,2,37</sup> who may score as many as eight points higher on intelligence tests than their formula-fed counterparts. As hypotonic babies may have disorders associated with neurocognitive impairment, the benefit of human milk feedings could make an important difference to their long-term outcome. Children with congenital heart disease who breastfeed have better growth, shorter hospital stays, and higher oxygen saturations than children with congenital heart disease who are formula fed.<sup>20</sup> Again, this may suggest potential benefit to hypotonic infants with heart disease, seen in a significant proportion of babies with Down syndrome. Thus although children with Down syndrome and other forms of hypotonia have not been specifically studied, based on the wealth of information available from studies in the general population, they may be expected to benefit from breastfeeding and/or expressed breast milk.

Some mothers of children with Down syndrome express anxiety and fear at the time of their child's diagnosis. Many express feeling "helpless"<sup>36</sup> or frustrated that they were not able to breastfeed or felt as if they were not given support for breastfeeding.<sup>30</sup> The ability to breastfeed their babies may empower these mothers.

Challenges to breastfeeding the hypotonic child exist, but many can successfully feed at the breast. No evidence exists that Down syndrome or other hypotonic infants feed better with the bottle than at the breast.<sup>18</sup> Further, no evidence suggests that these children need to feed from a bottle before going to breast.<sup>2</sup> Breastfeeding should be actively promoted and supported in these infants.

Sucking behavior, specifically in Down syndrome, has been documented to be less efficient than in normal-term infants with multiple parameters affected, including sucking pressure, frequency, and duration, as well as a deficiency in the smooth peristaltic tongue movement.<sup>23</sup> When followed longitudinally over the first year, sucking pressure increased significantly by 4 months and again by 8 months. Frequency increased by 4 months. Duration did not increase over time, and peristalsis only normalized in the minority of infants who were restudied at 8 months. However, the overall result was improvement in sucking efficiency over the first year. Mothers tended to report that feeding problems were substantially improved by 3 to 4 months of age. Understanding this time frame allows practitioners to effectively support these mothers and babies to improve breastfeeding skills, and reach and maintain a sufficient milk supply that may enable them to ultimately successfully breastfeed, even with the presence of significant difficulties at the beginning.

## Procedures

---

### EDUCATION

1. All mothers should be educated about the benefits of breastfeeding for themselves and their infants. A significant percentage of hypotonic infants can feed at the breast without difficulty.
2. All babies should be followed closely both before and after discharge from the hospital for assessment of further needs.

### FACILITATION AND ASSESSMENT OF FEEDING AT THE BREAST IN THE IMMEDIATE POSTPARTUM PERIOD

1. The first feeding should be initiated as soon as the baby is stable. There is no reason this cannot occur as early as the delivery room if the baby is physiologically stable.
2. Kangaroo (skin-to-skin) care should be strongly encouraged. If the baby does not feed well, the touching may be stimulating, so that the baby is easier to arouse for feedings. Skin-to-skin care has also been shown to help increase mother's milk supply,<sup>13</sup> and it can assist with bonding, which may be especially important for these families.
3. Assess the baby's ability to latch, suck, and transfer milk. This assessment should involve personnel specifically trained in breastfeeding evaluation and management.
4. Skin-to-skin contact will facilitate frequent attempts at the breast. For those attempts, particular attention should be given to providing good head and body support as the baby needs to spend effort sucking, not supporting body position. Use of a sling or pillows to support the infant in a flexed position allows the mother to use her hands to support both her breast and the infant's jaw simultaneously.
5. The "dancer hand" position (see Figure 14-1) may be helpful to the mother to try because it supports both her breast and her baby's chin and jaw while the baby is nursing. This involves cupping her breast in the palm of her hand (holding her breast from below), with the third, fourth, and fifth fingers curling up towards the side of her breast to support it, while simultaneously allowing the baby's chin to rest on the web space between her thumb and index finger (see Figure 14-1). The thumb and index finger can then give gentle pressure to the masseter muscle, which stabilizes the jaw.<sup>21,7</sup> Additionally, pulling the jaw slightly forward may allow the infant to better grasp the breast and form a seal. The other hand is

- free to be used to support the baby's neck and shoulders.
6. Other strategies to help the infant latch and transfer milk may also be effective. Some mothers facilitate milk transfer with the technique of breastfeeding used in conjunction with hand compression. Instead of placing the thumb and index finger on the baby's jaw for support (dancer position), the fingers are kept proximal to the areola, and milk is hand expressed as the baby suckles. A thin silicon nipple shield may be useful, if production is generous ( $>500$  mL/day) and mothers learn how to keep the reservoir filled by synchronizing breastfeeding with hand compression or using a nursing supplementation device simultaneously inside the shield.<sup>24</sup> By making the mother aware of various techniques, aids, and ideas, she is empowered to experiment and discover the best repertoire to fit her and her baby's individual needs.
  7. The mother, and family who is supporting her, should be counseled that more time may be necessary in the early weeks to complete a feeding. They should also know that in many cases the baby's ability to feed will improve over the first weeks to months.
  8. Trained personnel must reassess the baby frequently (a minimum of once every 8 hours) because these babies must be considered high (breastfeeding) risk, similarly to the near-term baby (see ABM Protocol #10 Breastfeeding the Near-Term Baby).<sup>5</sup> Encourage frequent nursing throughout the day as the ability to sustain suck may be impaired. Infants should go to breast as often as possible, aiming for at least 8 to 12 times per 24 hours. Prolonged periods of skin-to-skin contact will facilitate these frequent attempts at the breast. Assessments should include state of hydration and jaundice as possible complications of poor intake.
  9. Once transitional milk is present, test weighing with an appropriate digital scale may be an option to judge adequate milk transfer. Infants are weighed immediately prior to the feed on an electronic scale with accuracy at minimum 0.5 g, and then reweighed immediately after the feed with the exact same diaper, clothing, blankets, and so on, worn during the prefeed weight. Intake during the feed is reflected by weight gain, 1 g = 1 mL. Term infants with Down syndrome gain weight more slowly than normal full-term infants,<sup>6</sup> so this must be taken into consideration during the early weeks and months. Growth charts specific for Down syndrome are found at <http://www.growthcharts.com/charts/DS/charts.htm> (last accessed 21 Jan. 2007).
  10. Consider alternative modes of feeding if the baby is unable to nurse at the breast or sustain adequate suckling, including the use of a cup,<sup>19</sup> a spoon, or a wide-based silicone bottle. The use of a nursing supplementation aid alone (without a nipple shield—Section B6) may not be as helpful, as it works best with a baby who has an effective latch, the lack of which is often one of the significant problems of hypotonic infants.
  11. If supplementation is necessary, please see Academy of Breastfeeding Medicine Protocol #3 (Hospital Guidelines for the Use of Supplementary Feedings in the Healthy Term Breastfed Infant).<sup>31</sup> If the baby is attempting to suckle, following each breastfeeding encounter with breast milk expression (see later), followed by spoon or cup feeding of the expressed milk to the baby, provides more stimulation to the breasts and more milk to the baby.

## PREVENTATIVE MEASURES TO PROTECT A MILK SUPPLY

1. If the infant is unable to successfully and fully breastfeed, or if the mother is separated from her infant (e.g., neonatal intensive care unit admission), lactation must be initiated and/or maintained through pumping or hand expression. Anticipating the initial difficulty a hypotonic infant will likely have with sustaining frequent and effective milk removal, insufficient milk production may be prevented by encouraging mothers to express milk shortly after delivery, ideally within 2 hours (certainly within the first 6 hours as is recommended with preterm mothers),<sup>11</sup> and approximately every 3 hours thereafter. Aim to remove milk at least eight times in a 24-hour period, mimicking the stimulation of a vigorous term breastfeeding baby. Even if the baby shows some ability to go to breast, latch, and transfer milk, the mother will likely need to express or pump extra milk in the early weeks in order to build and maintain her milk supply at the higher level. A plentiful milk supply will enhance letdown for these less vigorous babies, and facilitate their feeding effort.
2. Most of the research on initiating and maintaining milk supply by expressing milk has been done on mothers of preterm infants. The strongest determinant of duration and exclusivity of breastfeeding the preterm infant is the volume of milk produced by the pump-dependent mother, while insufficient milk production is the most common reason for cessation of efforts to provide milk for these infants.<sup>35,16,9</sup> As the baby begins to improve with milk transfer,

- developing rhythms, and showing feeding cues, pumping times can be led by these cues (i.e., breast emptying by expression after each attempt at the breast). This pattern should continue until the couplet is reunited and/or the infant is able to sustain successful breastfeeding. It is critical that mothers be instructed on effective pumping, including both the use of a hospital-grade electric pump if available and manual expression.
3. Extrapolating from preterm research for guidance in the hypotonic baby, the production of 500 mL/day is commonly cited as the minimum volume enabling premature babies <1500 g to transition from tube or bottle feeding to successful, exclusive breastfeeding.<sup>23</sup> Until studies are done in the hypotonic infant population, this is a minimum volume from which to start and can be adjusted based on calculations of intake necessary for growth.
  4. Simultaneous pumping of both breasts with a hospital-grade pump has been shown to be more effective than single pumping. Recent research suggests manually assisted pumping improves effective emptying and production in pump-dependent women. In contrast to the usual practice of passively depending on the pump to suction milk from the breast, manual techniques, used in conjunction with pumping, enable mothers to enhance emptying by using their hands for breast compression, massage, and expression.<sup>15</sup>
  5. A pumping/feeding diary or log to enable health care providers to track maternal milk supply and intervene when needed can consist simply of a piece of paper with columns for date, time started pumping, time ended pumping, amount of milk expressed, and comments (such as where pumped, unusual stressors, etc.), or one can be ordered or used as a model from various websites, including: <http://www.cpqcc.org/Documents/NutritionToolkit/NutritionToolkit.pdf>, appendix "O" (last accessed 21 Jan. 2007).

## AT DISCHARGE AND IN THE NEONATAL PERIOD

1. If the baby will remain hospitalized, the mother's milk supply should be assessed daily including pumping frequency, 24-hour milk total, and any signs of breast discomfort. Carefully monitor the baby's weight gain and consider supplementation as necessary.
2. Inform mothers that sucking efficiency frequently continues to improve over the first year, such that the breastfeeding experience may "normalize" and may not continue to require interventions initially necessary for their own

infant; for example, supplementation, pumping, more frequent nursing, and so forth.

3. Provide information about local support groups for breastfeeding and for specific diagnoses such as Down syndrome families. Support and encouragement are particularly important for these mothers and families with the additional patience and time that is sometimes required to breastfeed these infants.
4. Maternal milk supply is affected by ineffective or infrequent pumping/expressing. Although stress, fatigue, and pain are frequently cited as determinants of slow milk supply, recent evidence refutes this.<sup>10</sup> However, it is not unreasonable to encourage maternal rest and analgesics as needed. Review and optimize breast milk expression frequency, schedule, and type of pump used, if necessary. A pumping diary/log (see earlier) can be useful.
5. If maternal milk supply does not equal or exceed the infant's needs or begins to slow despite optimal pumping, the use of galactagogues to enhance maternal milk supply may be considered. Please see Academy of Breastfeeding Medicine Protocol #9 (Use of Galactagogues in Initiating or Augmenting Maternal Milk Supply).<sup>26</sup>
6. In the presence of significant cardiac, gastrointestinal, or renal complications, it is sometimes necessary to increase the caloric density of breastmilk with extra fat, carbohydrate, or protein. If the mother's milk supply is greater than the baby's needs, a trial of feeding hindmilk (higher fat content, therefore more fat calories), either by expressing some of the foremilk before putting the baby to breast or, if supplements are being used, by pumping off a small volume of milk first (foremilk) and then in a separate container pumping the rest of the milk present (hindmilk) and feeding the baby only the hindmilk.

## Further Research

This protocol was developed for the Academy of Breastfeeding Medicine to give clinicians guidance based on the expert opinion of practitioners who have worked extensively with this population. There is little scientific evidence upon which to base recommendations. Specific areas recommended for further research include:

1. Methods of optimizing the hypotonic infant's suck and milk transfer need further study.
2. Use of pacifiers in premature infants as "practice" oral feeding during gavage feeds has assisted with the transition to breast and merits evaluation in hypotonic infants.<sup>22</sup>

3. Comparison of autonomic stability between breast- and bottle-fed infants with Down syndrome or other etiologies of hypotonia may be helpful.
4. Evaluation of weight gain in breastfed versus formula-fed hypotonic infants, once breastfeeding has been established.
5. Evaluation of different methods available to supplement hypotonic babies (cup, bottle, spoon) to determine efficacy and best practice.
6. Modifiable factors that may compound or ameliorate the difficulties with breastfeeding in these infants in particular, for example, labor analgesia/anesthesia, skin-to-skin contact perinatally, and others.

## APPENDIX J

# Protocol 17: Guidelines for Breastfeeding Infants with Cleft Lip, Cleft Palate, or Cleft Lip and Palate

Sheena Reilly, Julie Reid, Jemma Skeat, Petrea Cahir, Christina Mei, Maya Bunik, and the Academy of Breastfeeding Medicine

When a cleft lip (CL) occurs, the lip is not contiguous, and when a cleft palate (CP) occurs, there is communication between the oral and nasal cavities.<sup>44</sup> Clefts can range in severity from a simple notch in the upper lip to a complete opening in the lip extending into the floor of the nasal cavity and involving the alveolus to the incisive foramen.<sup>43</sup> Similarly, CP may involve just the soft palate or extend partially or completely through the hard and soft palates.<sup>44</sup> In CP, the alveolus remains intact. A CP may be submucous and not immediately detected if there are subtle or no corresponding clinical signs or symptoms.<sup>44</sup>

## Background

### INCIDENCE

The worldwide prevalence of CL and/or CP (CL/P) ranges from 0.8 to 2.7 cases per 1000 live births.<sup>14</sup> There are differences in incidence rates across racial groups, with the lowest reported incidence among African-American populations (approximately 0.5 per 1000)<sup>15,33</sup> and white populations (approximately 1 per 1000 births)<sup>14</sup> and higher

incidence among Native American (approximately 3.5 per 1000)<sup>12</sup> and Asian (approximately 1.7 per 1000)<sup>51</sup> populations.

Although reports vary considerably, it is estimated that out of the total number of infants with CL/P, approximately 50% have combined cleft lip and palate (CLP), whereas 30% have isolated CP, and 20% have isolated CL; CL extending to include the alveolus occurs in approximately 5% of cases.<sup>32</sup> Clefts are usually unilateral (Figure J-4); however, in approximately 10% of cases, clefts are bilateral.<sup>49</sup>

### BREASTFEEDING AND CL/P

In these guidelines, *breastfeeding* refers to direct placement of the baby to the breast for feeding, and *breastmilk feeding* refers to delivery of breastmilk to the baby via bottle, cup, spoon, or any other means except the breast. Babies use both suction and compression to breastfeed successfully. The ability to generate suction is necessary for attachment to the breast, maintenance of a stable feeding position, and, together with the letdown reflex, milk extraction. Normally, when a baby is feeding, his or her lips flange firmly against the areola, sealing the oral cavity anteriorly.

**Figure J-4.** Unilateral cleft lip. Photo courtesy of John A. Giroto, MD.

The soft palate rises up and back to contact the pharyngeal walls and seal the oral cavity posteriorly. As the tongue and jaw drop during sucking, the oral cavity increases in size, and suction is generated, drawing milk from the breast.<sup>8</sup> Compression occurs when the baby presses the breast between the tongue and jaw. Suction and compression help milk transfer delivery during breastfeeding.<sup>8,47,40</sup>

There is a relationship between the amount of oral pressure generated during feeding and the size/type of cleft and maturity of the baby.<sup>41</sup> For this reason, babies with CL are more likely to breastfeed than those with CP and CLP.<sup>42</sup> Some babies with small clefts of the soft palate generate suction,<sup>28</sup> but others with larger clefts of the soft and/or hard palate may not generate suction.<sup>28,31</sup> Newborns and premature babies generate lower suction pressures compared with older babies.<sup>41,30,9</sup> Babies with CP or CLP have difficulty creating suction<sup>45</sup> because the oral cavity cannot be adequately separated from the nasal cavity during feeding. For these infants, negative consequences may include fatigue during breastfeeding, prolonged feeding times, and impaired growth and nutrition.

The literature describing breastfeeding outcomes is limited, and the evidence is anecdotal and contradictory, making the recommendations that follow challenging.<sup>39</sup>

## Recommendations

Quality of evidence (levels of evidence I, II-1, II-2, II-3, and III) for each recommendation, as defined in the U.S. Preventive Services Task Force Appendix A Task Force Ratings,<sup>46</sup> is noted in parentheses.

## Summary of Recommendations for Clinical Practice

Based on the reviewed evidence, the following recommendations are made:

1. Mothers should be encouraged to provide the protective benefits of breastmilk. Evidence suggests that breastfeeding protects against otitis media, which is highly prevalent in this population<sup>2,21</sup> (II-2). Breastmilk feeding (via cup, spoon, bottle, etc.) should be promoted in preference to artificial milk feeding. Additionally, there is speculative information regarding possible benefits of breastfeeding versus bottle feeding on the development of the oral cavity.
2. At the same time, mothers should be counseled about likely breastfeeding success. Where direct breastfeeding is unlikely to be the sole feeding method, the need for breastmilk feeding should be encouraged, and, when appropriate, possible delayed transitioning to breastfeeding should be discussed.
3. Babies with CL/P should be evaluated for breastfeeding on an individual basis. In particular, it is important to take into account the size and location of the baby's CL/P as well as the mother's wishes and previous experience with breastfeeding. There is moderate evidence to suggest that infants with CL are able to generate suction<sup>45</sup> (III), and descriptive reports suggest that these infants are often able to breastfeed successfully<sup>18</sup> (III). There is moderate evidence that infants with CP or CLP have difficulty generating suction<sup>28</sup> (I) and have inefficient sucking patterns<sup>31</sup> (I) compared with normal infants. The success rates for breastfeeding infants with CP or CLP are observed to be lower than for infants with CL or no cleft<sup>42,18</sup> (III) ([Appendix J, Protocol 3](#)).
4. As in normal breastfeeding, knowledgeable support is important. Mothers who wish to breastfeed should be given immediate access to a lactation specialist to assist with positioning, management of milk supply, and expressing milk for supplemental feeds. Several studies have suggested that there is a need for and benefit from having access to a health professional who specializes in CL/P, such as a clinical nurse specialist, during the newborn/infant periods for specialized advice on feeding a baby with CL/P as well as referrals to appropriate services.<sup>10</sup> Surveys of parents with a child with CL, CLP, or CP indicated a desire

- for more instruction on feeding challenges as early as possible<sup>34</sup> (III).
5. Families may benefit from peer support around breastmilk feeding or breastfeeding found through associations like Wild Smile<sup>48</sup> in addition to routine referral to breastfeeding support groups.
  6. Monitoring of a baby's hydration and weight gain is important while a feeding method is being established. If inadequate, supplemental feeding should be implemented or increased. (See "ABM clinical protocol #3: Hospital guidelines for the use of supplementary feedings in the healthy term breastfed neonate, revised 2009."<sup>11</sup>) Infants with CL/P may require supplemental feeds for adequate growth and nutrition<sup>18</sup> (III). There is one study that demonstrated that additional maternal support by a clinical nurse specialist can both improve weight gain outcomes and also facilitate referral to appropriate services<sup>5</sup> (III).
  7. Modification to breastfeeding positions may increase the efficiency and effectiveness of breastfeeding. Positioning recommendations that have been made on the basis of weak evidence (clinical experience or expert opinion) and that should be evaluated for success are:
    - a. For infants with CL:
      - i. The infant should be held so that the CL is oriented toward the top of the breast<sup>16,7</sup> (for example, an infant with a [right] CL may feed more efficiently in a cross-cradle position at the right breast and a football/twin style position at the left breast) (III).
      - ii. The mother may occlude the CL with her thumb or finger<sup>7,24</sup> and/or support the infant's cheeks to decrease the width of the cleft and increase closure around the nipple<sup>4</sup> (III).
      - iii. For bilateral CL, a "face on" straddle position may be more effective than other breastfeeding positions<sup>7</sup> (III).
    - b. For infants with CP or CLP:
      - i. Positioning should be semiupright to reduce nasal regurgitation and reflux of breastmilk into the eustachian tubes<sup>7,24,3,22,19</sup> (III).
      - ii. A football hold/twin position (the body of the infant positioned alongside the mother, rather than across the mother's lap, and with the infant's shoulders higher than his or her body) may be more effective than a cross-cradle position<sup>19</sup> (III).
  - iii. For infants with CP it may also be useful to position the breast toward the "greater segment"—the side of the palate that has the most intact bone. This may facilitate better compression and stop the nipple being pushed into the cleft site<sup>29</sup> (III).
  - iv. Some experts suggest supporting the infant's chin to stabilize the jaw during sucking<sup>24</sup> and/or supporting the breast so that it remains in the infant's mouth<sup>4,26</sup> (III).
  - v. If the cleft is large, some experts suggest that the breast be tipped downward to stop the nipple being pushed into the cleft<sup>16</sup> (III).
  - vi. Mothers may need to manually express breastmilk into the baby's mouth to compensate for absent suction and compression and to stimulate the let-down reflex<sup>26</sup> (III).
  8. If a prosthesis is used for orthopedic alignment prior to surgery, caution should be used in advising parents to use such devices to facilitate breastfeeding, as there is strong evidence that they do not significantly increase feeding efficiency or effectiveness<sup>27,38</sup> (III).
  9. Evidence suggests that breastfeeding can commence/recommence immediately following CL repair and that breastfeeding may be slightly more advantageous than spoon feeding<sup>13,6</sup> (I). Breastfeeding can commence/recommence 1 day after CP repair without complication to the wound.<sup>13</sup> In a survey of CP surgeons regarding postoperative care after palatoplasty, two thirds of surgeons allowed mothers to breastfeed immediately after surgery<sup>25</sup> (III).
  10. Assessment of the potential for breastfeeding of infants with CL/P as part of a syndrome/sequence should be made on a case-by-case basis, taking into account the additional features of the syndrome that may have an impact on breastfeeding success.

## *Recommendations for Future Research*

---

The most pressing issue for health care professionals working with mothers who wish to breastfeed their infants with CL/P is the lack of evidence on which to base clinical decisions. Well-designed, data-driven investigations that document feeding success rates, management

strategies, and outcomes for infants with CL/P are imperative. Furthermore, investigators must clearly describe their sample of infants and intervention techniques so that the research outcomes are able to be generalized.

## Appendix: Frequently Asked Questions

### BREASTFEEDING INFANTS WITH CL, CP, OR CLP

Except where noted, the literature reviewed relates to infants with nonsyndromic clefts of the lip and/or palate.

#### 1. Can infants with CL breastfeed successfully?

There is no strong evidence with regard to breastfeeding of infants with CL. There was moderate (II-2) evidence that babies with CL create suction during feeding.<sup>28,45</sup> Descriptive (III) studies have demonstrated successful breastfeeding at rates approaching the normal population.<sup>21</sup> Expert opinion (III) suggests that infants with CL may find breastfeeding relatively easier than bottle feeding because the breast tissue molds to the cleft and occludes the defect more successfully than an artificial nipple.<sup>17,11,23</sup> Expert opinion suggests that modifications to positioning can facilitate breastfeeding for these infants.<sup>16,7,24,4</sup>

#### 2. Can infants with CP breastfeed successfully?

There is no strong evidence with regard to breastfeeding infants with CP. There was moderate (II-2) evidence that infants with CP do not create suction when bottle feeding.<sup>28,45</sup> Although infants with clefts of the soft palate may be able to create suction, this is not usually the case.<sup>41,28</sup> Descriptive studies indicate that breastfeeding success for infants with CP is much lower than for infants with CL.<sup>10,7</sup> There was weak (III) evidence to suggest that partial breastfeeding (with supplementation) can be achieved and that the size and location of the cleft are determining factors for breastfeeding success.<sup>22,19,11</sup> As with infants with CL, modifications to positioning are reported to increase breastfeeding success<sup>16,7,3,22,19</sup> (III).

#### 3. Can infants with CLP breastfeed successfully?

There is no strong evidence with regard to breastfeeding infants with CLP. There was moderate (II-2) evidence that infants with CLP are unable to create suction when measured using a bottle<sup>41,28,45</sup> and moderate to weak evidence that infants with CLP are sometimes able to breastfeed successfully.<sup>34</sup> Descriptive studies suggest breastfeeding success rates ranging from

0% to 40%.<sup>2,21</sup> Modifications to positioning to increase breastfeeding success are recommended by experts<sup>5,16,24,22,19,26</sup> (III).

#### 4. Is there evidence to guide assessment and management of breastfeeding in infants with CL/P?

Aside from strong evidence regarding the use of palatal obturators (considered separately), there was moderate evidence (II-3) that lactation education is important to facilitate feeding efficiency in infants with CL/P.<sup>23</sup> The remaining evidence is weak (III) and focuses on (a) areas for monitoring and (b) recommendations for supplementation.

#### 5. Is there evidence that palatal obturators facilitate breastfeeding success with infants with CLP or CP?

Breastfeeding outcomes may be affected by the use of feeding plates (which obturate some of the cleft and attempt to "normalize" the oral cavity for feeding)<sup>27</sup> or presurgical orthopedics (prosthesis to reposition the cleft segments prior to surgery). These are collectively referred to as "obturators" for this report. There was strong (I) evidence that obturators do not facilitate feeding or weight gain in breastfed babies with CLP<sup>27</sup> and that they do not improve the infant's rate of bottle feeding.<sup>38</sup> There was moderate (II-2) evidence that obturators do not facilitate suction during bottle feeding.<sup>9</sup> This is because obturators do not facilitate complete closure of the soft palate against the walls of the throat during feeding. Contradictory evidence exists supporting the use of obturators to facilitate breastfeeding in infants with CP or CLP, but it is from much weaker sources<sup>5,17,23</sup> (II-2, III).

#### 6. Is there evidence for additional benefits of breastfeeding for infants with CL/P compared with the normal population?

Several moderate to weak (II-2) studies exist, with the majority of evidence representing expert opinion (III). It is well accepted that breastfeeding and breastmilk feeding convey positive benefits to both mother and baby. With regard to babies with CP, there was moderate to weak evidence that feeding with breastmilk protects against otitis media in infants with CP.<sup>2,35</sup> These babies are more prone to otitis media than the general population because of the abnormal soft palate musculature.<sup>35</sup> There was moderate to weak evidence that breastmilk can promote intellectual development and school outcomes in babies with clefts.<sup>20</sup> Antibacterial agents in breastmilk promote postsurgical healing and reduce irritation of mucosa (compared with artificial milk)<sup>50</sup> (III). Additionally, experts have suggested that breastfeeding facilitates the development of oral facial musculature,<sup>5</sup> speech,<sup>5,19</sup> bonding,<sup>19</sup> and pacifying infants post surgery.<sup>5,11</sup>

7. Is there evidence to indicate when it is safe to commence/recommence breastfeeding following surgery for cleft lip or palate?

CL repair (cheiloplasty) is generally carried out within a few months of birth,<sup>51</sup> and CP repair (palatoplasty) often takes place between 6 and 12 months of age. There are several studies that have yielded strong evidence to inform this area (I, II-2). There is moderate to strong evidence (I, II-2) that it is safe to commence/recommence breastfeeding immediately following CL repair,<sup>13,6</sup> and there is moderate evidence (II-2) for initiating breastfeeding 1 day after CP repair.<sup>13</sup> There is strong evidence (I) that breastfeeding immediately following surgery is more effective for weight gain, with lower hospital costs, than spoon feeding.<sup>13</sup> Contradictory evidence exists, but it is from weaker sources (III) and is divided as to recommendations.<sup>24,4,3</sup>

8. Is there evidence to indicate whether infants with CP as part of a syndrome/sequence are able to breastfeed?

There are over 340 syndromes in which CL/P appears.<sup>22</sup> It is beyond the scope of this protocol to review and make recommendations for them all in detail. However, some key data are presented to guide breastfeeding practice. Moderate to weak evidence suggests that, as well as the cleft, the additional oral facial anomalies associated with these syndromes (e.g., hypotonia, micrognathia, glossoptosis) impact feeding success.<sup>22,37,36</sup> It is important to examine the influence of all anomalies on feeding and design treatment with this in mind.

## APPENDIX J

# *Protocol 18: Use of Antidepressants in Breastfeeding Mothers*

N.K. Sriraman, K. Melvin, S. Meltzer-Brody, and the Academy  
of Breastfeeding Medicine

## *Background*

Postpartum depression (PPD) (sometimes referred to as pregnancy-related mood disorder) is one of the most common and serious postpartum conditions, affecting 10% to 20% of mothers within the first year of childbirth.<sup>35</sup> Studies have found that up to 50% of women with PPD are undiagnosed.<sup>17</sup> Risk factors include a prior history of depression (approximately 25% to 30% risk of recurrence),<sup>90,53</sup> including PPD and depression during pregnancy. Other risk factors include recent stressful life events, lack of social support, and unintended pregnancy.<sup>70</sup> Women who are economically stressed, disadvantaged, low income, or black are at a higher risk of PPD, as well.<sup>22</sup> Moreover, studies of economically disadvantaged families have shown that approximately 25% of women will have ongoing depressive symptoms that last well beyond the initial postpartum year.<sup>28</sup>

Treatment approaches include nonpharmacological therapies, such as interpersonal psychotherapy or cognitive behavioral therapy, pharmacological therapies, or a combination of both. Antidepressant medications are one of the most commonly prescribed pharmacologic treatments of PPD. The mother and her provider should work together to make an individually tailored choice. Breastfeeding mothers may be concerned about continuing and/or starting medication for PPD. Some providers

are reluctant to prescribe for lactating mothers, due to lack of information about antidepressants and breastfeeding. The risks of untreated depression, the risks of the medication to the breastfeeding dyad, and the benefits of treatment must be fully considered when making treatment decisions.

This protocol will discuss the spectrum of disease, emphasize the importance of screening, and provide evidence-based information recommendations for treatment of PPD in breastfeeding mothers.

## **SPECTRUM OF DISEASE**

There has been controversy about whether PPD is a distinct entity. In the *Diagnostic and Statistical Manual of Mental Disorders*, fourth and fifth editions (DSM-IV and V, respectively), PPD is considered a subtype of major depression, and there is an associated specifier to denote onset in the postpartum period.<sup>57</sup> The newer DSM-V expanded the definition of PPD to include onset of symptoms during pregnancy through 4 weeks postpartum.<sup>3</sup> Diagnosis may be further complicated by other comorbid conditions, including anxiety and bipolar disorder. Postpartum mood disorders are common in the postpartum period. However, they differ according to timing and severity of symptoms and encompass a wide range of disorders.<sup>17,57,78</sup> "Postpartum blues"

is a condition characterized by emotional changes, insomnia, appetite loss, and feelings of being overwhelmed that can affect 30% to 80% of women.<sup>28,57</sup> It is a transient condition that usually peaks on postpartum day 5 and resolves by day 10. Unlike PPD, postpartum blues does not adversely affect infant care.

"PPD" is a major depressive episode that impairs social and occupational functioning. Symptoms cause significant distress and can include suicidal ideation. If untreated, symptoms may persist beyond 14 days and can last several months to a year.

"Postpartum psychosis" is a psychiatric emergency and is characterized by paranoia, hallucinations, delusions, and suicidal ideation, with the potential risk of suicide and/or infanticide. It can occur in one to three of every 1000 deliveries and usually has a rapid onset (within hours to a few weeks) after delivery.<sup>28,57</sup> Women with postpartum psychosis may have a prior history of postpartum psychosis or bipolar disorder, but in some women there is no prior psychiatric history.<sup>76,14</sup> Approximately 25% to 50% of women with bipolar disorder are at risk of developing postpartum psychosis.<sup>47</sup>

"Postpartum intrusive thoughts" and "obsessive compulsive disorder" commonly occur in women. With a wide range of severity of symptoms, they are concerns for postpartum women. Intrusive or obsessive thoughts are unwelcome and involuntary thoughts, images, or unpleasant ideas that may become obsessions. These thoughts are usually upsetting or distressing to the woman, and they can be difficult to manage or eliminate.<sup>1,74</sup>

## SCREENING FOR PPD

Research confirms that most mothers (80%) are comfortable with the idea of being screened for depression.<sup>35</sup> Internationally, guidelines and authorities recommend screening for PPD.<sup>61–62</sup>

Although definitive evidence of benefit is limited, the American College of Obstetricians and Gynecologists recommends that clinicians screen patients at least once during the perinatal period for depression and anxiety symptoms using a standardized, validated tool.<sup>18</sup> For the first time, a large U.S. multicenter study of screening and follow-up care for PPD in a family practice setting has shown improved maternal outcomes at 12 months.<sup>94</sup> (I) (Quality of evidence [levels of evidence I, II-1, II-2, II-3, and III] is based on the U.S. Preventive Services Task Force Appendix A Task Force Ratings<sup>85</sup> and is noted throughout this protocol in parentheses.)

Most physicians and maternal/child health care providers recognize the detrimental effects of PPD

and agree that screening new mothers is within the scope of their practice.<sup>69,16</sup> The American Academy of Pediatrics and the U.S. Surgeon General's Office recognize and call for the early identification and treatment of mental health disorders, including PPD.<sup>84,19</sup> It is important that screening for PPD be done systematically on a global scale, as detection and treatment have been shown to be beneficial in many countries.<sup>60</sup> (I)

## SCREENING INSTRUMENTS

The screening instrument that has been most studied throughout the world is the Edinburgh Postnatal Depression Scale (EPDS).<sup>28,20</sup> The EPDS is free and considered to be in the public domain. It is available in many languages and has cross-cultural validity. It has 10 questions to be completed by the mother based on symptoms over the past 7 days and takes approximately 5 minutes to complete.<sup>20</sup> There are multiple points of contact in which screening can occur. In well-child-care visits, EPDS screening could occur during the 1-, 2-, 4-, and 6-month visits.<sup>28,61–62,37–33</sup> The cesarean section incision check at 2 weeks and the postpartum visit at 4 to 8 weeks are also important screening opportunities. The EPDS can be readily administered and has demonstrated validity to detect postpartum mood disorders as early as 4 to 8 weeks postpartum.<sup>33,26</sup> (II-3) A score of 10 or higher or a positive response to Question 10 about suicidal thoughts is considered positive and indicates that the mother may be suffering from a depressive illness of varying severity.<sup>46</sup> (II-3) Providers caring for the infant must refer a mother with a positive screen for appropriate care.

## EFFECTS OF PPD

In addition to the obvious adverse effects on the mother, PPD affects the child, spouse and/or partner, and other family members. It can cause family dysfunction, prevent effective mother-baby bonding, lead to early cessation of breastfeeding, and adversely affect infant growth and brain development.<sup>28,86–48</sup> Rates of paternal depression are higher when the mother has PPD, which can compound the negative effects of depression on children. Infants of depressed mothers show less engagement and eye contact with their mother and are at risk for failure to thrive, attachment disorder, and development delay.<sup>17</sup>

A shared neuroendocrine mechanism among maternal mood, oxytocin levels, and maternal affect during breastfeeding has been demonstrated.<sup>81</sup> This strengthens the position that women with depression would benefit from early and sustained support with breastfeeding. Likewise, women with

negative early breastfeeding experiences may be more likely to have depressive symptoms at 2 months postpartum; thus women experiencing breastfeeding difficulties should be screened for depressive symptoms.<sup>86</sup>

## *Clinical Approach to Treating PPD*

Once a woman is identified as being at risk for PPD, treatment choices must be considered and offered to her. For mild to moderate depression in the breastfeeding mother, psychology/cognitive behavioral therapy, if available, should be considered as first-line therapy.<sup>67</sup> (II-2)

### *Treatment*

#### **NONPHARMACOLOGICAL**

##### **Psychological Therapy**

Psychological therapy is effective for the treatment of major depressive disorder in the postpartum period, and different types of therapies seem equally effective.<sup>25–21</sup> (I) There are three approaches to the administration of psychological therapy in the postpartum period, including interpersonal therapy, cognitive behavioral therapy, and psychodynamic psychotherapy (nondirective therapy).<sup>25–36</sup> Non-pharmacological treatment is not harmful to the infant and is often acceptable to mothers with PPD.

#### **Infant Feeding Considerations**

Breastfeeding difficulties and perinatal depression symptoms often present together, and management of depression should include a discussion of the mother's experience of breastfeeding. Some mothers with depression find that breastfeeding enhances bonding and improves their mood, whereas others find breastfeeding to be difficult. For dyads struggling with milk production and latch issues, efforts should be undertaken to simplify feeding plans to ensure that mother and infant have time to enjoy one another. The demands of nighttime breastfeeding can be challenging for mothers for whom interruption of sleep is a major trigger for mood symptoms. In these cases, it may be helpful to arrange for another caregiver to feed the infant once at night, allowing the mother to receive 5 to 6 hours of uninterrupted sleep. A caregiver may also bring the infant to the mother to feed at the breast and then assume responsibility for settling the baby back to sleep, thereby minimizing maternal sleep disruption. (III)

## **MEDICATIONS**

If psychological/cognitive behavioral therapy is unavailable, symptoms are severe, or mothers refuse this therapy, antidepressants are an effective option. Many factors must be considered when choosing an antidepressant during breastfeeding. All antidepressants are present in human milk to some extent. Data to inform clinical decisions are derived primarily from case reports or case series. Therefore the initial treatment choice should be based on an informed clinical approach that takes into account the patient's previous treatments for depression, especially use during the pregnancy, the targeted symptoms, family history of depression, and their experiences with antidepressants, current and past medical disorders, current medications, allergies, side effects of the medications, and maternal wishes. An individualized risk-benefit analysis of the treatments must be conducted (Table J-18).<sup>12</sup> (I)

#### *Clinical Factors Affecting Antidepressant Choice*

- Obtain a psychiatric history with a focus on previous episodes of mood and anxiety disorders and effective treatment interventions. If psychotropic medications were used, determine what treatments were effective with a tolerable side effect profile. Past treatment response is often the best predictor of future response.<sup>12</sup> (II-2)
- Obtain a family history of psychiatric illness and treatment response. An immediate family member's history may be indicative of the mother's treatment response.<sup>12</sup> (II-2)
- Consider the primary symptoms that the medication will be targeting and its potential side effect profile.
- Choose psychotropic medications with an evidence base in lactating women. Older medications with available data are preferred over newer antidepressants with limited safety information.

#### *Choosing an Antidepressant During Lactation*

When considering the use of any medication in a lactating woman, providers must consider both maternal and infant safety factors. The medication must be both efficacious for the mother and safe for the infant. Although infant serum levels of psychotropic medications are the most accurate measures of infant exposure, it is often difficult to measure

**TABLE J-18** Specific Antidepressants

Class	Drug	Dosage per Day	Indications	Maternal Side Effects	Infant Exposure Effects	Comments
SSRIs	Citalopram <sup>40,75</sup> Escitalopram <sup>7,11</sup> Fluoxetine <sup>11,64</sup> Fluvoxamine <sup>4,93</sup> Paroxetine <sup>42,56,54</sup> Sertraline <sup>42,29,27*</sup>	10-60 mg 10-20 mg 10-80 mg 50-300 mg 10-60 mg 25-200 mg (usually a daily dose). Start at 25 mg for 5-7 days, then increase to 50 mg	Depressive or anxiety disorders; may be prescribed for fibromyalgia, neuropathic pain, or premenstrual symptoms and disorders	Gastrointestinal distress, headaches, sexual dysfunction, nervousness, and sedation	All SSRIs have been detected in human milk. Paroxetine <sup>56,79</sup> and sertraline <sup>29,27</sup> have not exceeded the recommended 10% maternal level and are usually undetectable in infant serum. <sup>80</sup> Fluoxetine <sup>49,82</sup> and citalopram <sup>40,51</sup> have exceeded the 10% maternal level. <sup>45</sup> The infant adverse events reported include uneasy sleep, colic, irritability, poor feeding, and drowsiness. <sup>11,13,64,68,72</sup> The FDA indicated that fluoxetine should not be used by nursing mothers. <sup>64</sup>	Sertraline is the most likely SSRI to be prescribed. It's low to undetectable in milk and has a relative safety profile in pregnancy. Long-term effects on neurobehavior and development from exposure to any SSRI during pregnancy and lactation have a limited evidence base, but more recent studies are relatively reassuring <sup>11,13,68,5</sup>
SNRIs	Venlafaxine <sup>58,44</sup> Duloxetine <sup>8</sup> Desvenlafaxine <sup>72</sup>	37.5-225 mg 20-120 mg 50-100 mg	Depression	Galactorrhea	Venlafaxine and its active metabolite are in milk, and its metabolite can be found in the plasma of most breastfed infants, but no proved drug-related side effects. Monitor for sedation and adequate weight gain	Sporadic case reports for these medications. <sup>72,8</sup> Limited number to report significant outcomes for nursing infants
Other antidepressants (norepinephrine/dopamine/serotonin reuptake blockers)	Bupropion <sup>6,23</sup> Mirtazapine <sup>2</sup>	150-450 mg 15-30 mg	Depression	Dose-dependent drowsiness, dry mouth, increased appetite, weight gain, and dizziness	Very limited data, ranging from asymptomatic with undetectable infant serum levels to concerns with irritability and seizures  Limited infant data; no adverse side effects noted	Use is not a reason to discontinue breastfeeding. However, another drug may be preferred

TCAs/heterocyclics	Amitriptyline, amoxapine, clomipramine, desipramine, doxepin, maprotiline, nortriptyline, protriptyline, and trimipramine	Nortriptyline, 30-50 mg/day, in 3-4 divided doses, or the total daily dosage may be given once a day	Depression and anxiety disorders; often used in low doses for sleep and chronic pain	Hypotension, sedation, dry mouth, urinary retention, weight gain, sexual dysfunction, and constipation. In an overdose, these medications can cause cardiac arrhythmias and death	Only nortriptyline has a sufficient number of reported cases to comment on its use during lactation: it is generally undetectable in infant serum; no adverse events have been reported. <sup>91,89</sup> Use of doxepin is often cautioned because of a case report of hypotonia, poor feeding, emesis, and sedation in a breastfeeding infant that resolved after discontinuation of nursing. <sup>34</sup>	One of the older classes
Herbal/natural	St. John's wort ( <i>Hypericum perforatum</i> ) contains hypericin and hyperforin as well as flavonoids such as quercetin	300 mg	Depression	One study found a slightly increased frequency of colic, drowsiness, and lethargy among breastfed infants but none required treatment. <sup>50</sup>	Both hypericin and hyperforin are poorly excreted into human milk	Has been used for the treatment of mild to moderate depression for many years, especially in Europe. Its use as a treatment for depression is controversial in the United States
	Omega-3 fatty acids		Depression during pregnancy and the postpartum period <sup>32</sup>	Appears to be of little risk to mothers and infants. The primary negative side effect is the "fishy smell"		Lack of sufficient evidence at this time to consider it a treatment for depression
Antipsychotic	Quetiapine	Start at 25 mg, titrate. Maximum dose, 600 mg	Bipolar disorder, schizophrenia	Sedation	Sedation	
Mood stabilizer	Lithium	Start at 300 mg, titrate as per Li levels. Maximum dose, 900-1200 mg		Diarrhea, vomiting	Elevated TSH	Dosing is dictated by lithium blood levels in the mother, which need to be regularly checked

FDA, Food and Drug Administration; Li, lithium; SNRI, serotonin-norepinephrine reuptake inhibitors; TCA, tricyclic antidepressant; TSH, thyroid-stimulating hormone.

\*Best safety profile of selective serotonin reuptake inhibitors (SSRIs) in lactation.

infant serum levels in routine clinical practice. However, factors affecting the passage of medication into human milk must be considered, including the following:

1. Route of drug administration and pharmacokinetics<sup>39</sup>:
  - absorption rate
  - half-life and peak serum time
  - dissociation constant
  - volume of distribution
  - molecular size
  - degree of ionization
  - pH of plasma (7.4) and milk (6.8)
  - solubility of the drug in water and in lipids
  - binding to plasma protein
2. Amount of drug received by the infant in human milk<sup>39</sup>:
  - milk yield
  - colostrum versus mature milk
  - concentration of the drug in the milk
  - how well the breast was emptied during the previous feeding
  - the infant's ability to absorb, detoxify, and excrete the drug

Up-to-date information about medication use during lactation is easily available from the Internet on TOXNET LACTMED (<http://toxnet.nlm.nih.gov/newtoxnet/lactmed.htm>) (available in English) and e-lactancia (<http://e-lactancia.org/>) (available in both English and Spanish).

Most antidepressant studies provide milk levels, or a milk to mother's plasma ratio, that are not constant and depend on factors such as dose, frequency, duration of dosing, maternal variation in drug disposition, drug interactions, and genetic background. Few studies provide infant serum levels, although they are the best measure of infant exposure.<sup>39</sup>

## *Specific Antidepressants*

Data from a recent meta-analysis indicated that all antidepressants were detected in milk, but that not all were found in infant serum.<sup>87</sup> Infant serum levels of nortriptyline, paroxetine, and sertraline were undetectable in most cases. Infant serum levels of citalopram and fluoxetine exceeded the recommended 10% maternal level in 17% and 22% of cases, respectively. Few adverse outcomes were reported for any of the antidepressants. Conclusions could not be drawn for other antidepressants due to an insufficient number of cases. There is little or no evidence that ethnic or regional "medicines" are safe or effective; thus their use by health care

providers is strongly cautioned. (II-2) For specific antidepressant medications, see Table J-18.

## *Recommendations for Antidepressant Treatment in Lactating Women*

- Current evidence suggests that untreated maternal depression can have serious and long-term effects on mothers and infants and that treatment may improve outcomes for mothers and infants. Therefore treatment is strongly preferred. (II-2)
- However, it is important not to label mothers who are only suffering from mild cases of postpartum blues as "depressed." We must make a distinction. For women with mild symptoms who are in the first 2 weeks postpartum, close follow-up, rather than initiation of antidepressant medication, is suggested. (II-2)
- When available and when symptoms are in the mild to moderate range, psychological/cognitive behavioral therapy is the first line of treatment for lactating women, as it carries no known risk for the infant. Mothers must be monitored and reevaluated. If they are not improving or their symptoms are worsening, antidepressant drug treatment should be considered. (II-2)
- Both psychological/cognitive behavioral therapy and antidepressant medication are recommended for women with moderate to severe symptoms or for whom there are current stressors or interpersonal issues that psychological therapy may help address. Maternal lactation status should not delay treatment. (II-2)
- Women with moderate to severe symptoms may require only antidepressant drug treatment. In the setting of moderate to severe depression, the benefits of treatment likely outweigh the risks of the medication to the mother or infant.
- There is no widely accepted algorithm for antidepressant medication treatment of depression in lactating women. An individualized risk-benefit analysis must be conducted in each situation and take into account the mother's clinical history and response to treatment, the risks of untreated depression, the risks and benefits of breastfeeding, the benefits of treatment, the known and unknown risks of the medication to the infant, and the mother's wishes.
- If a mother has no history of antidepressant treatment, an antidepressant such as sertraline that has evidence of lower levels in human milk and infant serum and few side effects is an appropriate first choice. (II-2) Sertraline has the best safety profile during lactation. The

recommended starting dose is 25 mg for 5 to 7 days to avoid side effects, which then can be increased to 50 mg/day.

- If a mother has been successfully treated with a particular selective serotonin reuptake inhibitor, tricyclic antidepressant, or serotonin-norepinephrine uptake inhibitor in the past, the data regarding this particular antidepressant should be reviewed. It should be considered as a first line of treatment if there are no contraindications.
- Mothers who were being treated with a selective serotonin reuptake inhibitor, tricyclic antidepressant, or serotonin-norepinephrine uptake inhibitor during pregnancy with good symptom control should continue on the same agent during breastfeeding. It is important to reassure the mother that exposure to the antidepressant in breast milk is far less than exposure to the antidepressant during pregnancy. Moreover, ongoing treatment of the mood disorder is critical for the health of both mother and baby. Mothers should be provided with information regarding the known and unknown risks and benefits of the treatment to make an informed decision.
- Mothers should be monitored carefully in the initial stages of treatment for changes in symptoms, including worsening of symptoms. Specifically, women with histories of bipolar disorder, which may be undiagnosed, are at increased risk of developing an episode of depression, mania, or psychosis in the postpartum period. Although this situation is rare, mothers and partners should be made aware of the symptoms to watch for, such as increased insomnia, delusions, hallucinations, racing thoughts, and talking/moving fast. Women experiencing such symptoms should contact their mental health provider immediately.
- The mother's provider should communicate with the infant's provider to facilitate monitoring and follow-up. Infants should be monitored carefully by the physician/health care worker. Growth, in particular, should be carefully followed. Serum levels are not indicated on a regular basis without a clinical indication or concern. In addition, in most cases, the serum level would not provide helpful information unless it is a psychotropic that has a documented therapeutic window and laboratory norms (i.e., tricyclic antidepressants).
- A strategy that may be used to decrease infant exposure based on breastfeeding pharmacokinetic reports is medication administration immediately after feedings. (III)
- There are several Web-based and book references available for professionals and mothers

to assist in gaining knowledge and help regarding these issues ([Table J-19](#)).

## *Conclusions and Suggestions for Future Research*

---

Despite many publications about antidepressants and breastfeeding, the scientific literature continues to lack the depth of robust large-scale studies for clinicians and mothers to make confident decisions about individual medications. Multiple reviews of the literature broadly suggest tricyclic antidepressants and selective serotonin reuptake inhibitors are relatively safe, and all recommend individual risk-benefit assessments.<sup>58</sup>

Future research that would help guide clinical practice includes:

1. Randomized clinical trials in lactating women for any class of antidepressant that include the following:
  - a. sufficient control for level of depression;
  - b. provision of drug, information on infant serum levels, the amount detected in human milk, maternal serum levels, and the timing of sampling;
  - c. information on infant consumption of the milk;
  - d. information on infant behavioral outcomes; and
  - e. evaluation of impact of continued breastfeeding on mitigating infant withdrawal symptoms for those mothers treated antenatally.
2. Studies of reasons mothers and clinicians elect to defer treatment in lactating mothers and follow-up behavioral outcomes of these infants.

## APPENDIX J

# *Protocol 19: Breastfeeding Promotion in the Prenatal Setting*

## *Background*

Breastfeeding provides ideal infant nutrition and is the physiologic norm for mothers and children.<sup>3,1</sup> Mothers often make a decision regarding breastfeeding early in prenatal care, and many have already decided whether to breastfeed prior to conception.<sup>14</sup> Encouragement and education from health care providers result in increased breastfeeding initiation and duration.<sup>17,19,16</sup> In addition, ongoing educational and support programs can improve initiation and duration of breastfeeding.<sup>17</sup>

## *Recommendations*

1. Create a breastfeeding-friendly office.
  - Staff must be educated and committed to promote, protect, and support breastfeeding.
  - The primary clinician should be involved, but he or she does not need to do each of the following steps. Tasks may be assigned to multiple office staff members (nurses, medical assistants, lactation consultants, health and breastfeeding educators) if adequate training and support are provided for them.
  - Offices providing prenatal care should have a written breastfeeding policy to facilitate such support.<sup>19</sup>
  - Literature and samples provided by artificial formula companies should not be used because this advertising has been demonstrated to decrease breastfeeding initiation and shorten duration rates.<sup>9</sup>

- Information regarding the mother's intention to breastfeed should be included as part of all transfer-of-care materials, including prenatal records and hospital and birth center discharge summaries.

2. Integrate breastfeeding promotion, education, and support throughout prenatal care.
  - Actively state support of breastfeeding early in prenatal care and acknowledge that breastfeeding is superior to artificial feeding. Consider a statement such as, "As your doctor, I want you to know that I support breastfeeding. It is important for mothers and babies."
  - It is also helpful to let the prenatal patient know that her physician will actively help her, with statements such as, "I like to spend time helping my patients get the information, skills, and support they need to breastfeed successfully."
3. Take a detailed breastfeeding history as a part of the prenatal history.<sup>2</sup>
  - For each previous child, ask about breastfeeding initiation, duration of exclusive breastfeeding, total breastfeeding duration, who provided breastfeeding support, perceived benefits of breastfeeding, breastfeeding challenges, and reason(s) for weaning.
  - For women who did not breastfeed, consider asking about the perceived advantages of artificial feeding, as well as the perceived disadvantages. Inquire about what may have helped her breastfeed previous children.
  - It is also important to determine any family medical history that may make breastfeeding especially helpful for this child, such as asthma, eczema, diabetes, and obesity.<sup>1,3,11</sup>

4. Consider the culture of individual women, families, and communities.
  - Learn about the family structure of patients. In some cultures, enlisting the cooperation of a pivotal family member may greatly assist in the promotion of breastfeeding, whereas in others, the participation of a particular family member may be inappropriate.
  - Understand the partner's perspectives and beliefs that may affect breastfeeding success, and educate where appropriate.
  - Ensure that parents from diverse cultures understand the importance of breastfeeding to their children's growth and development.
  - Respect cultural traditions and taboos associated with lactation, adapting cultural beliefs to facilitate optimal breastfeeding, while sensitively educating about traditions that may be detrimental to breastfeeding.
  - Provide all information and instruction, wherever possible, in the mother's native language, and assess for literacy level when appropriate.
  - Understand the specific financial, work, and time obstacles to breastfeeding and work with families to overcome them.
  - Be aware of the role of the physician's own personal cultural attitudes when interacting with patients.<sup>1</sup>
5. Incorporate breastfeeding as an important component of the initial prenatal breast examination.<sup>12</sup>
  - Observe for appropriate breast development, surgical scars, and nipple contour.
  - Perform areolar compression if nipples are flat or inverted.
  - Review the physiologic changes of pregnancy, such as volume growth and leakage of colostrum.
  - Consider repeating the breast examination in the third trimester, as breast anatomy will change throughout pregnancy.
  - Assure the expectant mother that her anatomy is sufficient for successful breastfeeding, or discuss the availability of support and assistance if suggested by physical exam.
  - If the history and/or physical exam findings suggest that the woman is at high risk for breastfeeding problems, consider a prenatal lactation referral or early lactation support.
6. Discuss breastfeeding at each prenatal visit,
  - Breastfeeding can be addressed by clinicians and/or health care staff.
  - Consider use of the Best Start 3-Step Counseling Strategy<sup>12</sup> by:
    - Encouraging open dialog about breastfeeding by beginning with open-ended questions.
    - Affirming the patient's feelings.
    - Providing targeted education.<sup>20,10</sup>

- Address concerns and dispel misconceptions at each visit.

**During the first trimester**

- Incorporate and educate partners, parents, and friends about the benefits of breastfeeding for mothers and babies.<sup>13</sup>
- Address known common barriers such as lack of self-confidence, embarrassment, time and social constraints, dietary and health concerns, lack of social support, employment and child care concerns, and fear of pain.<sup>12,8</sup>
- Continue to ask open-ended questions.

**During the second trimester**

- Encourage women to identify breastfeeding role models by talking with family, friends, and colleagues who have breastfed successfully.
- Recommend attending a formal breastfeeding course for the patient and her partner in addition to office education.<sup>18</sup>
- Encourage participation in a breastfeeding peer support group. Provide a list of local educational options and breastfeeding resources for patients.<sup>4,5</sup>
- The second trimester visits often provide time for discussion of breastfeeding basics such as the importance of exclusive breastfeeding and supply/demand, feeding on demand, frequency of feedings, feeding cues, how to know an infant is getting enough to eat, avoiding artificial nipples until the infant is nursing well, and the importance of a good latch.

- The mother working outside the home should be encouraged to begin thinking about if and when she will return to work after the baby is born. If she is planning on returning to work, encourage the woman to consider what facilities are available for pumping and storage of breast milk, how much time she will take for maternity leave, and what company policies and legislation are available to support her.

**During the third trimester**

- At the 28-, 30-, or 32-week visits have the prenatal patient and her support persons use props such as dolls, balls, and balloons. Demonstrate how to hold the breast and positions of the baby such as the cradle, cross-cradle, and clutch holds.<sup>7</sup>
- Discuss what will happen in the delivery room under normal conditions. What will the mother do? What will the doctor do?
- Review the physiology of breastfeeding initiation and the impact of supplementation.
- Repeat the breast and nipple examination.
- Recommend the purchase of properly fitting nursing bras.

- Encourage another visit to a breastfeeding support group as the mother's interest and goals of attending may be different from when she attended early in the pregnancy.<sup>6</sup>
  - Recommend the mother discuss plans for infant health care and breastfeeding support with her pediatric care provider.<sup>15</sup>
7. Empower women and their families to have the birth experience most conducive to breastfeeding.
- Confirm postpartum follow-up plans.
  - Assure the mother has an adequate support system in place during the postpartum period.
  - Recommend the infant see a health care provider within 48 hours of discharge from the hospital to assure well-being and optimal breastfeeding.
  - Assure that the patient has information on how to get breastfeeding help.
  - Provide anticipatory guidance on topics such as engorgement, growth spurts, and nighttime feedings.
  - Inform patients about the Ten Steps to Successful Breastfeeding and how to advocate for breastfeeding-friendly hospital care.<sup>15</sup>
  - Discuss support of breastfeeding in the event of a cesarean section.

## *Recommendations for Further Research*

1. There are currently no studies examining only physician interaction in support of breastfeeding during prenatal visits and its effect on initiation, exclusivity, and maintenance.
2. Studies are needed that examine prenatal interventions alone and in combination and their effects on initiation, exclusivity, and duration of breastfeeding.
3. Studies examining the cost-effectiveness of making an outpatient practice breastfeeding-friendly are needed.
4. Research on specific challenges to providing support for breastfeeding during prenatal care (e.g., lack of community resources, cultural barriers, etc.) is needed.
5. Additional research is needed on the effect of varying prenatal breastfeeding interventions on multiple populations, including with women of different socioeconomic status and cultural backgrounds.

## APPENDIX J

# Protocol 20: *Engorgement*

---

### Purpose

The purpose of this protocol is to evaluate the state of evidence as to the prevention, recognition, and management of breast engorgement to encourage successful breastfeeding. The effect of medications on breast engorgement and lactation suppression will also be reviewed.

### Background

Engorgement has been defined as "the swelling and distention of the breasts, usually in the early days of initiation of lactation, caused by vascular dilation as well as the arrival of the early milk."<sup>15</sup> The concept put forward by Newton and Newton<sup>20</sup> in 1951 suggested that alveolar distention from milk then led to compression of surrounding ducts, which subsequently led to secondary vascular and lymphatic compression. Some degree of breast fullness in the second stage of lactogenesis is considered normal and reassuring to the mother and health care provider.

Engorgement symptoms occur most commonly between Days 3 and 5, with more than two-thirds of women with tenderness on Day 5 but some as late as Days 9 to 10.<sup>3,27</sup> Two-thirds of women experience at least moderate symptoms.<sup>23,12</sup> More time spent breastfeeding in the first 48 hours is associated with less engorgement.<sup>17</sup>

One difficulty when evaluating incidence and treatment options for this condition involves the spectrum of engorgement, from expected physiologic breast fullness through severely symptomatic engorgement. Additionally, more optimal lactation management and support in some institutions may

reduce the frequency of significant symptoms compared to less supportive environments.

### Assessment of Engorgement

#### TOOLS

No standardized reliable tool for assessing breast engorgement has been established. Various methods of subjectively rating engorgement have been utilized, such as visual descriptions, cup size, or hardness or firmness scales, but none has become clinically useful.<sup>20,12,13,19</sup>

#### PREDICTORS

1. The relationship between parity and engorgement remains unclear because of little research. Onset of lactogenesis occurs sooner in multiparous compared to primiparous women, but engorgement has not been studied in this regard.<sup>8</sup>
2. Women undergoing cesarean delivery typically experienced peak engorgement 24 to 48 hours later than those who delivered vaginally.<sup>17</sup> These women also initiated breastfeeding significantly later than did their vaginally delivered counterparts. This finding appears consistent with other research that has found that cesarean delivery may correlate with a higher likelihood of delayed onset of lactation.<sup>8</sup>
3. It is not uncommon for women who have undergone breast surgery to experience engorgement.<sup>4</sup>
4. The influence of length of labor, premature delivery, anesthetic options, and intravenous fluids remains unclear.<sup>16,21,11</sup>

## Differentiating Engorgement from Other Causes of Breast Swelling

- Mastitis.** Engorgement may be associated with a slight elevation of maternal temperature, but significant fever, especially when associated with breast erythema and systemic symptoms such as myalgias, suggests the diagnosis of mastitis. Typically, mastitis affects only one breast with a segmental pattern of redness. Engorgement is usually diffuse, bilateral, and not associated with breast erythema.<sup>15</sup>
- Gigantomastia.** Gigantomastia is a diffuse, bilateral process that occurs very rarely and does not typically present in the postpartum period. The reported incidence is approximately 1:100,000, but some feel that it is more common with a rate as high as 1:8000.<sup>1</sup> It is regarded as bilateral benign but progressive massive breast enlargement to an extent that tissue necrosis may occur and infection and sepsis may result. Histologic findings suggest marked lobular hypertrophy and ductal proliferation. No clear etiology for this condition has been elicited, although hormonal changes are likely involved.<sup>1,26,28,2</sup>

## Prevention and Treatment

### PREVENTION

There has been a great deal of research into medical therapies to suppress lactation, but limited research into prevention and treatment strategies for lactating women who may develop engorgement. Focused education to mothers regarding breastfeeding position and attachment or prenatal nipple conditioning has shown no difference in subsequent incidence of engorgement.<sup>7,25</sup> However, some breastfeeding techniques have been specifically associated with less engorgement, including emptying one breast at each feeding and alternating which breast is offered first.<sup>9</sup> Limited evidence suggests breast massage after feeds performed for the first 4 days postpartum may reduce the extent of engorgement.<sup>25</sup> Although commonly accepted as preventive of engorgement, frequent effective feeding patterns have not been studied.<sup>9</sup>

### TREATMENT

Adequate management of engorgement is important for successful long-term lactation.<sup>24,5</sup> Although experiencing engorgement may be temporarily uncomfortable for mothers, it appears to

be associated with a decrease in the likelihood of early weaning. At the same time, failure to effectively resolve *prolonged symptomatic* engorgement may additionally have a negative impact on continued adequate milk supply.

Both pharmacologic and nonpharmacologic therapies have been touted as beneficial for the treatment of engorgement. A systematic review of both randomized and "quasi-randomized" controlled studies assessing effectiveness of treatments for breast engorgement was done by Snowden et al.<sup>22</sup> in 2001. This analysis identified eight trials including 424 women. Therapies reviewed that outperformed placebos in decreasing symptoms are described below:

1. Serrapeptase® (Takeda Chemical Industries, Ltd., Osaka, Japan) (Danzen), an antiinflammatory enzyme agent, 10 mg three times daily, was compared to placebo three times daily for 3 days.<sup>14</sup> The Danzen group reported marked improvement in 23% of women compared to only 3% in the placebo group. Overall, 86% of the treatment group reported statistically significant marked or moderate improvement compared to 60% for the placebo group. Although the results suggest that the antiinflammatory agent may be beneficial, the study has the significant limitation that few women in the study were breastfeeding their infants.
2. Enzyme therapy using a protease complex enteric-coated tablet containing 20,000 units of bromelain and 2500 units of crystalline trypsin, another antiinflammatory agent, has been tested.<sup>18</sup> Women with breast swelling or induration on Days 3 to 5 and pain were given either the protease complex or placebo tablets (approximately 5 tablets per day) for 3 days for a total of 16 tablets. The protease complex was found to be effective in 83% of cases compared to 33% of those receiving placebo.
3. Reverse pressure softening technique uses gentle positive pressure to soften an area (1 to 2 in. or so) near the areola surrounding the base of the nipple. The goal is to temporarily move some swelling slightly backward and upward into the breast. Moving the edema away from the areola has been shown to improve the latch of the infant during engorgement.<sup>6</sup> The physiologic basis for this technique is the presence of increased resistance in the subareolar tissues during engorgement.
4. Snowden et al.<sup>22</sup> concluded that there is no benefit for the following treatments as compared with placebo: cabbage leaves, cabbage leaf extract, oxytocin, cold packs, and ultrasound.

It may be that some treatments help the discomfort without relieving the actual engorgement.

It should also be noted that many of the therapies listed above may not be available in certain countries.

## Other Considerations

- Herbal remedies:** At the present time herbal remedies for breast engorgement and oversupply have been described, but scientific investigation regarding their effectiveness is not available.
- Manual expression or pumping:** If the infant cannot successfully nurse, measures should be undertaken to assist the mother with manual expression or pumping, either for a few minutes to allow softening and compressibility of the nipple-areolar complex or for milk extraction. The milk can then be given to the infant by cup, and the mother can be encouraged to nurse more frequently prior to the recurrence of severe breast engorgement. All new mothers should also be instructed in the technique of manual breast expression.<sup>10</sup>
- Anticipatory guidance regarding the occurrence of breast engorgement should be given to all breastfeeding mothers prior to hospital discharge. In many countries where women may have longer hospital stays, engorgement may occur in the birth hospital. However, many women are discharged before the expected time of peak symptomatic engorgement. Mothers should be counseled about symptomatic treatment options for pain control. Acetaminophen (or paracetamol) and ibuprofen are both safe options for nursing mothers to take in appropriate doses. Additionally, contact information for breastfeeding supportive advice should be provided. Health care personnel seeing either the newborn or mother after discharge should routinely inquire about breast fullness and engorgement.

## Recommendations for Future Research

Currently there is inadequate research into both the physiologic process of engorgement and effective prevention and treatment strategies. A uniform measurement system for the severity of the engorgement should be developed to allow standardized measures and comparison of results among studies. Once an objective noninvasive bedside measure of breast engorgement has been developed, then clinical trials assessing correlation of objective measures of engorgement and treatment of engorgement with breastfeeding duration and

problems can be conducted. Knowledge about the influence of labor interventions and patient characteristics predisposing them to the development of significant engorgement would be useful in identifying patients at risk for engorgement and those who could benefit from counseling and closer follow-up. Nonpharmacologic remedies for the management of engorgement should be investigated. Double-blinded placebo-controlled studies of medications known to be safe during lactation and with potential to relieve symptomatic engorgement should be prioritized.

## APPENDIX J

# *Protocol 21: Guidelines for Breastfeeding and Substance Use or Substance Use Disorder*

Sarah Reece-Stremtan, Kathleen A. Marinelli, and the Academy of Breastfeeding Medicine

A central goal of the Academy of Breastfeeding Medicine is the development of clinical protocols for managing common medical problems that may impact breastfeeding success. These protocols serve only as guidelines for the care of breastfeeding mothers and infants and do not delineate an exclusive course of treatment or serve as standards of medical care. Variations in treatment may be appropriate according to the needs of an individual patient.

### *Purpose*

The choice of breastfeeding by a pregnant or newly postpartum woman with a history of past or current illegal/illicit drug abuse or legal substance use or misuse is challenging for many reasons. The purpose of this protocol is to provide literature-based guidelines for the evaluation and management of the woman with substance use or a substance use disorder who is considering breastfeeding.

### *Background*

Illicit drug use and legal substance use/abuse remain a significant problem among women of childbearing age. The 2013 National Survey on Drug Use

and Health revealed that among pregnant women 15 to 44 years of age in the United States, 5.2% had used illicit drugs in the past month, 9.4% reported current alcohol use, 2.3% reported binge drinking, 0.4% reported heavy drinking during the pregnancy, and 15.4% reported cigarette use in the past month.<sup>46</sup>

The health care provider presented with a pregnant or recently postpartum woman with a history of current or past illegal drug abuse or legal drug use or misuse who desires to breastfeed often faces multiple significant challenges. Substance use disorders frequently engender behaviors or conditions that independently signify risk for the breastfed infant, in addition to the drug exposure per se. These mothers may have coexisting risk factors such as low socioeconomic status (although substance use crosses all socioeconomic lines), low levels of education, poor nutrition, and little to no prenatal care. Multiple drug use is common, in addition to the use of other harmful legal substances, including tobacco and alcohol. Illicit drugs are frequently mixed and extended with dangerous adulterants that can pose additional threats to the health of the mother and the infant. Drug users are at high risk for infections such as human immunodeficiency virus and/or hepatitis B and C. Psychiatric disorders that require pharmacotherapeutic intervention are more prevalent with substance use,

making breastfeeding an even more complicated choice, as breastfeeding may not be recommended for women taking some psychotropic medications.

Despite the myriad factors that may make breastfeeding a difficult choice for women with substance use disorders, drug-exposed infants, who are at a high risk for an array of medical, psychological, and developmental issues, as well as their mothers, stand to benefit significantly from breastfeeding. Although many of the factors listed earlier may pose a risk to the infant, the documented benefits of human milk and breastfeeding must be carefully and thoughtfully weighed against the risks associated with the substance that the infant may be exposed to during lactation. Confounding many efforts to examine longer-term developmental outcomes in infants exposed to some substances is the lack of data evaluating infants who were not exposed during pregnancy but only during lactation.

Ideally, women with substance use disorders delivering an infant and desiring to breastfeed are engaged in comprehensive health care and substance abuse treatment during pregnancy, but this is not always the case. Substance abuse treatment for these women is often not available, not gender specific, and not comprehensive, forcing the mother's health care provider during and after pregnancy to rely on maternal self-report and a "best guess" at adequacy of services, compliance to treatment, length of "clean" time, community support systems, and so forth. In a recent retrospective study in the United Kingdom, significantly lower rates of breastfeeding initiation occurred in mothers who used illicit substances or opioid maintenance therapy during pregnancy (14% vs. 50% of the general population).<sup>17</sup> In Norway, among opioid-dependent women on opioid maintenance therapy, 77% (compared with 98% in the general population) initiated breastfeeding after delivery.<sup>53</sup>

The specific terms used to describe use and misuse of various legal and illegal substances continue to evolve and may vary from country to country and among different organizations. The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* combines the previous categories of substance

abuse and substance dependence into the category single substance use disorder, which is measured on a continuum from mild to severe.<sup>14</sup>

We would like to make it clear that drugs of any type should be avoided in pregnant and breastfeeding women, unless prescribed for specific medical conditions. The casual use of drugs—legal, illegal, illicit, dose appropriate or not—still may have ramifications for the developing fetus and infant that we have yet to determine; hence, in general, drugs of all types should be avoided unless medically necessary.

## Specific Substances

Perhaps the most critical challenge facing the health care provider for the woman with a substance use disorder who wishes to breastfeed is the lack of research leading to evidence-based guidelines. Table J-20 gives two online websites, one in English and one in both English and Spanish, that are kept updated and are easily accessible for current information on drugs and breastfeeding. There have been several comprehensive reviews of breastfeeding among substance-using women, essentially concluding that breastfeeding is generally contraindicated in mothers who use illegal drugs.<sup>12,48,47,16</sup> (III) (Quality of evidence [levels of evidence I, II-1, II-2, II-3, and III] is based on the U.S. Preventive Services Task Force Appendix A Task Force Ratings<sup>4</sup> and is noted throughout this protocol in parentheses.) Yet, research on individual drugs of abuse remains lacking and difficult to perform. Pharmacokinetic data for most drugs of abuse in lactating women are sparse and based on small numbers of subjects and case reports.<sup>47</sup> Most illicit drugs are found in human milk, with varying degrees of oral bioavailability.<sup>47</sup> Phencyclidine hydrochloride has been detected in human milk in high concentrations,<sup>30</sup> as has cocaine,<sup>54</sup> leading to infant intoxication.<sup>11</sup> There is little to no evidence to describe the effects of even small amounts of other drugs of abuse and/or their metabolites in human milk on infant development aside from those discussed later.

## METHADONE

For pregnant and postpartum women with opioid dependence in treatment, methadone maintenance has been the treatment of choice in the United States, Canada,<sup>56</sup> and many other countries. In contrast to other substances, concentrations of methadone in human milk and the effects on the infant have been studied. The concentrations of methadone found in human milk are low, and all authors have concluded that women on stable doses of methadone maintenance should be encouraged to breastfeed if desired, irrespective of maternal methadone dose.\* (II-1, II-2, II-3) Previously, no apparent effects of methadone exposure prenatally and in human milk were reported on infant neurobehavior at 30 days.<sup>27</sup> Recently an ongoing longitudinal follow-up study of methadone-exposed infants with 200 methadone-exposed and nonexposed, demographically matched families has shown neurocognitive delays in methadone-exposed 1-month-old infants compared with nonexposed infants. When retested at 7 months, methadone-exposed infants were similar to nonexposed, comparison infants. At 9 months of age, 37.5% of this sample of methadone-exposed infants showed clinically significant motor delays ( $\pm 1.5$  standard deviation) compared with low but typical development in the comparison group.<sup>36</sup> Exposed infants typically have high environmental risk profiles, which continue at birth, posing ongoing risk to the developing child.

The current thought is that environmental risk factors combine with prenatal exposures to promote epigenetic changes in gene expression and methylation patterns that have both immediate and long-term implications related to developmental programming.<sup>28</sup> Note that these findings relate to infants exposed to methadone both prenatally and after birth via breastfeeding, and there is little information available on infants with chronic methadone exposure via breastfeeding alone.

In addition, about 70% of infants born to women prescribed methadone during pregnancy will experience neonatal abstinence syndrome (NAS),<sup>32</sup> the constellation of signs and symptoms often presenting following in utero opioid exposure. Infants with significant NAS can experience difficulties with attaching and sucking/swallowing during breastfeeding that can impact their ability to breastfeed. However, given that there is increasing evidence supporting the conclusion that there is a reduction in the severity and duration of treatment of NAS when mothers on methadone maintenance therapy breastfeed, breastfeeding for these dyads should be encouraged.<sup>53,7,1,27</sup> (II-1, II-3) Unfortunately, the rate

of breastfeeding initiation in this cohort is generally low, less than half that reported in the U.S. general population.<sup>52</sup> A small recent qualitative study demonstrated that lack of support from the health care community and misinformation about the dangers of breastfeeding while on methadone therapy are significant, yet modifiable, barriers to breastfeeding success in these women.<sup>13</sup> Given the benefits to these mothers and infants to remain on methadone maintenance therapy and breastfeed, it is important for us to provide robust ongoing support for this vulnerable group.

## BUPRENORPHINE

Buprenorphine is a partial opioid agonist used for treatment of opioid dependency during pregnancy in some countries and increasingly in the United States. Multiple small case series have examined maternal buprenorphine concentrations in human milk. All concur that the amounts of buprenorphine in human milk are small and are unlikely to have short-term negative effects on the developing infant.<sup>26,19,38,29,18,43</sup> In one study, 76% of 85 maternal-infant pairs breastfed, with 66% still breastfeeding 6 to 8 weeks postpartum. The breastfed infants had less severe NAS and were less likely to require pharmacological intervention than the formula-fed infants, similar to methadone discussed earlier, although this did not reach statistical significance with the size of the sample studied.<sup>43</sup>

## OTHER OPIOIDS

Use of opioids in the United States has increased substantially over the past decade. A retrospective cross-sectional analysis of NAS in hospital births in the years from 2000 to 2009 found an increase in incidence from 1.2 to 3.39 per 1000 births. Antepartum maternal opioid use was also found to have risen from 1.19 to 5.63 per 1000 hospital births from 2000 to 2009; any use of opioids was included in data collection.<sup>44</sup> A recent Centers for Disease Control and Prevention Morbidity and Mortality Weekly Report highlighted data demonstrating that approximately one third of women of reproductive age filled a prescription for opioids each year between 2008 and 2012.<sup>10</sup>

When use of narcotics during pregnancy is determined to be consistent with an opioid use disorder rather than a modality for short-term pain relief, consideration of initiation of maintenance methadone or buprenorphine as previously discussed is strongly encouraged,<sup>56,2,57</sup> and these mothers should be supported in breastfeeding initiation. (III) Short courses of most other low-dose prescription opioids can be safely used by a breastfeeding mother,<sup>41,22</sup> but caution is urged with

\*Refs. 53,55,39,6,7,1,27,40,36,28.

codeine, as CYP2D6 ultra-rapid metabolizers may experience high morphine (metabolite) blood levels, and there has been a single case report of a breastfeeding neonatal death after maternal use.<sup>37</sup> (III) Information is lacking on the safety of breastfeeding when moderate to high doses of opioids are used for long periods of time. There is also a lack of information available about transitioning mothers from short-acting opioids to opioid maintenance therapy while breastfeeding rather than during pregnancy.

## MARIJUANA

Uniform guidelines regarding the varied use of marijuana by breastfeeding mothers are difficult to create and cannot hope to cover all situations. The legality of possessing and using marijuana varies greatly from country to country; in the United States, there are increasing numbers of states where it is legal for "medicinal use" with a prescription, and a few states where it is legal for "recreational use," but under federal law, it remains illegal in all states. Therefore, basing recommendations on marijuana use and concurrent breastfeeding from a purely legal standpoint becomes inherently complex, problematic, and impossible to apply uniformly across all settings and jurisdictions. As laws shift and marijuana use becomes even more common in some areas, it becomes increasingly important to carefully weigh the risks of initiation and continuation of breastfeeding while using marijuana with the risks of not breastfeeding while also considering the wide range of occasional, to regular medical, to heavy exposure to marijuana.

In addition to the potential legal risk, the health risks to the infant from the mother's marijuana use must be carefully considered. Δ9-Tetrahydrocannabinol (THC), the main compound in marijuana, is present in human milk up to eight times that of maternal plasma levels, and metabolites are found in infant feces, indicating that THC is absorbed and metabolized by the infant.<sup>45</sup> It is rapidly distributed to the brain and adipose tissue and stored in fat tissues for weeks to months. It has a long half-life (25 to 57 hours)<sup>21</sup> and stays positive in the urine for 2 to 3 weeks,<sup>21</sup> making it impossible to determine who is an occasional versus a chronic user at the time of delivery by urine toxicology screening. Evidence regarding the effects of THC exposure on infant development via breastfeeding alone is sparse and conflicting,<sup>5,49</sup> and there are no data evaluating neurodevelopmental outcomes beyond the age of 1 year in infants who are only exposed after birth. Also notable in this discussion of risk is that the potency of marijuana has been steadily increasing, from about 3% in the 1980s to 12% in 2012, so data from

previous studies may no longer even be relevant.<sup>51</sup> Additionally, current concern over marijuana use during lactation stems from possible infant sedation and maternal inability to safely care for her infant while directly under its influence; however, this remains a theoretical problem and has not been well established in the literature.<sup>24</sup>

Human and animal evidence examining the behavioral and neurobiological effects of exposure to cannabinoids during pregnancy and lactation shows that the endocannabinoid system plays a crucial role in the ontogeny of the central nervous system and its activation, during brain development. As Campolongo et al.<sup>8</sup> concluded, cannabinoid exposure during critical periods of brain development can induce subtle and long-lasting neurofunctional alterations. Several preclinical studies highlight how even low to moderate doses during particular periods of brain development can have profound consequences for brain maturation, potentially leading to long-lasting alterations in cognitive functions and emotional behaviors.<sup>8</sup> Exposure to second-hand marijuana smoke by infants has been associated with an independent two times possible risk of sudden infant death syndrome (SIDS)<sup>31</sup> (III); because breastfeeding reduces the risk of SIDS, this needs to be additionally considered. Thus careful contemplation of these issues should be fully incorporated into the care plans of the lactating woman in the setting of THC use. Breastfeeding mothers should be counseled to reduce or eliminate their use of marijuana to avoid exposing their infants to this substance and advised of the possible long-term neurobehavioral effects from continued use. (III)

## ALCOHOL

Use of alcohol during pregnancy is strongly discouraged, as it can cause fetal alcohol syndrome, birth defects, spontaneous abortion, and premature births, among other serious problems.<sup>3,9</sup> (III) Many women who significantly decrease or eliminate their alcohol intake during pregnancy may choose to resume consuming alcohol after giving birth, with approximately half of breastfeeding women in Western countries reported to consume alcohol at least occasionally.<sup>20</sup> Alcohol interferes with the milk ejection reflex, which may ultimately reduce milk production through inadequate breast emptying.<sup>34</sup> (III) Human milk alcohol levels generally parallel maternal blood alcohol levels, and studies evaluating infant effects of maternal alcohol consumption have been mostly mixed, with some mild effects seen in infant sleep patterns, amount of milk consumed during breastfeeding sessions, and early psychomotor development.<sup>34</sup> (III) Possible long-term effects of alcohol in maternal milk remain

unknown. Most sources advise limiting alcohol intake to the equivalent of 8 oz of wine or two beers, and waiting 2 hours after drinking to resume breastfeeding.<sup>12,48,47,57</sup> (III) To ensure complete elimination of alcohol from breastmilk, mothers may consult a nomogram devised by the Canadian Motherisk program to determine length of time needed based on maternal weight and amount consumed.<sup>33</sup> (III)

## TOBACCO

Approximately two thirds as many pregnant women as nonpregnant women smoke tobacco, with decreasing numbers of women smoking as pregnancy progresses.<sup>46</sup> Many mothers quit during pregnancy, but postpartum relapse is common, with about 50% resuming tobacco use in the first few months after birth.<sup>58,35,50</sup> Data on the epidemiology of breastfeeding mothers who smoke cigarettes remains complex, and smoking in many series has been found to be associated with reduced rates of breastfeeding.<sup>25,42</sup> Nicotine and other compounds are known to transfer to the infant via milk, and considerable transfer of chemicals via second-hand smoke also occurs when infants are exposed to environmental tobacco smoke. Increases in the incidence of respiratory allergy in infants and in SIDS are just two significant well-known risks of infant exposure to environmental tobacco smoke.<sup>16</sup> (III) Most sources endorse promotion of breastfeeding in the setting of maternal smoking while vigorously supporting smoking cessation.<sup>15</sup> (III) Some smoking cessation modalities (nicotine patch, nicotine gum, and possibly bupropion) are compatible with breastfeeding and can be encouraged in many circumstances.<sup>48,47,23</sup> (III)

## Recommendations

---

### GENERAL (CIRCUMSTANCES FAVORABLE WITH CONSIDERATION)

Infants of women with substance use disorders, at risk for multiple health and developmental difficulties, stand to benefit substantially from breastfeeding and human milk, as do their mothers. A prenatal plan preparing the mother for parenting, breastfeeding, and substance abuse treatment should be formulated through individualized, patient-centered discussions with each woman. This care plan should include instruction in the consequences of relapse to drug or excessive alcohol use during lactation, as well as teaching regarding potential for donor milk, formula preparation, and bottle handling and cleaning should breastfeeding be or become contraindicated. In the perinatal period

each mother-infant dyad should be carefully and individually counseled on breastfeeding prior to discharge from maternity care. This evaluation must consider several factors, including (III)

- drug use and substance abuse treatment histories, including medication-assisted treatment with methadone or buprenorphine;
- medical and psychiatric status;
- other maternal medication needs;
- infant health status (to include ongoing evaluation for NAS and impact on ability to breastfeed);
- the presence or absence and adequacy of maternal family and community support systems; and
- plans for postpartum care and substance abuse treatment for the mother and pediatric care for the child.

Optimally, the woman with a substance use disorder who presents a desire to breastfeed should be engaged in treatment pre- and postnatally. Maternal written consent for communication with her substance abuse treatment provider should be obtained prior to delivery if possible. (III)

Any discussion with mothers who use substances with sedating effects should include counseling on safely caring for her infant and instruction on safe sleep practices. (III)

Encourage women under the following circumstances to breastfeed their infants (III):

- Engaged in substance abuse treatment; provision of maternal consent to discuss progress in treatment and plans for postpartum treatment with substance abuse treatment counselor; counselor recommendation for breastfeeding.
- Plans to continue in substance abuse treatment in the postpartum period.
- Abstinence from drug use for 90 days prior to delivery; ability to maintain sobriety demonstrated in an outpatient setting.
- Toxicology testing of maternal urine negative at delivery.
- Engaged in prenatal care and compliant.

### OPIOIDS/NARCOTICS

- Encourage stable methadone- or buprenorphine-maintained women to breastfeed regardless of dose.
- Management of mothers who use chronic opioid therapy for pain should be closely supervised by a chronic pain physician who is familiar with pregnancy and breastfeeding (III):
  - a. Length of time on these medications, total dose, and whether the medications were used during pregnancy should all help inform the

- decision of whether breastfeeding may be safely undertaken in certain cases.
- b. Judicious amounts of oral narcotic pain medication, when used in a time-limited situation for an acute pain problem, are generally compatible with continued breastfeeding if supervision and monitoring of the breastfeeding infant are adequate.<sup>41,22</sup>
  - Rapidly increasing narcotic dosing in a breastfeeding mother should prompt further evaluation and reconsideration of the safety of continued breastfeeding.

## NICOTINE

- Counsel mothers who smoke cigarettes after giving birth to reduce their intake as much as possible, and not to smoke around their infant, to reduce infant exposure to second-hand smoke. Smoking cessation and nicotine replacement modalities such as nicotine patches and gum may be useful for some mothers. (III)
- Give mothers who smoke tobacco additional support, as maternal smoking appears to be an independent and associated risk factor for non-initiation and early cessation of breastfeeding, to help ensure its success. (III)

## ALCOHOL

- Counsel mothers who wish to drink occasional alcohol that alcohol easily transfers into human milk. Recommendations from the American Academy of Pediatrics, the World Health Organization, and others advise waiting 90 to 120 minutes after ingesting alcohol before breastfeeding, or expressing and discarding milk within that time frame.<sup>12,48,47,57</sup> (III)

## CANNABIS (THC)

- Information regarding the long-term effects of marijuana use by the breastfeeding mother on the infant remains insufficient to recommend complete abstention from breastfeeding initiation or continuation based on the scientific evidence at this time. However, extrapolation from in utero exposure and the limited data available helps to inform the following recommendations (III):
  - a. Counsel mothers who admit to occasional or rare use to avoid further use or reduce their use as much as possible while breastfeeding, advise them as to its possible long-term neurobehavioral effects, and instruct them to avoid direct exposure of the infant to marijuana and its smoke.
  - b. Strongly advise mothers found with a positive urine screen for THC to discontinue

exposure while breastfeeding and counsel them as to its possible long-term neurobehavioral effects.

- c. When advising mothers on the medicinal use of marijuana during lactation, one must take into careful consideration and counsel on the potential risks of exposure of marijuana and benefits of breastfeeding to the infant.
- d. The lack of long-term follow-up data on infants exposed to varying amounts of marijuana via human milk, coupled with concerns over negative neurodevelopmental outcomes in children with in utero exposure, should prompt extremely careful consideration of the risks versus the benefits of breastfeeding in the setting of moderate or chronic marijuana use. A recommendation of abstaining from any marijuana use is warranted.
- e. At this time, although the data are not strong enough to recommend not breastfeeding with any marijuana use, we urge caution.

## GENERAL (CIRCUMSTANCES CONTRAINDICATED OR REQUIRING MORE CAUTION)

Counsel women under any of the following circumstances not to breastfeed (III):

- Not engaged in substance abuse treatment or engaged in treatment and failure to provide consent for contact with counselor.
- Not engaged in prenatal care.
- Positive maternal urine toxicology screen for substances other than marijuana at delivery [see (b) in the preceding list].
- No plans for postpartum substance abuse treatment or pediatric care.
- Women relapsing to illicit drug use or legal substance misuse in the 30-day period prior to delivery.
- Any behavioral or other indicators that the woman is actively abusing substances.
- Chronic alcohol use.

Evaluate carefully women under the following circumstances, and determine appropriate advice for breastfeeding by discussion and coordination among the mother, maternal care providers, and substance abuse treatment providers (III):

- Relapse to illicit substance use or legal substance misuse in the 90- to 30-day period prior to delivery.
- Concomitant use of other prescription medications deemed to be incompatible with lactation.
- Engaged later (after the second trimester) in prenatal care and/or substance abuse treatment.

- Attained drug and/or alcohol sobriety only in an inpatient setting.
- Lack of appropriate maternal family and community support systems.
- Report that they desire to breastfeed their infant to either retain custody or maintain their sobriety in the postpartum period.

In the United States, women who have established breastfeeding and subsequently relapse to illegal drug use are counseled not to breastfeed, even if milk is discarded during the time period surrounding relapse. There are no known pharmacokinetic data to establish the presence and/or concentrations of most illicit substances and/or their metabolites in human milk and effects on the infant, and this research is unlikely to occur given the ethical dilemmas it presents. The lack of pharmacokinetic data for most drugs of abuse in recently postpartum women with substance use disorders precludes the establishment of a "safe" interval after use when breastfeeding can be reestablished for individual drugs of abuse. Additionally, women using illicit substances in the postnatal period may exhibit impaired judgment and secondary behavioral changes that may interfere with the ability of the mother to care for her infant or to breastfeed adequately. Passive drug exposures may pose additional risks to the infant. Therefore, any woman relapsing to illicit drug use or legal substance misuse after the establishment of lactation should be provided an appropriate human milk substitute (donor milk, formula) and intensified drug treatment, along with guidance on how to taper milk production to prevent mastitis. (III)

The woman with a substance use disorder who has successfully initiated breastfeeding should be carefully monitored, along with her infant, in the postpartum period. Ongoing substance abuse treatment, postpartum care, psychiatric care when warranted, and pediatric care are important for women with substance use disorders. Lactation support is particularly important for infants experiencing NAS and their mothers. Communication among all care providers involved with the health, welfare, and substance abuse support of the mother and the child should provide an interactive network of supportive care for the dyad. (III)

## Recommendations for Future Research

1. Long-term randomized controlled trials or paired cohort evaluations of infants exposed to methadone or buprenorphine via human milk, including infant developmental assessments.
2. Further evaluations of maternal milk and plasma and infant plasma pharmacokinetic data regarding

prescription opioids and lactation, especially for mothers who were on chronic high-dose medications during pregnancy that are continued when breastfeeding.

3. Long-term controlled evaluations of infants exposed to marijuana via human milk, to include infants and later neurodevelopmental outcomes, including those exposed to marijuana in a controlled manner, such as with legalized medical marijuana.
4. Evaluation of nicotine replacement patches, gum, and vaporized cigarettes as substitutes for tobacco smoking in pregnant and lactating women, to determine if these can or should be widely recommended in place of tobacco products.

## APPENDIX L

# Glossary

### A

**Acinus** The tube leading to the smallest lobule of a compound gland; it is characterized by a narrow lumen.

**ACNM** American College of Nurse-Midwives.

**ACOG** American Congress of Obstetricians and Gynecologists.

**ACOP** American College of Osteopathic Pediatricians.

**Adipose tissue** See *Panniculus adiposus*.

**Afferent** Conducting inward to, or toward, the center of an organ, gland, or other structure or area. Applies to sensory nerves, arteries, and lymph vessels.

**AHRQ** See DHHS/Agency for Healthcare Research and Quality.

**Alactogenesis** Familial puerperal alactogenesis is a genetically transmitted, isolated prolactin deficiency.

**ALPP** Academy of Lactation Policy & Practice.

**Alveolus** A glandular acinus or terminal portion of the alveolar gland, where milk is secreted and stored, that measures 0.12 mm in diameter. From 10 to 100 alveoli, or tubulosacular secretory units, make up a lobulus.

**Ankyloglossia** A tight lingual frenulum (the membrane attaching the tongue to the bottom of the mouth). This condition is also referred to as *tongue-tie*. When the frenulum is tight, it can restrict the movement of the tongue, resulting in breastfeeding problems for some mothers and babies.

**Ampulla** Elastic portion of the duct, just proximal to the nipple, that expands as milk fills the breast.

**Apocrine** A term descriptive of a gland cell that loses part of its protoplasmic substance.

**Apt test** A test, named after its developer, performed on fresh blood to distinguish between

adult and fetal hemoglobin. The blood is suspended in saline, and an equal amount of 10% sodium hydroxide (NaOH) is added and mixed; adult hemoglobin turns brown, and fetal hemoglobin remains red. A control sample of known adult blood should also be tested for comparison.

**Arborization** Development of a branched arrangement or structure.

**Areola mammae** Areola. The pigmented area surrounding the papilla mammae, or nipple.

**Australian posture or position** A breastfeeding position where the baby is above the mother (or the mother is "down under" the baby—the reason for the name of the posture).

**Autophagic vacuole** Autophagosome. A membrane-bound body within a cell containing degenerating cell organelles.

### B

**BALT** Bronchus-associated immunocompetent lymphoid tissue, to which the mammary gland may act as an extension. See *GALT* and *MALT*.

**Basal lamina** The layer of material, 50 to 80 mm thick, that lies adjacent to the plasma membrane of the basal surfaces of epithelial cells. It contains collagen and certain carbohydrates. It is often called the *basement* membrane.

**Block nursing** Nursing on the same breast for two or more feedings without nursing or otherwise releasing milk from the other breast. This strategy is often used to decrease an overly abundant milk supply.

### C

**Casein** A derivative of caseinogen. The fraction of milk protein that forms the tough curd in cow's milk.

**CGBI** Carolina Global Breastfeeding Institute.

**CLC** Certified Lactation Counselor. Breastfeeding care provider who has completed a course of study resulting in certification as a lactation counselor.

**Cluster feeding** The tendency of young babies to have a cycle of short, closely spaced feedings interspersed with periods of rest or sleep.

**Colostrum** The first milk. This yellow, sticky fluid is secreted during the first few days postpartum and provides nutrition and protection against infectious disease with its high level of immune globulins. It contains more protein, less sugar, and much less fat than mature breast milk.

**Columnar secretory cell** A type of secretory cell in the shape of a hexagonal prism; it appears rectangular when sectioned across the long axis, the length being considerably greater than the width.

**Cooper's ligaments** Triangular ligaments stretching between the mammary gland, the skin, the retinacula cutis, the pectenial ligament, and the chorda obliqua. These ligaments underlie and support the breasts.

**Corpus mammae** The mammary gland, breast mass after freeing breast from deep attachments and removal of skin, subcutaneous connective tissue, and fat.

**Creamatocrit** Measurement for estimating the fat content and therefore the caloric content of a milk sample. A microhematocrit tube is filled with milk (usually a mix of foremilk and hindmilk) and spun in a microcentrifuge for 15 min. The layer of fat is measured as a percentage, as one measures a blood hematocrit.

**Cross nursing** When a lactating woman breastfeeds a baby who is not her own, often temporarily, in the role of a child care arrangement.

**Cuboidal secretory cell** A secretory cell that has similar height and breadth measurements.

**Cytokines** A generic term for nonantibody proteins that are part of the immune system; examples include interferon- $\gamma$  and interleukin 6.

**Cytosol** Cell fluid.

## D

**Doula** An individual who surrounds, interacts with, and aids the mother at any time within the period that includes pregnancy, birth, and lactation; this may be a relative, friend, or neighbor and is usually, but not necessarily, female. One who gives psychological encouragement and physical assistance to a new mother. These are lay individuals who train to assist the mother during labor and delivery.

## E

**Efferent** Carrying impulses away from a nerve center.

**Ejection reflex** A reflex initiated by the suckling of the infant at the breast, which triggers the pituitary gland to release oxytocin into the bloodstream. The oxytocin causes the myoepithelial cells to contract and eject the milk from the collecting ductules. Also called *let-down reflex* or *draught*.

**Engorgement** The swelling and distention of the breasts, usually in the early days of initiation of lactation, caused by vascular dilatation as well as the arrival of the early milk.

**Eosinophil** A granular leukocyte possessing large conspicuous granules in the cytoplasm and containing a bilobed nucleus.

## F

**Finger feeding** Stimulation of an infant's tongue with a finger to initiate sucking. A feeding tube attached to a syringe of milk along the finger will provide milk to the infant when suckling is correct.

**Foremilk** The first milk obtained at the onset of suckling or expression. It contains less fat than later milk of that feeding (i.e., the hindmilk).

## G

**Galactocele** A cystic tumor in the ducts of the breast that contains a milky fluid.

**Galactagogue** A material or action that stimulates the production of milk.

**Galactopoiesis** The development of milk in the mammary gland. The maintenance of established lactation.

**Galactorrhea** Abnormal or inappropriate lactation.

**Galactose** ( $C_6H_{12}O_6$ ). A simple sugar that is a component of the disaccharide lactose, or milk sugar.

**Galactosemia** A congenital metabolic disorder in which there is an inability to metabolize galactose because of a deficiency of the enzyme galactose-1-phosphate uridylyltransferase. It causes failure to thrive, hepatomegaly, and splenomegaly.

**GALT** Gut-associated lymphoid tissue to which the mammary gland may act as an extension. See *BALT* and *MALT*.

**Gigantomastia** The excessive enlargement of the breast beyond physiologic needs during pregnancy and lactation, usually of unknown cause. When it occurs in association with medications that cause galactorrhea (calcium-channel blockers), it can be reversed by stopping the drug.

**Glandular hypoplasia** Lack of breast growth during pregnancy. Nipples point downward, and there is a tubular shape to the breast, and little palpable glandular tissue. This occurs with failure of lactogenesis.

**Golgi apparatus** A specialized region of the cytoplasm, often close to the nucleus, that is composed of flattened cisternae, numerous vesicles, and some larger vacuoles. In secretory cells, it is concerned with packaging the secretory product. It is also probably concerned with the secretion of polysaccharides in some cells, but its full range of functions has not yet been elucidated.

## H

**Heterophagic vacuole** Heterophagosome. A membrane-bound body within a cell, containing ingested material.

**Hindmilk** Milk obtained later during the nursing period, that is, the end of the feeding. This milk is usually high in fat and probably controls appetite.

**Homocystinuria** A rare inborn error of amino acid metabolism characterized by mental deficiency, epilepsy, dislocation of the lens, growth disturbance, thromboses, and defective hair growth.

**Hyperadenia** The existence of mammary tissue without nipples.

**Hypergalactia** The excessive, uncontrolled production of milk over and above the needs of a suckling infant.

**Hyperlactation** An oversupply of milk beyond the needs or capacity of the infant.

**Hypermastia** The existence of accessory mammary glands.

**Hyperthelia** The existence of abundant, more or less developed nipples without accompanying mammary tissue.

## I

**Immunoglobulin** The protein fraction of globulin, which has been demonstrated to have immunologic properties. Immunoglobulins include IgA, IgG, and IgM. They are factors in breast milk that protect against infection.

**Induced lactation** Process by which a nonpuerperal female (or male) is stimulated to lactate.

## K

**Kosher** Food that is considered ritually fit according to Jewish law (concerning both the source and preparation of the food).

## L

**Lactiferous ducts** The main ducts of the mammary gland, which number from 15 to 30 and open onto the nipple. They carry milk to the nipple and are very elastic.

**Lactobacillus bifidus** Organism of the intestinal tract of breastfed infants.

**Lactocele** Cystic tumor of the breast caused by the dilatation and obstruction of a milk duct that is usually filled with milk.

**Lacto-engineering** The process of enhancing the nutrient value of human milk by adding nutrients obtained by drying and separating out specific nutrients, such as protein, from pooled human milk.

**Lactoferrin** An iron-binding protein of external secretions, including human milk. It inhibits the growth of iron-dependent microorganisms in the gut.

**Lactogenesis** Initiation of milk secretion.

**Let-down reflex** See *Ejection reflex*.

**Ligand** A low-molecular-weight substance that binds trace elements loosely for ready availability (e.g., zinc ligands in human milk).

**Lobulus** A subunit of the parenchymal structure of the breast made up of 10 to 100 alveoli, or tubulosaccular secretory units. From 20 to 40 lobuli make up a lobus.

**Lobus** A subunit of the parenchymal structure of the breast made up of 20 to 40 lobuli. From 15 to 25 lobuli are arranged like the spokes of a wheel with the nipple as the central point.

**Lymphocyte** A mature leukocyte derived through the intermediate stage of lymphoblast from the reticuloendothelium found in lymphatic tissue.

**Lyophilization** The process of rapidly freeze-drying a fluid in a vacuum, resulting in a solid.

## M

**MALT** Mucosal-associated lymphoid tissue, which includes gut, lung, mammary gland, salivary and lacrimal glands, and genital tract. There is traffic of cells between secretory sites. Immunization at one site may be an effective means of producing immunity at distant sites. See *GALT* and *BALT*.

**Mamilla** The nipple; any teatlike structure.

**Mammogenesis** Growth of the mammary gland.

**Mastalgia** Painful breasts.

**Mastitis** Inflammation of the breast, including cellulitis and, occasionally, abscess formation.

**Matrescence** The state of becoming a mother or motherhood as a new event in an individual's life.

**Megaloblastic anemia** Defective red blood cell formation caused by megaloblastic hyperplasia of the marrow; there are often megaloblasts, or primitive nucleated red blood cells, in the peripheral blood.

**Merocrine** Pertaining to the type of secretion in which the active cell remains intact while forming and discharging the secretory product.

**Mesencephalon** The midbrain.

**Methylmalonic aciduria** The condition of the urine being acidic from an accumulation of methylmalonic acid caused by an inborn error of metabolism.

**Milk fever** A syndrome of fever and general malaise associated with early engorgement of the breasts or with sudden weaning from the breast.

**Mitogen** A substance capable of stimulating cells to enter mitosis.

**Montgomery glands** Small prominences, sebaceous glands in the areola of the breast, which become more marked in pregnancy and lactation. They number 20 to 24 and secrete a fluid that lubricates the nipple and areola.

**Morgagni's tubercle** Small sinuses into which the miniature ducts of the Montgomery glands open in the epidermis of the areola.

**Myoepithelial cell** An epithelial cell, usually around a glandular acinus, in which part of the cytoplasm has contractile properties, serving to empty the sinus of its secretion.

## N

**Nonnutritive sucking** The act of suckling the breast with little or no secretion of milk. Infant may suckle when distressed or to be calmed or quieted.

**Nonpuerperal lactation** The production of milk in a woman who has not given birth.

**Nucleotides** Compounds derived from nucleic acid by hydrolysis and consisting of phosphoric acid combined with a sugar and a purine or pyrimidine derivative. The milk nucleotides are secreted from glandular epithelial cells.

## O

**Opsonic** Belonging to or characterized by opsonin, a substance in mammalian blood that has the power to render microorganisms and blood cells easier to absorb by phagocytes.

**Oxytocin** An octapeptide that is synthesized in the cell bodies of neurons, located mainly in the paraventricular nucleus and, in smaller amounts, in the supraoptic nucleus of the hypothalamus. Oxytocin stimulates the ejection reflex by the stimulation of the myoepithelial cells in the mammary gland.

## P

**Panniculus adiposus** Adipose tissue. The superficial fascia, which contains fatty pellicles.

**Papilla mammae** Mamilla. The nipple of the breast.

**Pareve (parve)** Food that does not include any meat or dairy derivatives. This includes milk from any mammal except human. Rabbis have defined human milk as pareve but have prohibited the mixing of human milk with other foods.

**Perinatal** Around birth. The time from conception through birth, delivery, lactation, and at least 28 days postpartum.

**Plasma cell** Cell derived from the B cell series, which manufactures and secretes antibodies.

**Prolactin** A hormone present in both males and females and at all ages. During pregnancy, it stimulates and prepares the mammary alveolar epithelium for secretory activity. During lactation, it stimulates synthesis and secretion of milk. At other ages and in the male, it interacts with other steroids.

## R

**Rachitic** Relating to, characterized by, or affected by rickets.

**Relactation** Process by which a woman who has given birth but did not initially breastfeed is stimulated to lactate (also applies to reinstituting lactation after it has been discontinued).

## S

**Squamous epithelium** A sheet of flattened, scale-like epithelium adhering edge to edge.

**Stroma** The connective tissue basis or framework of an organ.

**Suck training** A special technique developed to help an infant who cannot coordinate the undulating (peristaltic) motion of the tongue. See *finger feeding*.

**Switch nursing** Nursing in which the mother moves the baby from one breast to the other and back again during the feeding with the hope that this will stimulate the milk supply.

## T

**Tail of Spence** The axillary tail of the breast that can reach the axilla.

**Transitional milk** The milk produced early in the postpartum period as the colostrum diminishes and the mature milk develops.

**Tubuloalveolar** Having both tubular and alveolar qualities.

**Tubulosaccular** Having both tubular and saccular character.

**Turgescence** The swelling up of a part. The unusual turgid feeling that results from swelling with fluid.

## W

**Whey protein** Protein remaining when the curds of casein have been removed. The mixture of proteins present is complex and includes  $\beta$ -lactoglobulin and  $\alpha$ -lactalbumin and enzymes.

**Witch's milk** Product of neonatal galactorrhea or neonatal breast secretion caused by placental prolactin in the infant's circulation.

**CLINICAL KEY**

Smarter search. Faster answers.

# Smarter, Faster Search for Better Patient Care

**Unlike a conventional search engine, ClinicalKey is specifically designed to serve doctors by providing three core components:**

## 1 Comprehensive Content

The most current, evidence-based answers available for every medical and surgical specialty.

## 2 Trusted Answers

Content supplied by Elsevier, the world's leading provider of health and science information.

## 3 Unrivaled Speed to Answer

Faster, more relevant clinical answers, so you can spend less time searching and more time caring for patients.

**Start searching with ClinicalKey today!**
