## Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

## *Foreword*

---

The 5 years since the publication of the seventh edition of this excellent book have been a time of incredible advances in understanding several previously unknown physiologic and behavioral processes directly linked to or associated with breastfeeding and beautifully described in this new volume.

These findings change our view of the mother-infant relationship and signal an urgent need to completely review present perinatal care procedures. These new research results include the observation that, when an infant suckles from the breast, there is a large outpouring of 19 different gastrointestinal hormones, including cholecystokinin, gastrin, and insulin, in both mother and infant. Several of these hormones stimulate the growth of the baby's and the mother's intestinal villi, thus increasing the surface area for the absorption of additional calories with each feeding. The stimulus for these changes is touching the nipple of the mother or the inside of the infant's mouth. The stimulus in both infant and mother results in the release of oxytocin in the periventricular area of the brain, which leads to production of these hormones via the vagus nerve. These pathways were essential for survival thousands of years ago, when periods of famine were common, before the development of modern agriculture and the storage of grain.

The discovery of the additional significance of a mother's breast and chest to the infant comes from the studies of Swedish researchers who have shown that a normal infant, placed on the mother's chest, and covered with a light blanket, will warm or maintain body temperature as well as an infant warmed with elaborate, high-tech heating devices. The same researchers found that, when infants are skin-to-skin with their mothers for the first 90 minutes after birth, they hardly cry at all compared with infants who are dried, wrapped in a towel, and placed in a bassinet. In addition, the researchers demonstrated that if a

newborn is left quietly on the mother's abdomen after birth he or she will, after about 30 minutes, gradually crawl up to the mother's breast, find the nipple, self-attach, and start to suckle on his or her own.

It would appear that each of these features—the crawling ability of the infant, the absence of crying when skin-to-skin with the mother, and the warming capabilities of the mother's chest—evolved genetically more than 400,000 years ago to help preserve the infant's life.

Research findings related to the 1991 Baby Friendly Hospital Initiative (BFHI) of WHO and UNICEF provided insight into an additional basic process. After the introduction of the BFHI, which emphasized mother-infant contact with an opportunity for suckling in the first 30 minutes after birth and mother-infant rooming-in throughout the hospital stay, there has been a significant drop in neonatal abandonment reported in maternity hospitals in Thailand, Costa Rica, the Philippines, and St. Petersburg, Russia.

A key to understanding this behavior is the observation that, if the lips of an infant touch the mother's nipple in the first half hour of life, the mother will decide to keep the infant in her room 100 minutes longer on the second and third days of hospitalization than a mother whose infant does not touch her nipple in the first 30 minutes. It appears that these remarkable changes in maternal behavior are probably related to increased brain oxytocin levels shortly after birth. These changes, in conjunction with known sensory, physiologic, immunologic, and behavioral mechanisms, attract the mother and infant to each other and start their attachment. As pointed out back in the fifth edition, a strong, affectionate bond is most likely to develop successfully with breastfeeding, in which close contact and interaction occur repeatedly when an infant wishes and at a pace that fits the

needs and wishes of the mother and the infant, resulting in gratification for both. Thus breastfeeding plays a central role in the development of a strong mother-infant attachment when begun with contact immediately after birth, which in turn has been shown to be a simple maneuver to significantly increase the success of breastfeeding. All of these exciting findings provide further evidence of why breastfeeding has been so crucial in the past and deserves even strong support now.

In addition, the past few years have been associated with fundamental biochemical findings, including the importance of docosahexaenoic acid (DHA) in optimal brain development. All in all, the many new observations described in this eighth edition place milk and the process of breastfeeding in a key position in the development of many critical functions in human infants and their mothers. We salute the author for her special skill in bringing together these many unique and original observations in this new and most valuable book.

# Preface

---

Almost five decades ago, work began on the first edition of this text. Much has changed in the field of human lactation and in the world at large. The trickle of scientific work on the subject in 1975 has swollen into a river overflowing its banks. The Lactation Study Center at the University of Rochester has more than 50,000 documents in its database that describe peer-reviewed scientific studies and reports, and there are thousands more unfiled documents that recount individual experience and anecdotal reports of events. The field has abandoned the dogmatic rules about breastfeeding that demanded rigid scheduling of hospitalized dyads. Thoughtful contemplation and recognition of the variability of the human condition are recognized as key. Well-trained, skilled clinicians recognize the value of flexibility and the need for individualized care. The Baby Friendly Hospital Initiative BFHI, which was conceived to set women free from rigid dicta requires specific protocols and policies. Mothers tell their doctors that they cannot breastfeed because there are too many rules, an impression created by overzealous teaching of too much detail. Medicine, in the era of managed care, has come forth with care guidelines for one disease or circumstance after another. The electronic record has made recording care a rigid series of boxes to check. It consumes inordinate amounts of time that could be spent with the patient but hopefully will not return us to the rigid mandates of the 1950s. The Academy of Breastfeeding Medicine, founded for the promotion and support of breastfeeding, is 20 years old. It was designed to provide physicians around the world and from every discipline a forum for scientific learning and discussion about breastfeeding and human lactation. Its members form a nucleus of medical professionals dedicated to the advancement of breastfeeding. In December, 1997, the American Academy of Pediatrics proclaimed that

mothers should breastfeed for 6 months exclusively and then continue breastfeeding while introducing weaning foods through the first year and for as long thereafter as desired by mother and infant. The Section on Breastfeeding of the American Academy of Pediatrics reaffirmed that position in 2005 and again more strongly in 2010 statement. The AAP urged human milk for the premature infant in the reissued policy of 2010. The health care provider can promote these goals most effectively when armed with sufficient information. The AAP has provided the mandate that has driven progress.

The intent of this volume is to provide the basic tools of knowledge and experience that will enable a clinician to provide the thoughtful counseling and guidance to the breastfeeding family that is most applicable to that particular breastfeeding dyad and its circumstances, problems, and lifestyle. No protocol, however, should ever replace thinking.

As the field has become more complex, it is clear that one of the most difficult issues centers on infection in the mother or infant and sometimes both. Robert Michael Lawrence, MD, Clinical Professor of Pediatrics and Immunology at the University of Florida College of Medicine, has again produced the chapters on immunology and infectious disease, as well as Appendix F, to bring the most accurate information in these areas to these pages. He has also assisted in the editing of many other chapters. The drug chapter has been thoroughly revamped. It has been replaced with a chapter explaining drug pharmacology and physiology during lactation. Specific drug information is referenced in LACT-MED electronically available at the NIH website. The thousands of queries to the Lactation Study Center at the University of Rochester have served as a basis for new topics and new clinical discussions.

The eighth edition is secure in cyberspace. Gone are the days when cut and paste meant cut

with scissors and paste with glue. A process that used to be simple is much more complicated, now requiring the expertise of computer wizards. David Lawrence (my son, Rob's brother) entered every chapter digitally and created the extensive tables and charts, keyboarding with the speed of sound from raw, handwritten manuscript. In my office, Jane Eggiman printed copy after copy. Adina Flynn, a born computer wizard, rescued fresh data from library archives, searching out the many citations, bibliographies, and elusive details. I thank all

the lactation consultants and medical doctors who have called the center with their challenging clinical issues.

I continue to be grateful to Rosemary Disney (1923–2014) for the creation of the enduring breastfeeding symbol on the cover. I thank my friends and family who have tolerated my home and office in chaos with 23 piles of reprints, one for each chapter, spilling over the floor, along with boxes of reference books, pamphlets, and disks.

## CHAPTER 1

# *The Revolution in Infant Feeding*

---

There is a reason behind everything in nature.

ARISTOTLE

The discussion is over! Human milk is for the human infant. This bold statement was made by David Myers, MD, of the Agency for Healthcare Research and Quality (AHRQ) at the first Breastfeeding Summit on the twenty-fifth anniversary (2009) of the Surgeon General's Workshop on Breastfeeding originally held in 1984 in Rochester, New York.<sup>1</sup> The data confirming the benefits of breastfeeding for both infant and mother are overwhelming.

It has been further proclaimed by the American Academy of Pediatrics (AAP)<sup>2</sup> that it is not a matter of choice; it is a matter of public health. No longer are the major health agencies and organizations tip-toeing around the issue. Breastfeeding is the norm for infants across the entire world. Other choices are a compromise. Getting to this point in the third millennium has been an arduous task.

Breastfeeding has assumed a critical role in public health, child health, child nutrition, child survival, maternal health, and national and international strategies. Breastfeeding initiation rates have increased substantially, and duration rates have begun to improve. Discrepancies among cultures continue.

Scientists have provided the evidence-based data for clinicians to take an aggressive stand in promoting, protecting, and supporting breastfeeding. Women have heard the message and are making informed decisions to breastfeed their children. Peer support is becoming an important element of success in all socioeconomic groups. Programs continue to target high-risk groups who have not been breastfeeding in recent decades.

This movement is not without obstacles. The fear of inducing guilt in those who do not choose to breastfeed is still a major defense that health

care providers use for not mentioning it. There is no scientific evidence to support this position, and there is evidence that women do not feel guilty when they have made an informed decision. Other barriers are presented by formula manufacturers that have been hastily developing additives for formula in an effort to advertise cow milk and soy milk formulas as similar to human milk, even though the benefits of mother's milk are significant.

Scientists and clinicians confronted with questions of infant nutrition are also being challenged in the popular press by reporters and freelance writers, some of whom may even represent mothers with personal arguments or vendettas. Decades have been spent in the laboratory deciphering the nutritional requirements of the growing neonate. A considerably greater investment in time, talent, and money has been put toward the development of an ideal substitute for human milk. At the same time, artificial feeding has been described as the world's largest experiment without controls.<sup>12</sup> In veterinary medicine, careful studies of the science of lactation in other species, especially bovine, have been performed because of the commercial significance of a productive herd.

Advances in technology have allowed the gathering of much data about human milk, which unarguably is best for human infants. More of the world's finest scientists have turned their attention to human lactation. Time and talent are providing a wealth of resource information about this remarkable fluid—human milk. Old dogmas are being reviewed in the light of new data, and previous data are being reworked with newer methods and technology. A worldwide interface for the

*Healthy People 2010* is a statement of national opportunities. Although the federal government facilitated its development, it is not intended as a statement of federal standards or requirements. It is the product of a national effort involving 22 expert working groups, a consortium that has grown to include almost 300 national organizations and all the state health departments and the Institute of Medicine of the National Academy of Sciences, which helped the U.S. Public Health Service to manage the consortium, convene regional and national hearings, and receive testimony from more than 750 individuals and organizations. After extensive public review and comment involving more than 10,000 people, the objectives were revised and refined to produce this report.

From U.S. Department of Health and Human Services: *Healthy People 2010* [Conference Edition in Two Volumes], Washington, DC, January 2000.

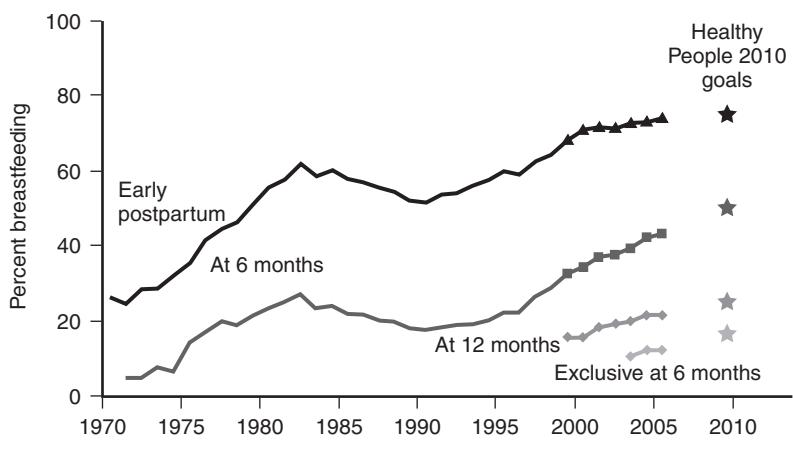

exchange of scientific information about issues of human lactation, breastfeeding, and human milk is developing. The more detail that is obtained about the specific macro- and micronutrients in human milk, the clearer it becomes that human milk is precisely engineered for the human infant.<sup>3</sup> A clinician should not have to justify a recommendation for breastfeeding; instead, a pediatrician should have to justify replacement with a cow milk substitute. Harnessing the expanding stream of scientific information into a clinically applicable resource has been challenged by the need to identify reproducible, peer-reviewed scientific information and to cull the uncontrolled, poorly designed studies and reports even though they have appeared in print. Many scientists were unable to publish credible work because the best journals had no space for the increasing numbers. The journal *Breastfeeding Medicine* was created to fill this need in 2006.

The *Healthy People 2020* goals,\* first published in 1978 and restated in 1989 and in 1999, recommend

that the nation increase the proportion of mothers who exclusively or partially breastfeed their babies in the early postpartum period to at least 75% and the proportion who continue breastfeeding until their babies are 5 to 6 months old to at least 50% ([Table 1-1](#)). Furthermore, at least 25% of babies should be breastfed at a year postpartum ([Figure 1-1](#)). A midcourse correction was developed by the Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) in 2005 to add a 3-month goal of 50% breastfeeding. The health goals for 2020 are shown in [Table 1-1](#). Focus groups, town meetings, and professional think tanks were working for several years to develop the new goals. The final draft can be found at <http://www.womenshealth.gov/breastfeeding>.

The report further states that special populations should be targeted (see [Table 1-1](#)) because breastfeeding is the optimal way of nurturing infants and simultaneously benefiting the lactating mother, and minority populations have continued to lag behind the majority in every category. Former Surgeon General of the United States C. Everett Koop stated in 1984, "We must identify and reduce the barriers which keep women from beginning or continuing to breastfeed their infants."<sup>6</sup>

\**Healthy People 2000: National health promotion and disease prevention objectives*, DHHS Pub. No. (PHS) 91-50213. Washington, DC, 1990, U.S. Department of Health and Human Services, Public Health Service, U.S. Government Printing Office.

**Figure 1-1.** National trends in rate of breastfeeding. Data source: pre-1999, Ross Mothers Survey<sup>2,4,5</sup>; 1999-present, CDC, NIS. (Modified from Grummer-Strawn LM, Shealy KR: Progress in protecting, promoting, and supporting breastfeeding. *Breastfeeding Med* 4(Suppl 1):533, 2009.)

Former Surgeon General David Satcher developed the Health and Human Services Blueprint for Action on Breastfeeding in 2000, saying, "Breastfeeding is one of the most important contributions to infant health. In addition, breastfeeding improves maternal health and contributes economic benefits to the family, health care system, and work place."<sup>7</sup>

Each surgeon general has taken a strong and visible stand on breastfeeding. In 2011, the U.S. Department of Health and Human Services released "The Surgeon General's call to action to support breastfeeding." This report is available at <http://www.surgeongeneral.gov/library/calls/breastfeeding/index.html> (accessed 11 Dec 2014).

Another targeted need for the nation was public education about the subject.<sup>8</sup> To put breastfeeding in the mainstream and to classify it as normal behavior, education has to start with preschoolers and continue through the educational system. Courses in biology, nutrition, health, and human sexuality should include the breast and its functions.

New York State has taken a leadership position for education of its youth. In 1994, a curriculum from kindergarten through twelfth grade was jointly developed by the Department of Education and the Department of Health\* and reviewed by teachers and school districts. The curriculum is not a separate course but provides recommendations about how to include age-appropriate information on breastfeeding and human lactation throughout the school years. The senior high-school materials are more detailed and are designed

to be included in subject matter regarding reproduction and family life.

This commitment to policy for breastfeeding has been part of the Code for Infant Feeding of the World Health Assembly, described as the World Health Organization Code (WHO Code). The WHO Code seeks to protect developing countries from being inundated with formula products, which discourage breastfeeding, because infant survival in these countries depends on being nourished at the breast.<sup>9-12</sup>

Although the major countries of the world endorsed the WHO Code in 1981, the United States did not. Finally, on May 9, 1994, President Clinton supported the worldwide policy of the WHO International Code of Marketing of Breast Milk Substitutes by joining with the other member nations at the World Health Assembly in Geneva, signaling a tremendous policy shift. Despite many efforts by the United States, Italy, and Ireland to add weakening amendments, the Swaziland delegation, speaking for the African nations, voted to strengthen the resolution even more, and all amendments were dropped. One by one, all the countries, including the United States, agreed to Resolution 47.5, and it was ratified.<sup>13</sup>

The battle to control formula distribution worldwide has not been won. The pandemic of acquired immunodeficiency syndrome (AIDS) has provided a new reason to distribute formula to developing countries to stop the spread of human immunodeficiency virus (HIV) to infants from their HIV-positive mothers. Careful studies of the issues have proved that exclusive breastfeeding is protective for the first 6 months of life. It is the addition of herbal teas and other foods that irritate the gut and allow invasion by the virus.

**Box 1-1** provides a summary of interventions presented at the Surgeon General's Workshop.<sup>1</sup>

\*New York State Health Department: Breastfeeding: first step to good health—a breastfeeding education activity package for grades K-12. Albany, NY, 1995, NYS Health Research Inc.

A federally funded national conference held in 1994 in Washington, DC, came to the same conclusions as in 1984. A conference held in Washington, DC, sponsored by the Academy of Breastfeeding Medicine (ABM) and the Kellogg Foundation focused on a follow-up 25 years after the original Surgeon General's Workshop looked

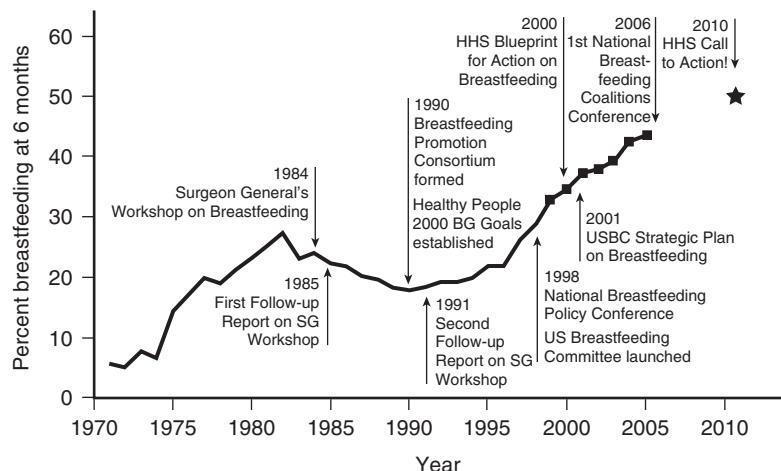

at disparity issues. Progress is illustrated in Figure 1-2.

Although these recommendations have been promoted since 1984, many hospitals and health care facilities have not achieved them.<sup>14</sup> As a result, United Nations Children's Fund (formerly United Nations International Children's Emergency Fund,

### **BOX 1-1. Key Elements for Promotion of Breastfeeding in the Continuum of Maternal and Infant Health Care**

1. Primary care settings for women of childbearing age should have:
  - A supportive milieu for lactation
  - Educational opportunities (including availability of literature, personal counseling, and information about community resources) for learning about lactation and its advantages
  - Ready response to requests for further information
  - Continuity allowing for the exposure to, and development over time of, a positive attitude regarding lactation on the part of the recipient of care
2. Prenatal care settings should have:
  - A specific assessment at the first prenatal visit of the physical capability for, and emotional predisposition to, lactation. This assessment should include the potential role of the father of the child and other significant family members. An educational program about the advantages of, and ways of preparing for, lactation should continue throughout the pregnancy
  - Resource personnel—such as nutritionists/dietitians, social workers, public health nurses, La Leche League members, childbirth education groups—for assistance in preparing for lactation
  - Availability and utilization of culturally suitable patient education materials
  - An established mechanism for a predelivery visit to the newborn care provider to ensure initiation and maintenance of lactation
  - A means of communicating to the in-hospital team the infant-feeding plans developed during the prenatal course
3. In-hospital settings should have:
  - A policy to determine a patient's infant-feeding plan on admission or during labor
  - A family-centered orientation to childbirth, including the minimum use of intrapartum medications and anesthesia
  - A medical and nursing staff informed about, and supportive of, ways to facilitate the initiation and continuation of breastfeeding (including early mother-infant contact and ready access by the mother to her baby throughout the hospital stay)
  - The availability of individualized counseling and education by a specially trained breastfeeding coordinator to facilitate lactation for those planning to breastfeed and to counsel those who have not yet decided about their method of infant feeding
4. Postpartum ambulatory settings should have:
  - A capacity for telephone assistance to mothers experiencing problems with breastfeeding
  - A policy for telephone follow-up 1 to 3 days after discharge
  - A plan for an early follow-up visit (within first week after discharge)
  - The availability of lactation counseling as a means of preventing or solving lactation problems
  - Access to lay support resources for the mother
  - The presence of a supportive attitude by all staff
  - A policy to encourage bringing the infant to postpartum appointments
  - The availability of public-community-health nurse referral for those having problems with lactation
  - A mechanism for the smooth transition to pediatric care of the infant, including good communication between obstetric and pediatric care providers

## Breastfeeding progress: 1984-2009

**Figure 1-2.** Federal activities in support of breastfeeding (BF). HHS, U.S. Department of Health and Human Services; SG, surgeon general. (Modified from Grummer-Strawn LM, Shealy KR: Progress in protecting, promoting, and supporting breastfeeding. *Breastfeed Med* 4(Suppl 1):531, 2009.)

UNICEF) and WHO initiated the Baby Friendly Hospital Initiative, which has been implemented in developing countries with considerable success. **Box 1-2** lists the 10 steps to becoming a designated Baby Friendly Hospital. A joint WHO/UNICEF statement, *Protecting, promoting, and supporting breastfeeding*, describes suggested actions for maternity services.<sup>10</sup>

#### BOX 1-2. Toward Becoming a Baby Friendly Hospital: 10 Steps to Successful Breastfeeding

Every facility providing maternity services and care for newborn infants should:

1. Have a written breastfeeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breastfeeding.
4. Help mothers initiate breastfeeding within a half hour of birth.
5. Show mothers how to breastfeed and how to maintain lactation even if they should be separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in—allow mothers and infants to remain together—24 hours a day.
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers (also called dummies or soothers) to breastfeeding infants.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

In 1996, Evergreen Hospital in Kirkland, Washington, was the first Baby Friendly Hospital designated in the United States. This initiative has been reorganized and reestablished through Healthy Children, a not-for-profit organization that created Baby Friendly, USA. The program is slowly expanding. For certification for Baby Friendly, the hospital must provide evidence that it has met the 10 criteria (see **Box 1-2**) and must demonstrate its effectiveness to a visiting team of assessors. In 2014, hospitals in the United States with the Baby Friendly designation reached 200.

## The History of Breastfeeding

The world scientific literature, predominantly from countries other than the United States, includes many tributes to human milk. Early writings on infant care in the 1800s and early 1900s pointed out the hazards of serious infection in bottle-fed infants. Mortality charts were clear on the difference in mortality risk between breastfed and bottle-fed infants.<sup>15</sup> Only in recent years have the reasons for this phenomenon been identified in terms comparable with those used to define other antiinfectious properties. The identification of specific immunoglobulins and determination of the specific influence of the pH and flora in the intestine of the breastfed infant are examples. It became clear that the infant receives systemic protection transplacentally and local intestinal tract protection orally via the colostrum and mature milk. The intestinal tract environment of a breastfed infant continues to afford protection against infection by influencing the bacterial flora until the infant is

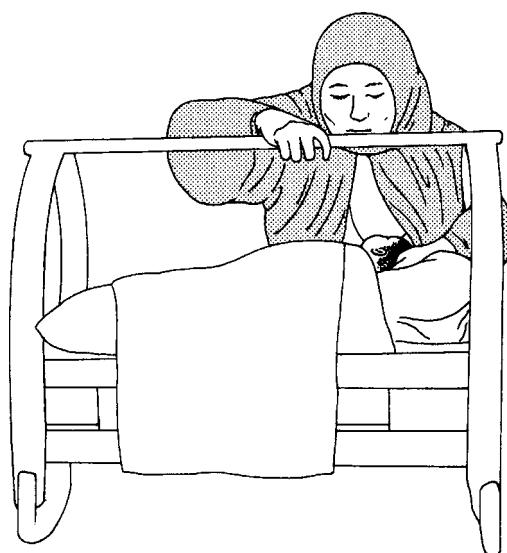

weaned. Breastfed infants also have fewer respiratory infections, occurrences of otitis media, gastrointestinal infections, and other illnesses. The immunologic protection afforded by specific antibodies such as respiratory syncytial virus and rotavirus also protects the infant from illness.

Refinement in the biochemistry of nutrition has afforded an opportunity to restudy the constituents of human milk. Attention to brain growth and neurologic development emphasizes the unique constituents of human milk that enhance the growth and development of the exclusively breastfed infant. Because the human brain doubles in size in the first year of life, the nutrients provided for brain growth are critical (see Chapter 7). A closer look at the amino acids in human milk has demonstrated clearly that the array is physiologically suited for the human newborn. Forced by legislation in the 1970s that mandated mass newborn screening for phenylalanine in all hospitals, physicians were faced with the problem of the newborn that had high phenylalanine or tyrosine levels. It became apparent that many traditional formulas provided an overload of these amino acids, which some infants were unable to tolerate even though they did not have phenylketonuria.

The mysteries and taboos about colostrum go back to the dawn of civilization.<sup>8</sup> Most ancient peoples let several days pass before putting the baby to the breast, with exact times and rituals varying from tribe to tribe. Other liquids were provided in the form of herbal teas; some were pharmacologically potent, and others had no nutritional or pharmacologic worth. Breastfeeding positions varied as well.<sup>14</sup> In most cultures, mothers held their infants while seated; however, Armenian and some Asian women would lean over the supine baby, resting on a bar that ran above the cradle for support (Figure 1-3). The infants were not lifted for the purpose of burping. Many groups carried infants on their backs and swung them into position frequently for feedings, a method that continues today. These infants are also not burped but remain semierect in the swaddling on the mother's back. The ritual of burping is actually a product of necessity in bottle-feeding because air is so easily swallowed.

Although modern women may be selectively chastised for abandoning breastfeeding because of the ready availability of prepared formulas, paraphernalia of bottles and rubber nipples, and ease of sterilization, this is not a new issue. Meticulous combing of civilized history reveals that almost every generation had to provide alternatives when the mother could not or would not nurse her infant.

Hammurabi's Code from about 1800 BC contained regulations on the practice of wet nursing, that is, nursing another woman's infant, often for

**Figure 1-3.** Armenian woman suckling her child. (Redrawn from Wickes IG: A history of infant feeding, *Arch Dis Child* 28:151, 1953.)

hire. Throughout Europe, spouted feeding cups have been found in the graves of infants dating from about 2000 BC.

Although ancient Egyptian feeding flasks are almost unknown, specimens of Greek origin are fairly common in infant burials. Paralleling the information about ancient feeding techniques is the problem of abandoned infants. Well-known biblical stories report such events, as do accounts from Rome during the time of the early popes. In fact, so many infants were abandoned that foundling homes were started. French foundling homes in the 1700s were staffed by wet nurses who were carefully selected and their lives and activities controlled to ensure adequate nourishment for the foundlings.

In Spartan times a woman, even if she was the wife of a king, was required to nurse her eldest son; plebeians were to nurse all their children.<sup>16</sup> Plutarch, an ancient scribe, reported that a second son of King Themistes inherited the kingdom of Sparta only because he was nursed with his mother's milk. The eldest son had been nursed by a stranger and therefore was rejected.

No known written works describe infant feeding from ancient times to the Renaissance.<sup>17</sup> In 1472, the first pediatric incunabulum, written by Paul Bagellardus, was printed in Padua, Italy. It described the characteristics of a good wet nurse and provided counseling about hiccups, diarrhea, and vomiting. Thomas Moffat (1584) wrote of the medicinal and therapeutic use of human milk for men and women of "riper years, fallen by age or by sickness into compositions." His writings

referred to the milk of the ass as being the best substitute for human milk at any age when nourishment was an issue. The milk of an ass is low in solids compared with that of most species, low in fat and protein, and high in lactose.

From AD 1500 to 1700, wealthy English women did not nurse their infants, according to Fildes,<sup>18</sup> who laboriously and meticulously reviewed infant feeding history in Great Britain. Although breastfeeding was well recognized as a means of delaying another pregnancy, these women preferred to bear anywhere from 12 to 20 babies than to breastfeed them.<sup>19</sup> They had a notion that breastfeeding spoiled their figures and made them old before their time. Husbands had much to say about how the infants were fed. Wet nurses were replaced by feeding cereal or bread gruel from a spoon. The death rate in foundling homes from this practice approached 100%.

The Dowager Countess of Lincoln wrote on "the duty of nursing, due by mothers to their children" in 1662.<sup>20</sup> She had borne 18 children, all fed by wet nurses; only one survived. When her son's wife bore a child and nursed it, the countess saw the error of her ways. She cited the biblical example of Eve, who breastfed Cain, Abel, and Seth. She also noted that Job 39:16 states that to withhold a full breast is to be more savage than dragons and more cruel than ostriches to their little ones. The noblewoman concluded her appeal to women to avoid her mistakes: "Be not so unnatural as to thrust away your own children; be not so hardy as to venture a tender babe to a less tender breast; be not accessory to that disorder of causing a poorer woman to banish her own infant for the entertaining of a richer woman's child, as it were bidding her to unlove her own to love yours."

Toward the end of the eighteenth century in England, the trend of wet nursing and artificial feeding changed, partially because medical writers drew attention to health and well-being and mothers made more decisions about feeding their young.

In eighteenth-century France, both before and during the revolution that swept Louis XVI from the throne and brought Napoleon to power, infant feeding included maternal nursing, wet nursing, artificial feeding with the milk of animals, and feeding of pap and panada.<sup>7</sup> Panada is from the French *panade*, meaning bread, and means a food consisting of bread, water or other liquid, and seasoning and boiled to the consistency of pulp (Figure 1-4). The majority of infants born to wealthy and middle-income women, especially in Paris, were placed with wet nurses. In 1718, Dionis wrote, "Today not only ladies of nobility, but yet the rich and the wives of the least of the artisans have lost the custom of nursing their infants." As early as

**Figure 1-4.** Pewter pap spoon, circa AD 1800. Thin pap, a mixture of bread and water, was placed in bowl. Tip of bowl was placed in child's mouth. Flow could be controlled by placing finger over open end of hollow handle. If contents were not taken as rapidly as desired, one could blow down on handle.

1705, laws controlling wet nursing required wet nurses to register, forbade them to nurse more than two infants in addition to their own, and stipulated that a crib should be available for each infant, to prevent the nurse from taking a baby to bed and causing suffocation.<sup>21</sup> On the birth of the Prince of Wales (later George IV) in 1762, it was officially announced: wet nurse, Mrs. Scott; dry nurse, Mrs. Chapman; rockers, Jane Simpson and Catherine Johnson.<sup>17</sup>

A more extensive historical review would reveal other examples of social problems in achieving adequate care of infants.<sup>22</sup> Long before our modern society, some women failed to accept their biologic role as nursing mothers, and society failed to provide adequate support for nursing mothers (Figure 1-5).<sup>\*</sup> Breastfeeding was more common and of longer duration in stable eras and rarer in periods of "social dazzle" and lowered moral standards. Urban mothers have had greater access to alternatives, and rural women have had to continue to breastfeed in greater numbers.<sup>12</sup>

In the 1920s, women were encouraged to raise their infants scientifically. "Raising by the book" was commonplace. The U.S. government published *Infant Care*, referred to as the "good book," which was the bible of child rearing read by women from all walks of life. It emphasized cod liver oil, orange juice, and artificial feeding. A quote from *Parents* magazine in 1938 reflects the attitude of women's magazines in general, undermining even the staunchest breastfeeders: "You hope to nurse him, but there are an alarming number of young mothers today who are unable to breastfeed their

\*The National Convention of France of 1793 passed laws to provide relief for infants of indigent families. The provisions are quite similar to those in our present-day welfare programs.<sup>23</sup>

**Figure 1-5.** Arnold Steam Sterilizer advertisement. (From *N Y Med J* June 22, 1895.)

babies and you may be one of them.<sup>24</sup> Apple detailed the transition from breastfeeding to raising children scientifically, by the book, and precisely as the doctor prescribes.<sup>25</sup>

There are encouraging trends, however. The acceptance or rejection of breastfeeding is being influenced in the Western world to a greater degree by the knowledge of the benefits of human milk and breastfeeding. Cultural rejection, negative attitudes, and lack of support from health professionals are being replaced by well-educated women's interest in child rearing and preparation for childbirth.<sup>26</sup> This has created a system that encourages a prospective mother to consider the options for herself and her infant.<sup>27-29</sup> The attitude in the Western world toward the female breast as a sex object to the exclusion of its ability to nurture has influenced young mothers in particular not to breastfeed. The emancipation of women, which began in the 1920s, was symbolized by short hair, short skirts, contraceptives, cigarettes, and bottle-feeding. In the second half of the twentieth century, women sought to be well informed, and many wanted the right to choose how they fed their infants.

The first action began in the 1940s when Edith Jackson, MD, of Yale University School of Medicine and the Grace-New Haven Hospital was awarded a federal grant to establish the First Rooming-In Unit in the United States. This project included the first program to prepare women for childbirth modeled after the British obstetrician Grantly Dick-Read's *Child Birth Without Fear*. This

was developed with the Department of Obstetrics to reduce maternal medication during birth and keep mother and baby alert and together. Of course, it included breastfeeding. Trainees from this program in Pediatrics and Obstetrics spread across the country starting programs elsewhere. Mothers chimed in when La Leche League was organized in the late 1950s. Professional organizations such as the AAP, American College of Obstetrics and Gynecology (ACOG), and American Academy of Family Practice (AAFP) were slow to speak out as they wrestled with the grip the formula companies had on medical education.

The great success of the mother-to-mother program of the La Leche League and other women's support groups in helping women breastfeed or, as with International Childbirth Education Association (ICEA), in helping women plan and participate in childbirth, is an example of the power of social relationships.<sup>30</sup> Raphael<sup>31</sup> described the doula as a "friend from across the street" who came by at the birth of a new baby to support the mother. She would "mother the mother." The doula is now known as a key person for lactation support, especially in the first critical days and weeks after delivery.

Bryant<sup>32</sup> explored the social networks in her study of the impact of kin, friend, and neighbor networks on infant-feeding practices in Cuban, Puerto Rican, and Anglo families in Florida. She found that these networks strongly influenced decisions about breastfeeding, bottle-feeding, use of supplements, and introduction of solid foods. Network members' advice and encouragement contributed to a successful lactation experience. The impact of the health care professional is inversely proportional to the distance of the mother from her network. The health care worker must work within the cultural norms for the network. For individuals isolated from their cultural roots, the health care system may have to provide more support and encouragement to ensure lactation success and adherence to health care guidelines.<sup>33</sup>

The trend in infant feeding among mothers who participated in the Women, Infants, and Children (WIC) program in the late 1970s and early 1980s was analyzed separately by Martinez and Stahl<sup>34,35</sup> from the data collected by questionnaires mailed quarterly as part of the Ross Laboratories Mothers Survey. The responses represented 4.8% of the total births in the United States in 1977 and 14.1% of the total births in the United States in 1980. WIC participants in 1977, including those who supplemented with formula or cow milk, were breastfeeding in the hospital in 33.6% of cases. A steady and significant increase occurred in the frequency of breastfeeding; it rose to 40.4% in 1980 ( $p < 0.5$ ). WIC data continue to be collected, and the trends have paralleled other groups.

The Food and Consumer Service (FCS) of the U.S. Department of Agriculture (USDA) entered into a cooperative agreement with Best Start, a not-for-profit social marketing organization that promoted breastfeeding to develop a WIC breastfeeding promotion project that was national in scope and implemented at the state level. The project consisted of six components: social marketing research, a media campaign, a staff support kit, a breastfeeding resource guide, a training conference, and continuing education and technical assistance. With an annual \$8 million budget for WIC, the project's goals are to increase the initiation and duration of breastfeeding among clients of WIC and to expand public acceptance and support of breastfeeding. Breastfeeding women are favored in the WIC priority system when benefits are limited; they can continue in the program for a year, but those who do not breastfeed are limited to 6 months. All pregnant participants of WIC are encouraged to breastfeed.

Montgomery and Splett<sup>36</sup> reported the economic benefits of breastfeeding infants for mothers enrolled in WIC. Comparing the costs of the WIC program and Medicaid for food and health care in Colorado, administrative and health care costs for a formula-fed infant minus the rebate for the first 180 days of life were \$273 higher than those for the breastfed infant. These calculations did not include the pharmacy costs for illness. When these figures were translated to large WIC programs in high-cost areas (e.g., New York City, Los Angeles) and multiplied by millions of WIC participants, the savings from breastfeeding were substantial (Table 1-2). If the goal of 75% breastfeeding women by the year 2010 had been realized among WIC recipients, the cost savings could have been at least \$4 million a month for the WIC program.<sup>36</sup> Since 2000, WIC programs have energetically promoted breastfeeding, but the street value of the package for bottle-feeders has been popular. A new WIC package has been developed and slowly supported through the system. It increased the food allowance for lactating women. Progress continues slowly.

The WIC program, through the extensive actions of the directors and staff, has increased the numbers of WIC mothers choosing to breastfeed. Many programs have hired and trained peer support mothers with breastfeeding experience to help other clients.

## Frequency of Breastfeeding

Data collected in the 1970s in the Ross Laboratories Mothers Survey MR77-48, which included 10,000 mothers, revealed a general trend toward breastfeeding.<sup>37</sup> In 1975, 33% of the mothers started out breastfeeding, and 15% were still breastfeeding at 5 to 6 months. In 1977, 43% of the

TABLE 1-2		Percentage of Breastfeeding among WIC Participants 1977 to 2002
Year	In Hospital (%)	At 6 Months of Age (%)
1977	33.6	12.5
1978	34.5	9.7
1979	37.0	11.2
1980	40.4	13.1
1981	39.9	13.7
1982	45.3	16.1
1983	38.9	11.5
1984	39.1	11.9

1986	38.0	10.7
1987	37.3	10.6
1988	35.3	9.2
1989	34.2	8.4
1990	33.7	8.2
1991	36.9	9.0
1992	38.8	10.1
1993	41.6	10.8
1994	44.3	11.6
1995	46.6	12.7
1996	46.6	12.9
1997	50.4	16.5
1998	56.8	18.9
1999	56.1	19.9
2000	56.8	20.1
2001	58.2	20.8
2002	58.8	22.1

Data collected from Martinez GA, Stahle DA: The recent trend in milkfeeding among WIC infants, *Am J Public Health* 72:68, 1982; Ryan AS, Rush D, Krieger FW: Recent declines in breastfeeding in the United States, 1984 through 1989, *Pediatrics* 88:719, 1991; Krieger FW: A review of breastfeeding trends. Presented at the Editor's Conference, New York, September 1992; Ross Laboratories Mothers Survey, unpublished data, Columbus, Ohio, 1992; Mothers Survey, Ross Products Division, Abbott Laboratories, unpublished data, 1998; Ryan AS: The resurgence of breastfeeding in the United States, *Pediatrics* 99:2, 1997 (electronic article); Mothers Survey, Ross Products Division, and Abbott Laboratories—Breastfeeding Trends 2002.

mothers left the hospital breastfeeding, and 20% were still breastfeeding at 5 to 6 months. Other studies have shown a regional variation, with a higher percentage of mothers breastfeeding on the West Coast than in the East.

A continuation of the study of milk-feeding patterns in 1981 in the United States by Martinez and Dodd<sup>34</sup> showed a sustained trend toward breastfeeding in 55% of the 51,537 new mothers contacted by mail. Although mothers who breastfeed continue to be more highly educated and have a higher income, the greatest increase in breastfeeding occurred among women with less education. From

1971 to 1981, breastfeeding in the hospital more than doubled (from 24.7% to 57.6%), with an average rate of gain of 8.8%. For infants 2 months old, breastfeeding more than tripled (from 13.9% to 44.2%) in this 10-year period ([Table 1-3](#)).

The National Natality Surveys (NNS) conducted by the CDC in 1969 and 1980 included questions for married women about infant-feeding practices after birth.<sup>38,39</sup> Questionnaires were mailed at 3 and 6 months postpartum. In 1969, 19% of white women and 9% of black women were exclusively breastfeeding. The highest rate was among white women up to 34 years old, with three to six children. In 1980, 51% of white women and 25% of black women were exclusively breastfeeding, and they were more highly educated and primiparous.<sup>39</sup>

The Ross surveys continue, and 725,000 surveys are mailed annually. The results have documented the persistent decline in the number of women initially breastfeeding, from a high in 1982 of 61.9% to an apparent low in 1991 of 51%, with the decline finally involving all categories of women, including those with higher socioeconomic status and higher education.

The Mothers Survey included 1.4 million questionnaires mailed in 2001, and this time two categories of questions were asked: any amount of breastfeeding and exclusive breastfeeding. Record high levels of any breastfeeding were reported: 69.5% initiation rate and 32.5% at 6 months postpartum with increases across all sociodemographic groups. The greatest increases were among young mothers (older than 20 years of age), the less educated, primiparous mothers, and those employed at the time of the survey. Mothers who practiced exclusive breastfeeding at hospital discharge (46.2%) and at 6 months (17.2%) were older and better educated.<sup>29</sup>

The CDC took an active role in gathering breastfeeding data in 1988 and gradually established a system for monitoring progress. The Breastfeeding Report Card was established, and the CDC's Maternity Practices in Infant Nutrition and Care (MPINC) survey assesses and scores how well maternity care practices at hospitals and birth centers support breastfeeding on a scale of 0 to 100—the higher the score, the better the practices. The national average from 2009 to 2011 increased from 65 to 70. The number of babies born in Baby Friendly Hospitals increased from less than 2% in 2008 to 6% in 2012.

## Ethnic Factors

The Pediatric Nutrition Surveillance System (PedNSS) is a child-based public health surveillance system that monitors the nutritional status of

low-income children in federally funded maternal and child health programs. The process begins in the clinic, it aggregates at the state level, and the data are submitted to the CDC for analysis. In 2001, 39 states, the District of Columbia, Puerto Rico, American Samoa, and six tribal governments participated, representing 5 million children from birth to 5 years of age; 37% of findings were from children younger than 1 year old from the six major ethnic groups.

In 2001, PedNSS reported 50.9% of children were ever breastfed, 20.8% were breastfed for at least 6 months, and 13.6% were breastfed for at least 12 months ([Figure 1-6](#)). Breastfeeding rates improved 45% from the 1992 rate of 34.9% across all racial and ethnic groups. The CDC has continued to monitor breastfeeding rates and issued a breastfeeding report card in 2007; 73.8% of infants born in 2004 were ever breastfed, and only 41.5% were still breastfeeding at 6 months and 20.9% at 12 months. Exclusive breastfeeding was 30.5% at 3 months and 11.3% at 6 months. [Tables 1-4](#) and [1-5](#) show the states that have met the 2010 breastfeeding objectives.<sup>9</sup>

International trends are difficult to summarize because definitions vary and population assessments may be more or less complete. In an effort to improve reporting and implement its global strategy, WHO has prepared a tool for assessing national practices, policies, and programs entitled, "Infant and Young Child Feeding in 2003." It is detailed and extensive and is available at <http://www.who.int/nutrition/publications/infantfeeding/9241562218/en/>.<sup>9</sup>

Breastfeeding practices in developing countries have been improving since 1990, according to population reports. The level of exclusive breastfeeding in the first 3 months increased 10% in 35 countries predominantly because mothers stopped the introduction of nonmilk foods so early. Malawi improved 59% in exclusive breastfeeding. The trend is to delay complementary foods until 6 months as recommended by WHO ([Table 1-6](#)). Still, exclusive breastfeeding dropped in Jordan, Benin, Turkey, Niger, and Rwanda. Surveys have continued to confirm the impact of breastfeeding on child survival. With other factors accounted for, an infant is four times more likely to die if a mother stops any breastfeeding at 2 to 3 months of age than an infant who continues to breastfeed. At 9 to 12 months, if the infant is not breastfed, the risk of death is 2.3 times greater ([Figure 1-7](#)).

Almost all infants in developing countries are at least partially breastfed in the first 3 months. In 56 countries, one third of infants are exclusively breastfed for 4 months. Breastfeeding to age 2 years with appropriate complementary feeding after 6 months contributes to good nutrition and the prevention of diarrhea. At 12 to 15 months, 78% are

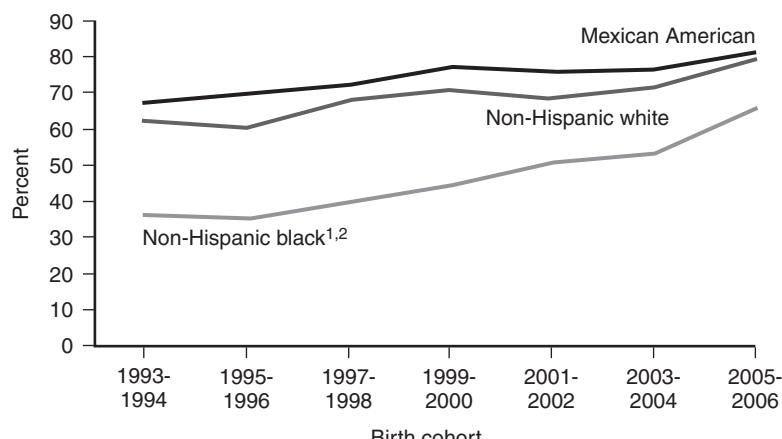

**TABLE 1-3** Summary of Federally Funded Datasets Assessing Breastfeeding Outcomes of Individuals

	<b>Methods</b>	<b>Format</b>	<b>Timing of Data Collection</b>	<b>Languages Conducted</b>	<b>Year Last Conducted</b>	<b>Frequency</b>	<b>Nationally Representative</b>
ECLS-B	Longitudinal study with cross-sectional assessment of breastfeeding status	In-person, computer assisted interviews +self-administered questionnaires	BF questions on 9 mo pp survey	English, Spanish, others if translator available	Ongoing with children born in 2001	Not previously conducted	Yes
IFPSII	Longitudinal	One brief telephone interview, multiple mailed questionnaires	Data collected prenatally, just after birth, 3 wk pp and 2, 3, 4, 5, 6, 7, 9, 10, 12 mo pp	English	2007	Previously conducted in 1993/1994	No, consumer opinion panel
NHANES	Cross-sectional	In-person	Variable, asked for each child $\leq$ 6 yr	English, Spanish, translator used for other languages	Ongoing	Biennial	Yes
NIS	Cross-sectional	Telephone interview for parents, mailed survey to MDs	19-35 mo pp	English, Spanish, others (1.7%) via AT&T language line	Ongoing	Annual	Yes
NSCH	Cross-sectional	Telephone	$\leq$ 6 yr	English, Spanish, others via AT&T language line	2007	Every 4 yrs	Yes
NSECH	Cross-sectional	Telephone interview	4-35 mo pp	English and Spanish	2000	One time survey	Yes
NSFG	Cross-sectional	In-person	Variable, asked for each child $\leq$ 18 yr	English	Ongoing	Annual	Yes
PedNSS*	Program-based surveillance	Utilized predominantly (86%) WIC data	Variable, assesses BF practices through 24 mo	English, Spanish, other languages spoken in WIC offices	Ongoing	Annual	No, reflects predominantly WIC participants from PedNSS contributors (approx 40 states, Washington DC, Puerto Rico, and 5 tribal governments)
PNSS*	Program-based surveillance	Utilizes predominantly (99%) WIC program data	2-5 mo pp	English, Spanish, other languages spoken in WIC offices	Ongoing	Annual	No, reflects WIC participants from PNSS contributors (approx 26 states, 5 tribal governments, 1 U.S. territory)
PRAMS	Cross-sectional	Predominantly mail, telephone follow-up with nonresponders	Surveyed approximately 2-6 mo pp	English and Spanish	Ongoing	Annual	Random sample in 37 participating states
WPPC	Cross-sectional	Utilizes WIC program data	6-13 mo pp	English, Spanish, and other languages spoken in WIC offices	2006 <sup>†</sup>	Biennial	No, reflects WIC population

Note: Numbers in bold are those that have met the *Healthy People 2010* goal.

From Centers for Disease Control and Prevention: *National immunization survey, 2004 births*, Washington, DC, 2007, U.S. Department of Health and Human Services. CDC: MMWR 56(30):760–763, 2007

breastfeeding and by 24 months only 45%. Mothers in sub-Saharan Africa and Asia are almost twice as likely to continue breastfeeding through the second year, as are those in other developing regions ([Tables 1-7 through 1-9](#)).

## Demographic Factors

The demographic factors associated with a higher incidence of breastfeeding have remained the same since the low point in the 1970s.<sup>25</sup> The rate for well-educated, higher socioeconomic status families was more than 80% initiation at birth in 2002 ([Table 1-10](#)). In 2002, 45.8% of the infants in this

group were still breastfeeding at 5 to 6 months of age and older with an average of all groups at 5 to 6 months of 32.5%. The rate among black women was 21.9% and among participants of WIC only 20.8% at 6 months, an increase in all groups.

Study after study has confirmed the relationship of breastfeeding to education, social status, marriage, and other demographic factors. The well-educated, well-to-do groups of all races breastfeed. In a study by Wright et al.<sup>17</sup> of 1112 healthy infants in a health maintenance organization (HMO) in Arizona, 70% were breastfed with a mean duration of almost 7 months. Education and marriage were associated with breastfeeding. Maternal employment

**Figure 1-7.** Effect of stopping breastfeeding on infant and child mortality. (Figure 2 from Zlidor VM, Gardner R, Rutstein SO, et al: *New survey findings: the reproductive revolution continues*, Population Reports, Series M, No 17, Baltimore, The Johns Hopkins Bloomberg School of Public Health, The INFO Project, Spring 2003; Rutstein S: *Effect of birth intervals on mortality and health*, Calverton, Maryland, Measure/DHS+, Macro International, Inc.)

outside the home and ethnicity (being Hispanic rather than white) were related to higher rates of bottle-feeding. The authors suggest that effects of ethnicity are independent of those of education. New immigrants who would have breastfed in their homeland tend to bottle-feed in the United States because they think this practice is "American."

Impoverished mothers choose to bottle-feed not because they are working; statistics show they are staying home and bottle-feeding. When mothers were interviewed about their infant feeding choice at a prenatal WIC clinic, they knew mother's milk was best.<sup>39</sup> They said it was too difficult to breastfeed and there were too many rules. In the classes on breastfeeding given by lactation experts, the

World Health Statistics 2009, Geneva, Switzerland, 2009, WHO Press.

## Duration of Breastfeeding

A sharp decline in breastfeeding occurs by age 6 months. Overall, 21.7% of infants were breastfed at 6 months in 1996, 41.5% in 2007 (a 50% improvement), and 47.2% in 2012 (Figures 1-8 and 1-9).

The two types of breastfeeding, as Newton<sup>42</sup> pointed out, are *unrestricted* and *token*. Unrestricted breastfeeding usually means that the infant is put to the breast immediately after delivery and breastfed on demand thereafter, without rules or limitations. There may be 10 or 12 feedings per day in the early weeks, with the number gradually decreasing over the first year of life. Breast milk continues to be a major source of nourishment during infancy.

BF, Breastfeeding; NA, not available.

Breastfeeding is considered exclusive when a child receives no food or liquid other than breast milk. Predominant breastfeeding is defined as infrequent feedings of vitamins, minerals, water, juice, or ritualistic feedings in addition to breast milk. No food-based fluids other than fruit juice or sugar water are allowed under this definition (Labbok<sup>40</sup> and World Health Organization.<sup>14</sup> Population Reports).

\*Exclusive: breast milk only.

†Predominant: breast milk and water and other nonmilk liquids.

‡Complemented: breast milk and solid or semisolid foods.

§Continued: any breastfeeding, independent of type of supplements.

||Data NA for 1998 survey.

FPL, Federal poverty level.

\*Sample sizes vary slightly because of missing data on some variables.

<sup>†</sup>The NSFG sample was limited to most recent singleton live births to women 18 to 44 years old at delivery. Weighted percentages are reported.

<sup>‡</sup>Tests were conducted to evaluate differences between NSFG and IFPS characteristics, which required that all variables be dichotomized. Multilevel variables were categorized by keeping one category and collapsing all others. The <sup>†</sup> for multilevel variables indicates the category that was kept and that it was significantly different across the two samples at  $p < 0.05$ . For dichotomous variables, the <sup>‡</sup> indicates that the variable was significantly different across samples.

<sup>c</sup>Category was kept and was not significantly different across the two samples.

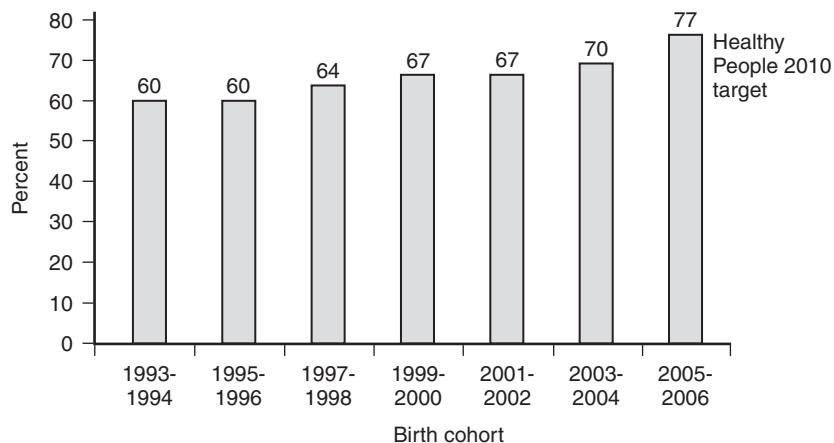

**Figure 1-8.** National trends in breastfeeding rates. (From Grummer-Strawn: Breastfeeding progress 1984–2009. *Breastfeeding Med* 4(Suppl):S32, 2009.) USA.

Token breastfeeding, in contrast, is characterized by constant restrictions on the time and duration of nursing. Usually the feedings are scheduled. Even the amount of mother-infant contact is limited initially, and the infant is often offered water or glucose water by bottle. Comparative studies

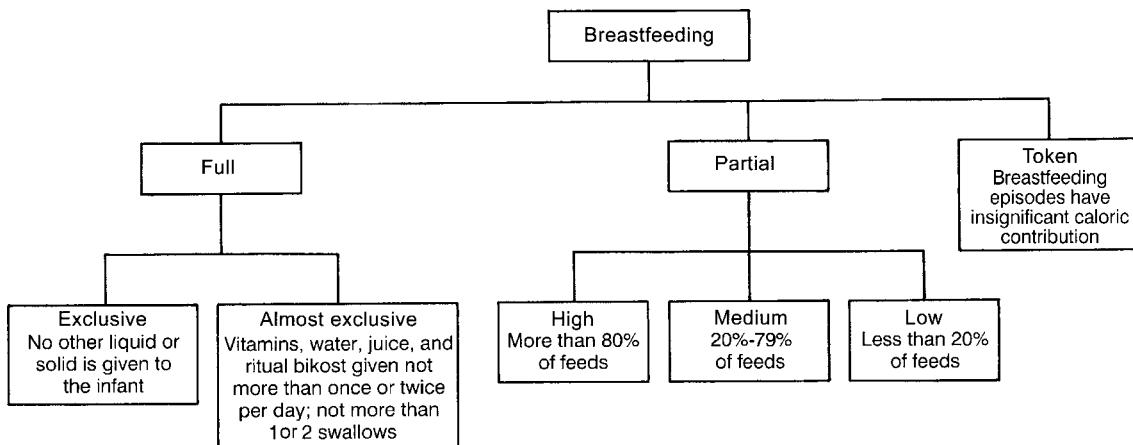

have been plagued with problems of definitions of breastfeeding.

In 1988, the Interagency Group for Action on Breastfeeding met to develop a set of definitions that could be used as standardized terminology for the collection of information on breastfeeding

*Note:* The trend over time is statistically significant.

**Figure 1-9.** Percentage of infants who were ever breastfed by birth cohort: United States, 1993 to 2006. (From U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Health Statistics.)

**Figure 1-10.** Schema for breastfeeding definition. Modified from Labbok M, Krasovec K: Toward consistency in breastfeeding definitions, *Stud Fam Plan* 21:226, 1990.

behavior. The recommendations were then reviewed extensively by researchers and providers, and a schema was finalized (Figure 1-10).<sup>43</sup>

1. Acknowledge that the term breastfeeding alone is insufficient to describe the numerous types of breastfeeding behavior.
2. Distinguish full from partial breastfeeding.
3. Subdivide full breastfeeding into categories of exclusive and almost-exclusive breastfeeding.
4. Differentiate among levels of partial breastfeeding.
5. Recognize that token breastfeeding has little or no nutritional impact.

The group hoped that the schema and framework would assist researchers and agencies in efforts to describe and interpret breastfeeding practices accurately (see Figure 1-10).

The definition of breastfeeding continues to be debated. The Breastfeeding Promotion Consortium (BFC) of the USDA and the United States Breastfeeding Committee (USBC) have put forth a document of final recommendations that these groups support. Different contexts in which breastfeeding is defined include benefit eligibility, surveillance, monitoring, policies, guidelines, and research. The results were presented in a complex report.<sup>44</sup>

Cultural differences also affect duration of breastfeeding.<sup>45</sup> In societies not yet industrialized that maintain ancient cultural patterns of child rearing, the duration is substantially more than a year. A study of 46 such societies by Ford<sup>46</sup> revealed that weaning at about 2 to 3 years of age occurred in three fourths of them. One fourth of the groups began weaning at 18 months of age, and one culture started at 6 months. A similar anthropologic investigation of primitive child-rearing practices found a

distinct correlation between the time of weaning and the behavior of the tribes.<sup>46</sup> In tribes in which weaning was delayed, the culture was peaceful. In contrast, tribes that abruptly weaned their infants at 6 months of age and practiced other rigid disciplinary practices were warlike.

When weaning practices were evaluated among 945 women in Guinea-Bissau, West Africa, the data revealed that all infants had been breastfed for at least 18 months. Among the reasons for terminating breastfeeding were that the child became ill, the mother became ill, or the mother became pregnant. By 23 months, weaning occurred because the infant was healthy and old enough.<sup>47</sup> Although there are few studies since the 1980s focusing on the reasons why women wean early, a study by Schwartz et al.<sup>28</sup> of women in Michigan and Nebraska revealed that the reasons for weaning are similar. They reported a prospective cohort study of 946 women over the first 12 weeks postpartum. The demographic features were similar to older studies. Women older than 30 years with a bachelor's degree were most likely to continue breastfeeding throughout the study. In the first 3 weeks, "not enough milk" was the most common reason to stop, and after 4 weeks the most common reason was a "return to work." ([Table 1-11](#)).

In a study by Ramos and Almeida<sup>48</sup> in a baby-friendly maternity hospital in Brazil, 24 mothers who weaned their infants by 4 months were interviewed in depth. The reasons for weaning were similar to studies from decades before: weak or little milk, problems with breasts (sore nipples), lack of experience, disparity between needs of mother and needs of the baby, and work. Earlier, House et al. described a sense of isolation and solitude on the part of the mother and need for support from health care providers and society in general.<sup>49</sup> They concluded that breastfeeding should be treated as an act to be learned by women and protected by society. These studies point out the pivotal role for the pediatrician in the successful maintenance of lactation and the importance of the postpartum environment<sup>10,49</sup> ([Tables 1-12](#) and [1-13](#)).

The positive and negative emotional and physical experiences of 152 long-term breastfeeding American and Canadian women were reported by Reamer and Sugarman.<sup>22</sup> This sample of mothers was randomly selected from 1038 women who responded to a request for volunteers in a La Leche League newsletter. All answered the eight-page questionnaire, which had 51 short-answer and 52 free-response questions. The respondents were older, better educated, predominantly white, and had belonged to the league at some time. The average age was 29.4 years, age at first child was 25, 77% had more than 1 year of college, and 44% had 4 or more years of college. Far fewer were

employed than the national average (13% full or part time versus 34% nationally). The average weaning age for the 339 children represented by this study was 18 months, with a range of 3 weeks to 5 years. At the time of the study, 136 children were still being breastfed. Two mothers thought there were no positive effects of prolonged nursing of their children, but others offered more than one perceived positive consequence ([Table 1-14](#)). Emotional security, happiness, mutual love, and future independence were the key positive outcomes of long-term nursing in the mothers' views. Good health was mentioned by 22%.

When asked to list the negative aspects of nursing longer than 6 months, 47% of mothers said there were none at 6 months, but only 26% of mothers had no negative feelings about nursing past 12 months. Perceived social hostility was the major negative effect, reported by 24% of mothers at 6 months and by 42% at 12 months ([Table 1-15](#)). Ninety percent felt there were no negative effects for the children. The social stigma has driven many well-educated, caring, dedicated mothers to conceal nursing, called "closet nursing." Unfortunately, this leads physicians and the public alike to think that breastfeeding in the United States terminates by 6 months of age.

## *Impact of Commercial Discharge Packs*

Several studies have evaluated whether commercial discharge packs result in diminished breastfeeding duration. Unfortunately, none of the studies was so well randomized and controlled that the answer was clear. The studies that did mention use of bottles in the hospital noted a stronger correlation between bottle use and diminished duration of breastfeeding.<sup>13</sup> What had not been measured was the impact of office prenatal formula advertising on breastfeeding. In a study by Howard et al.<sup>45</sup> of 547 women randomized to receive formula company gift packs or specially designed educational packs at their first prenatal visit, feeding method was recorded at delivery. The 294 women who chose to breastfeed were interviewed at 2, 6, 12, and 24 weeks postpartum. Women who received the commercial pack were more likely to discontinue breastfeeding by 2 weeks. Among women who had indefinite goals of breastfeeding for less than 12 weeks, exclusive, full, and overall breastfeeding duration were shortened.

In New York State, regulations regarding breastfeeding support instituted in July 1984, among other things, disallowed discharge packs to breastfeeding women unless requested by the mother or

<sup>§</sup> $\chi^2=4.40$ ; df=1; p<0.05.

Modified from Buxton KE, Gielen AC, Faden RR, et al: Women intending to breastfeed: predictors of early infant feeding experiences, *Am J Prev Med* 7:101, 1991.

A significant plank in the Baby Friendly ten steps is the banning of commercial discharge packs or supplies. This is strengthened by the requirement that the hospital pay market price for the formula it uses, in order to meet Baby Friendly Requirements.

**TABLE 1-14** Positive Consequences of Long-Term Nursing as Perceived by the Mother

Perceived Consequences	Mothers (n=130)	%*
Positive emotional effect on child; child is more secure	65	50.0
Better physical health (fewer allergies)	29	22.3
Child is loving, friendly, cheerier	27	20.8
Child can separate more easily; relative independence achieved with less stress	22	16.9
Enhanced maternal sensitivity	19	14.6
Close relationship of mother and child	18	13.8
Positive influence or education for older siblings	11	8.5
Child easily comforted during crisis, pain, or teething	10	8.0
Broad, all-encompassing positive effect	6	4.6
Incidental positive consequences	13	10.4
No positive effects perceived	2	1.5

\*Mothers could give multiple responses; thus percentages add up to more than 100%.

From Reamer SB, Sugarman M: Breastfeeding beyond six months: mothers' perceptions of the positive and negative consequences, *J Trop Pediatr* 33:93, 1987.

The real problem is inadequate counseling about breastfeeding and a system to support the mother who needs it. Baby Friendly addresses the counseling and support in the hospital but has yet to develop a substantial support system following discharge. WIC and other programs are making an effort to provide these services.

A force that is difficult to measure is the public advertising of infant formula, a direct violation of

**TABLE 1-15** Mothers' Responses to the Question, "What Do You Think Are the Negative Aspects of Nursing Past 6 Months (Past 1 Year)?"

Negative Aspects Listed by Mothers	Past 6 Months (Total Responses = 132)		Past 12 Months (Total Responses = 133)	
	No.	(%)	No.	(%)
Mother states there are no negative aspects	62	47.1	35	26.4
Social stigma; negative attitudes of others	32	24.3	56	41.9
Mother's activities are restricted	19	14.7	9	6.6

Breast discomfort/leaking, soreness	2	1.5	1	0.7
Sex life interrupted; less interest in sex	2	1.5	2	1.5
Mother believes she should ignore negative aspects	2	1.5	1	0.7
Intrudes upon mother's time with siblings	0	—	1	0.7
Baby care, not nursing, causes negative aspects	0	—	1	0.7

From Reamer SB, Sugarman M: Breastfeeding beyond six months: mothers' perceptions of the positive and negative consequences, *J Trop Pediatr* 33:93, 1987.

**TABLE 1-16** Savings and Costs Associated with Improved Breastfeeding from a Societal Perspective

Perspective	Savings	Costs
Infant and parent	Infant formula; physician copays; prescription copays; hospital deductible; over-the-counter medications; transportation costs; lost wages or sick child care; decreased quality of life associated with permanent sequelae of illnesses, e.g., hearing loss, short bowel; reduced intelligence quotient	Food intake of breastfeeding mother; breast pump; human breast milk storage
Employer	Less employee absence; less lost productivity; lower insurance premiums; less employee turnover; less employee recruitment	Breastfeeding room with breast pump and refrigerator; promotion of lactation program; work schedule flexibility
Payer	Fewer physician fees (minus copays); specialty referrals (minus copays); emergency room/urgent care visits (minus copays); prescriptions (minus copays); hospitalization (minus deductible); laboratory procedures; increased provider availability caused by lower visit rate of infants	Lactation consultant referrals; provider time used for breastfeeding counseling and management
Federal and state governments	Formula purchase for WIC program; medical care for children in Medicaid; worker productivity and global competition	Legislative or program costs to promote a breastfeeding-friendly culture

Breastfeeding has broad social and economic implications. Insufficient breastfeeding is expensive for the U.S. government, which finances infant nutrition through the Women, Infants, and Children (WIC) program and infant health care through the Medicaid program. Compared with formula-fed infants, infants enrolled in WIC who were breastfed saved \$478 each month in WIC costs and Medicaid expenditures during the first 6 months of life. Other costs, equally important but more difficult to measure, also must be considered, including long-term health concerns.

From Bell TM, Bennett DM: The economic impact of breastfeeding, *Pediatr Clin North Am* 48:253–262, 2001.

the letter and the intent of the WHO Code (see earlier discussion). Some formula companies have television advertisements that include a subliminal message that their product is equal to breastfeeding.<sup>50</sup> Furthermore, when the message says, "Just ask your doctor," it implies that physicians agree. Sending free samples and coupons aimed at a vulnerable woman 2 to 4 weeks postpartum, when she

is likely fatigued and overwhelmed, can undermine the confidence of even a dedicated breastfeeding mother. In addition to the pregnant woman or new mother, the audience consists of the world of television viewers. The daily repetition of the message that bottle-feeding is just as good as breastfeeding cemented the national image that it is "American" to bottle-feed.<sup>3</sup>

Infants in Latin America were less likely to be breastfed than infants in Africa and Asia, and the duration was 6 months compared with 12 months or more in Asia and Africa. A significant increase in the Latin American rates resulted after an aggressive breastfeeding promotion program (PROALMA) was initiated and supported by various governments.<sup>52,53</sup>

A number of hospital routines were found to be potentially detrimental to breastfeeding. These included interruption of mother-infant contact, supplementation, and restricted feedings. The AAP and the ABM have both prepared guidelines for hospital management to promote breastfeeding.

## *Attitudes of Health Care Professionals*

A 1980 survey of physicians' and nurses' medical and educational practices regarding breastfeeding was published when breastfeeding was at its zenith. A follow-up survey was completed in the summer of 1991, after several years of decline. A comparison of the results of these two surveys showed little change in the current practices of health care professionals regarding breastfeeding, their attitudes toward breastfeeding, and who among them they believed to be primarily responsible for managing breastfeeding and supporting breastfeeding mothers. Twenty years later, attitudes among professionals are very supportive.

In terms of responsibility for managing breastfeeding mothers and infants, more than 80% of pediatricians believed that medical encouragement or support of breastfeeding was primarily a responsibility of the infant's physician. Approximately two thirds of family practitioners thought that both the mother's physician and the infant's physician were responsible.

The respondents viewed the mother's employment as the main reason for the decline in breastfeeding.<sup>54</sup> Most obstetricians have always supported breastfeeding according to Queenan,<sup>53</sup> an active advocate of breastfeeding, but some have appeared to be neutral. He stated that mothers should be informed of the strikingly valuable health benefits of breastfeeding so the mother can make an informed choice; "It's your gift to the mother and it's her gift to her baby."<sup>53</sup> A follow-up study of pediatricians' attitudes and practices regarding breastfeeding in 1995 versus 2004, reported by Feldman-Winter et al.,<sup>55</sup> was included in the periodic Surveys of Fellows of the AAP. Fewer responses were received—875 (53.5%) compared to 1132 (70.7%)—in 1995. Feeding practices for their own children showed an increase in breastfeeding from 37% to 72% in 2004.

## *Morbidity and Mortality Studies in Breastfed and Artificially Fed Infants*

Assessing the mortality rate of breastfed infants compared with bottle-fed infants is difficult today because many breastfed infants also receive supplements of formula and solid foods. The risk of death in the first year of life diminished in developed countries in the twentieth century following the advent of antibiotics, additional immunizations, and many other advances in pediatric care.<sup>56</sup> Data from previous decades and other nations do show a significant difference, however.<sup>15</sup> Knodel<sup>57</sup> presented a complete table, including rates from cities in Germany, France, England, Holland, and the United States (Table 1-17). The mortality rate among breastfed infants is clearly lower than that among bottle-fed infants. Knodel<sup>57</sup> pointed out that early neonatal deaths, in the first week or so of life, were excluded. In the early twentieth century, posters that urged mothers to breastfeed that were part of the National Campaign to lower infant mortality rates were displayed everywhere by the health department without fear of inducing guilt in mothers. According to Wolf, the language was direct: "To lessen baby death let us have more mothers breastfeed"; "For your baby's sake, nurse it."<sup>17</sup> Little has changed in a century.

Woodbury<sup>58</sup> reported the trends in infant feeding (Figure 1-11) and in another study in 1922 reported mortality rates of infants by type of feeding. Mortality rate is lower at all ages for breastfed infants. Overwhelming evidence of the impact of human milk on mortality rate is displayed in the widely publicized statistics currently available on third world countries, where infant formulas have replaced human milk. The death rate is higher, malnutrition starts earlier and is more severe, and the incidence of infection is greater in formula-fed infants (Figures 1-12 and 1-13). Data from the work of Scrimshaw et al.<sup>29</sup> show a mortality rate of 950 of 1000 live births in artificially fed infants and 120 of 1000 in breastfed infants. The data were collected in Punjab villages from 1955 through 1959. The deaths were predominantly caused by diarrheal disease. The Pan American Health Organization has reported similar correlations among malnutrition, infection, and mortality. In the work by Puffer and Serrano<sup>52</sup> in 1973 in São Paulo, death rates among breastfed infants and proportions from diarrheal disease and malnutrition were also lower than among bottle-fed infants.

The incidence of illness or morbidity among artificially fed infants in third world countries is as dramatic as the mortality rate. Observations of

**TABLE 1-17** Mortality Rates and Survivorship to Age 1 Year in Breastfed and Artificially Fed Infants\*

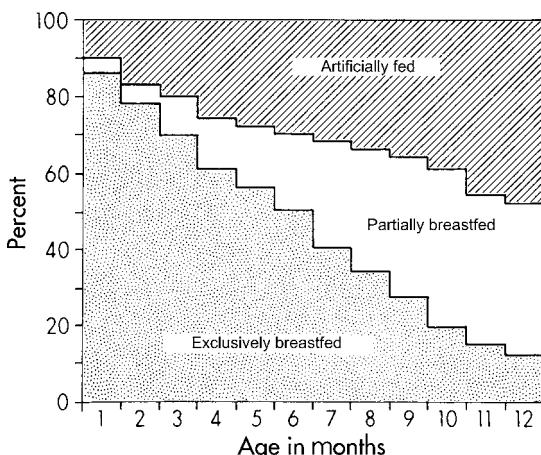

Study Area	Date	Mortality Rate (per 1000)		Survivors to Age 1 yr (per 1000)

Great Britain	1946-1947	9	18	991	982	9

\*Most of these rates do not include deaths in the first few days or weeks of life; mortality rate is therefore underestimated and survival rate overestimated. Only the rates for the eight U.S. cities in 1911 to 1916 represent mortality rate from birth; deaths that occurred before any feeding are proportionately allocated to the two feeding categories. The rates for Berlin, Bremen, Hanover, Cologne, and the eight U.S. cities were derived by applying life table techniques to mortality rates given by single months of age.

<sup>†</sup>Comparison of breastfed infants with infants artificially fed from birth.

<sup>‡</sup>Comparison of breastfed infants with all infants artificially fed in the period of observation.

**Figure 1-11.** Percentage of infants who were breastfed, partially breastfed, and artificially fed by age in months. (Modified from Woodbury RM: The relation between breast and artificial feeding and infant mortality, *Am J Hyg* 2:668, 1922.)

Arab villages in Israel showed hospitalization rates vary with method of feeding. Only 0.5% of breastfed infants required hospitalization; infants who were breastfed more than 3 months but less than 6 months had a 2.9% hospitalization rate, and infants who were bottle-fed had a 24.8% rate. This is a 50-fold difference.

There is a bias against bottle-feeding, because sicker, smaller infants are bottle-fed. Infants who

**Figure 1-12.** Death rate per 1000 infants by type of feeding and age in months. (Modified from Woodbury RM: The relation between breast and artificial feeding and infant mortality, *Am J Hyg* 2:668, 1922.)

die are weaned early by death. The benefits of breastfeeding are enhanced by these confounding variables. Habicht et al.<sup>23</sup> point out that had there been no breastfeeding in the sample, twice as many infants would have died after the first week of life. In 1968, Hill<sup>60</sup> articulated what many physicians believed: "Formula feeding has become so simple, safe, uniformly successful that breastfeeding no

### The message on breast-feeding isn't new

**Figure 1-13.** "Value of Natural Feeding" poster used in 1918 to educate parents. Text explains that the mortality rate of bottle-fed infants (Flaschenkinder) is seven times higher than that of breastfed infants (Brustkinder). (From Langstein R: *Atlas der Hygiene des Sauglings und Kleinkindes*, Berlin, 1918, Springer-Verlag.)

longer seems worth the bother." This statement ignores the protective qualities of human milk, not only in the third world but in industrialized nations as well. It neglects the immunologic protection.

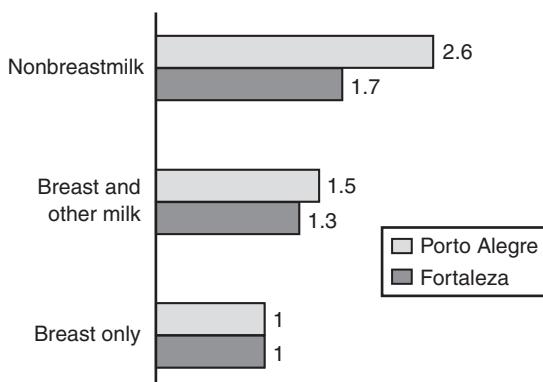

Evidence for protection by breastfeeding against infant death from infectious diseases in Brazil in 1987 is even more persuasive, as noted in a carefully controlled study by Victora et al.<sup>16,61,62</sup> Compared with infants who were breastfed without supplementation, those who were completely bottle-fed had a relative risk 14.2-times greater for death from diarrhea and a relative risk 3.6 times greater for death from respiratory infection. Partial breastfeeding was less protective. Formula and cow milk were equally hazardous. The greatest risk from diarrhea was in the first 2 months of life.

Demonstrating the differences in morbidity between breastfed and bottle-fed infants has become even more complex in industrialized countries since the resurgence of breastfeeding. Among the confounding variables are the inherent differences between mothers who choose to breastfeed and those who choose to bottle-feed. Although many investigators have recognized the necessity of controlling these variables, none has succeeded totally because an unavoidable factor of self-selection makes random assignment of infants impossible. There is a one-way flow of infants from the breastfed group to the bottle-fed group because a baby may change from breast to bottle but rarely from bottle to breast. Documenting breastfeeding practices is difficult when the possibility exists that some bottle-feedings are included or that solid foods have been introduced.

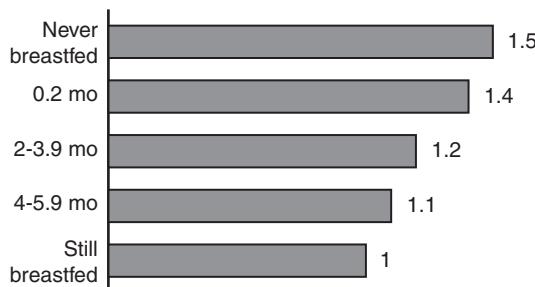

Differences between breastfed and bottle-fed infants in the incidence of morbidity associated with diarrhea, respiratory infections, otitis media, and pneumonia are documented. The relationship between breastfeeding versus bottle-feeding and respiratory illness in the first year of life among nearly 2000 cohort children was reported by Watkins et al.<sup>63</sup> in England. There was a significant advantage to breastfeeding. Mothers who smoked were less likely to breastfeed, but even when smoking was considered, the breastfeeding advantage remained. A number of well-controlled studies of industrialized countries have shown at least a two-fold relative risk of respiratory infection with bottle-feeding and that the infections breastfed infants do experience are usually less severe.<sup>64</sup> A meta-analysis by Bachrach et al.<sup>65</sup> in 2003 revealed that "among generally healthy infants in developed nations, more than a tripling in severe respiratory tract illnesses resulting in hospitalizations was noted for infants who were not breastfed compared with those who were exclusively breastfed for 4 months."

When Victora presented his studies of the impact of early weaning on infection and disease at a workshop held by the Pontifical Academy of Sciences and The Royal Society,<sup>66</sup> he stated that a 40% reduction in nonbreastfeeding would prevent up to 15% of diarrhea deaths and 7% of pneumonia deaths. He noted that even the introduction of water or herbal teas to a previously exclusively breastfed infant increases morbidity and mortality rates. Figures 1-14 and 1-15 illustrate the relative risks of pneumonia and otitis media.

Breastfeeding was associated with a higher level of parental education, but controlling for that

**Figure 1-14.** Risk of pneumonia (odds ratio for incidence) in children under 2 years of age at two Brazilian sites, Porto Alegre and Fortaleza, in 1993 to 1995 according to type of milk. (Modified from Victora CG: Infection and disease: the impact of early weaning, *Food Nutr Bull* 17:390, 1996.)

**Figure 1-15.** Risk of otitis media (odds ratio for incidence in last month) in infants 6 months of age in Brazil in 1993 and 1994 according to duration of breastfeeding. (Modified from Victora CG: Infection and disease: the impact of early weaning, *Food Nutr Bull* 17:390, 1996.)

factor, the difference in the morbidity rate is even more significant.<sup>62</sup>

In the United States, diarrheal disease is uncommon in breastfed infants, and the treatment is usually to continue to breastfeed.<sup>2</sup> Similarly, breastfed infants have fewer episodes of respiratory illness and otitis media. When afflicted with such febrile illnesses, the breastfed infant does not become dehydrated and rapidly toxic.<sup>51</sup>

The issue is not as clear in other Western countries because of the associated variables among those who bottle-feed infants, that is, young mothers with low socioeconomic status and less education and small, sick infants who are more likely to be bottle-fed.

Despite the clear-cut data on mortality and morbidity rates from past generations and from cultures seemingly remote from industrialized and medically sophisticated societies, pediatricians had discounted any but the psychologic advantages of breastfeeding for many years.<sup>67</sup> The current increase in illness in young infants in daycare

centers is providing a new study group. To date, breastfeeding appears to be protective for the few children whose mothers continue to nurse them while in daycare.

In the third millennium, adequate consumption of human milk as an infant and toddler is still a powerful guarantor of health and long life. Pediatricians must recognize that failure to consume sufficient human milk carries vital implications for public health.<sup>68</sup> There is abundant literature confirming the impact of breastfeeding on outcomes in infancy. The report by the AHRQ<sup>69</sup> has collected and reviewed all of the literature for the past decade and confirmed the impact of breastfeeding on infant mortality and morbidity (Table 1-18).

Evidence of the long-term effects of breastfeeding published by WHO from systematic reviews and meta-analyses from the world literature also confirmed the value of breastfeeding. It reported lower mean blood pressure and total cholesterol, as well as higher performance in intelligence tests. The prevalence of overweight and obesity as well as type 2 diabetes was also noted to be lower when an infant was breastfed.

## Sudden Infant Death Syndrome and Other Issues

Recent interest in sudden infant death syndrome (SIDS) has generated several studies investigating the position in which the infant is put down in the crib and the occurrence of SIDS.<sup>21,66,70</sup> The New Zealand Cot Death Study showed the prone sleeping position to be a greater risk, but not greater than the risk for not being breastfed.<sup>54</sup> Other investigators have shown the importance of breastfeeding as a risk-lowering factor.<sup>21</sup> Although breastfeeding does not eliminate SIDS, its incidence is lower among breastfed infants.

No single consistent factor has been a predictor of SIDS.<sup>21</sup> Prone sleeping has continued to be a cofactor in studies, but maternal smoking is a relative causative factor as well. Breastfeeding has been shown to be the strongest protection. Infants of smokers who breastfeed and sleep supine have a reduced risk for SIDS. Several studies confirmed a reduced risk while breastfeeding, and one study linked the effect to a dose response of the amount of breastfeeding. The National Maternal and Infant Health Survey of 100,000 births and 6000 deaths of infants born in 1988 and 1989 was analyzed using a consistent "dosage definition" of breastfeeding while controlling for major confounding factors. These factors included birth weight, maternal age, race, and education; smoking; prenatal cocaine use; lack of private insurance; household smoking;

**TABLE 1-18** Illness, Disease, and Development with Feeding Measure and Risk Ratio Range

	Feeding Measure	Risk Ratio Range*	Reference(s)
<b>Common illnesses</b>			
Acute diarrhea	Breastfed <3 mo	6.10 (4.1-9.0)	Victoria and Barros (2000)
Lower respiratory tract infections	Breastfed <4 mo/sharing bedroom	3.29 (1.8-6.0)	Wright et al. (1989)
Pneumonia	No breastfeeding	16.7 (7.7, 36.0)	César et al. (1999)
Ear infections (recurring vs. acute)	Breastfed <6 mo	1.61 (1.27, 1.79)*	Duncan et al. (1993)
Asthma	Breastfed <4 mo	1.25 (1.02, 1.52)	Oddy et al. (1999)
Atopy	Breastfed <4 mo	1.30 (1.04, 1.61)	Oddy et al. (1999)
<b>Less common illnesses</b>			
Necrotizing enterocolitis	39% formula fed/7% breastfed	4.50 (3.00, 6.00)*	Lucas and Cole (1990)
Urinary tract infections	Never breastfed	1.62 (1.35, 1.78)*	Mårlild et al. (1990, 1989) and Pisacane et al. (1992)
Insulin-dependent diabetes mellitus	Breastfed <4 mo	1.63 (1.22, 2.17)	Fort et al. (1986)
Acute lymphoblastic leukemia	Never breastfed	1.21 (1.09, 1.30)*	Shu et al. (1999)
Sudden infant death syndrome	Current infant formula-feeding	1.35 (1.09, 1.54)*	Ford et al. (1993)
Cholera	Not breastfeeding	1.70 ( $p < 0.0001$ )*	Clemens et al. (1990)
<b>Immunologic diseases</b>			
Celiac disease	Breastfed <3 mo	1.63 (1.36, 1.79)*	Falth-Magnusson et al. (1996) and Peters et al. (1996)
Crohn's disease	Lack of breastfeeding	1.90 (1.50, 3.60)	Corrao et al. (1998) and Koletzko et al. (1989)
Ulcerative colitis	Lack of breastfeeding	1.50 (1.10, 2.10)	Corrao et al. (1998) and Koletzko et al. (1991)
Juvenile rheumatoid arthritis	Lack of breastfeeding	1.60 (1.19, 1.80)	Mason et al. (1995)
Multiple sclerosis	Breastfed <7 mo	1.62 (1.26, 1.81)	Pisacane et al. (1994)
<b>Development</b>			
Cognitive development in preterm	Lack of breastfeeding	↓ Mean IQ of 8.3 pts*	Lucas et al. (1992)
Cardiovascular disease	Lack of breastfeeding	↑ Mean total cholesterol*	Bergstrom et al. (1995)
Metabolic development	Lack of breastfeeding	↑ ApoB values*	Bergstrom et al. (1995)
Obesity	Breastfed <6 mo	1.25 (1.02, 1.43)	von Kries et al. (1999)

*ApoB*, Apolipoprotein B.

\*The risk ratios have been adjusted to reflect a level of risk of infant formula rather than protection of breast milk. This was done to ensure consistency of results. Some results are given as  $p$  value or other measurement effect.

From Oddy W: The impact of breastmilk on infant and child health, *Breastfeeding Rev* 10:5, 2002.

daycare, and household size. In 7102 control subjects, 499 SIDS deaths and 584 non-SIDS deaths occurred. Fredrickson et al.<sup>15a</sup> reported that "the risk of SIDS for black infants increased by 1.19 for every month of not breastfeeding, and 2.13 for every month of not exclusively breastfeeding. Among white infants, the risk increased by 1.19 and 2.0 times, respectively. These associations remained even when deaths within the first month of life were excluded. A similar protective association existed for non-SIDS deaths."

The Committee on SIDS of the AAP then recommended pacifiers for all children. Recognizing the

early use of pacifiers as a risk factor for early discontinuance of breastfeeding, the AAP recommended that breastfeeding infants not be given a pacifier until 2 weeks of age. It has resulted in an excessive use of pacifiers in all infants. A decrease in SIDS has not been reported.

Sleep patterns of infants have been the subject of much study.<sup>21</sup> In the early weeks of life, infants have rapid eye movement (REM) sleep, active body movements, and rapid, irregular heart and respiratory rates. At about 2 to 3 months of age, they begin to increase the proportion of quiet sleep, which coincides with the peak incidence of SIDS. When

breastfeeding decreased, the advantage of co-sleeping seemed to diminish. Child care became very organized and focused on encouraging the infant to sleep alone and through the night. Only in about the last century have Western industrialized societies considered breastfeeding and infant sleep location to be separate issues. McKenna and Bernstein<sup>40</sup> and Mosko<sup>71</sup> describe the physiologic benefits to infants sleeping in proximity to their caregivers. They have documented the physiologic changes infants experience as they move from a solitary sleep environment to co-sleeping. They monitored a group of mother-infant pairs in the sleep laboratory, using each pair as their own control (i.e., co-sleeping and sleeping separately). Infants moved from one stage of sleep to the other more frequently when co-sleeping than when sleeping alone, even when briefly waking and increasing their heart and respiratory rates. The authors commented that modern technology, including baby monitors, breathing teddy bears, and other gadgets, has replaced traditional co-sleeping.<sup>71</sup> Accidental suffocation and strangulation in bed has increased four times since 1984 in spite of the back to sleep program and the introduction of pacifiers that were predicted to reduce SIDS. In 2012, the Committee on SIDS of the AAP<sup>2</sup> issued an update of their recommendations regarding the avoidance of SIDS. The most significant issue for breastfeeding families and their physicians is the strong prohibition of bed sharing. The leading modifiable risk factors for SIDS are smoking, infant sleeping prone, formula feeding, baby sleeping unattended, and poverty. Sofas and soft sleep surfaces and sleeping in lounge chairs and rockers are great risks, as well as parental use of alcohol and drugs.

Bed sharing has been publicized and promoted as the solution to SIDS. The practice of bed sharing was analyzed in 2014 by Blair et al.<sup>24</sup> who demonstrated the risk of bed sharing was with an impaired caretaker and a premature infant. They showed that sleeping on a sofa was more dangerous. An evidence-based infant sleep recommendation was reported by Bartwick and Smith<sup>72</sup> that reviewed the world literature on risky behavior regarding infant sleep. They concluded that efforts need to be focused on impaired caregivers, lack of breastfeeding, and risky surfaces such as sofas, lounge chairs, and rockers to make the greatest difference in the incidence of SIDS.

## *The Mammary Gland and Science*

Newer additions to the laboratory have permitted rapid advances in the understanding of the mammary gland, especially actions of hormones and enzymes.<sup>19</sup> The "knock-out mouse" is a concept

of using mice in which DNA (deoxyribonucleic acid) has been altered to "knock out" a specific gene that controls a specific hormone, such as one important to lactation. Observations of growth and development in these animals provide new insights into the physiology of the mammary gland. In evolutionary biology, lactogenesis is one of the most important functions for the survival of the species. Advances in molecular biology have provided biologists with a better understanding of the mechanisms that produce milk and its specific nutrient constituents. Mammary epithelial cells secrete milk. In an innovative experimental model, mammary epithelial cells are cultured in a petri dish and form a mammosphere, a micromodel of the mammary gland. The advantage of bioengineering the mammary gland, initially focused on the dairy species, is to advance our knowledge and understanding of human lactation in the laboratory so that more women may nurse their infants successfully.<sup>6</sup>

## *Support for the Breastfeeding Women of the World*

On May 12, 1995, His Holiness John Paul II\* granted a Solemn Papal Audience in the Apostolic Palace of the Vatican to the participants of the Working Group on Breastfeeding: Science and Society.<sup>66</sup> In response to the group report, the Holy Father pronounced the following discourse (in part):

*The advantages of breastfeeding for the infant and the mother include two major benefits to the child: proper nourishment and protection against disease. This natural way of feeding can create a bond of love and security between mother and child and enable the child to assert its presence as a person through interaction with the mother. Responsible international agencies are calling on governments to ensure that women are enabled to breastfeed their children for four to six months from birth and to continue this practice, supplemented by other appropriate foods, up to the second year of life and beyond.<sup>66</sup>*

## *A National Campaign to Promote Breastfeeding*

In an attempt to capture the attention of the American public and improve the national statistics on breastfeeding initiation and duration, the Office of Women's Health (OWH) and the USBC

---

\*John Paul II was proclaimed a Saint by rigorous due process in Rome in April 2014.

initiated a national advertising campaign with the professional expertise of the National Advertising Council in 2002. Considerable effort and study went into the planning and design. It included 36 focus groups in four cities nationwide with an ethnic, sex, and age mix. The Ad Council recommended and designed a risk-focused campaign.

In 2003, as the campaign was about to be released, a massive effort was launched on the part of formula companies to defuse and delay the program. Several of the television spots were withdrawn at the insistence of the Department of Health and Human Services. Objections to the risk-focused approach were voiced loudly even by some pediatricians who were unaware of the evidence-based research supporting the statements of the risk of not breastfeeding. The campaign was carried out using four posters illustrating the risk of not breastfeeding. They appeared on billboards and television in 17 selected cities of the country. Follow-up surveys indicated the campaign had little impact. The slogan, however, lives on and is undisputed: "Babies are born to breastfeed."

In the United States, the formation of the USBC occurred in 2000. Membership includes the major medical and nursing organizations. Similar committees have existed in other countries as suggested by WHO in their breastfeeding mandates. The USBC is working with the OWH and Maternal and Child Health to educate the public and the professional.

## CHAPTER 2

# *Anatomy of the Breast*

### *Gross Anatomy*

The mammary gland, as the breast is medically termed, received its name from *mamma*, the Latin word for breast. The human mammary gland is the only organ that is not fully developed at birth. It experiences dramatic changes in size, shape, and function from birth through pregnancy, lactation, and ultimately involution. Mediated by large changes in gene expression, there are drastic changes in composition, architecture, and function during the life cycle of the human mammary gland. The gland only reaches full maturity when pregnancy occurs. This is the most significant stage of the breast because of the very high metabolic demand that utilizes 25% of the maternal energy intake. Pregnancy and lactation create permanent breast changes that provide a protective, yet not well understood, effect against breast malignancy. The gland undergoes three major phases of growth and development before pregnancy and lactation: *in utero*, during the first 2 years of life, and at puberty.

### *Embryonic Development*

The milk streak appears in the fourth week, when the embryo is 2.5 mm long. It becomes the milk line, or ridge, during the fifth week (2.5 to 5.5 mm). Mammary glands begin to develop in the 6-week-old embryo, continuing their proliferation until milk ducts are developed by the time of birth<sup>32</sup> (Tables 2-1 and 2-2). Embryologically, the mammary glands develop as ingrowths of the ectoderm into the underlying mesodermal tissue.<sup>17</sup> In the human embryo, a thickened, raised area of the ectoderm can be recognized in the region of

the future gland at the end of the fourth week of pregnancy. The thickened ectoderm becomes depressed into the underlying mesoderm, the surface of the mammary area soon becomes flat, and it finally sinks below the level of the surrounding epidermis. The mesoderm in contact with the ingrowth of the ectoderm is compressed, and its elements become arranged in concentric layers, which at a later stage give rise to the gland's stroma. The ingrowing mass of ectodermal cells soon becomes pouch or pear shaped and then grows out into the surrounding mesoderm as a number of solid processes that represent the gland's future ducts. These processes, by dividing and branching, give rise to the future lobes and lobules and, much later, to the alveoli.

By 16 weeks' gestation, the branching stage has produced 15 to 25 epithelial strips or solid cords in the subcutaneous tissue that represent future secretory alveoli. The smooth musculature of nipple and areola are developed. By apoptosis of the central epithelial cells, branching and canalization continue. By 32 weeks' gestation the primary milk ducts appear and the mammary vascular system is completely developed. At this time, the secondary mammary anlage (primordium) develops. The secondary mammary anlage then develops with elements of hair follicles, sebaceous glands, and sweat glands, along with the Montgomery glands, around the alveoli. Mesenchymal cells differentiate into the smooth muscle of the nipple and areola between 12 and 16 weeks' gestation.<sup>26</sup> Thus far, development is independent of hormone stimulation. By 28 weeks' gestation, placental sex hormones enter the fetal circulation and induce canalization in the fetus.<sup>26</sup>

The lumina develop in the outgrowths, forming the lactiferous ducts and their branches. The lactiferous ducts open into a shallow epithelial depression

**TABLE 2-1** Embryonic Timetable of Breast Development in the Human

Age of Embryo (wk)	Crown-Rump Length of Embryo (mean)	Developmental Stage
4	2.5 mm	Mammary streak
5	2.5-5.5 mm	Milk line, or milk ridge
6	5.5-11 mm	Parenchymal cells proliferate
7-8	11-25 mm	Mammary disk progresses to globular stage
9	25-30 mm	Cone stage: Inward growth of parenchyma
10-12	30-68 mm	Epithelial buds sprout from invading parenchyma
12-13	68 mm to 5 cm	Indentation buds become lobular with notching at epithelial-stromal border
15	10 cm	Buds branch into 15-25 epithelial strips
20-24	20 cm	Solid cords canalize by desquamation and lysis
24-32	30 cm	Further canalization
32-40	35-50 cm	Lobular-alveolar development

Data from Russo J, Russo IH: Development of the human mammary gland. In Neville MC, Daniel CW, editors: *The mammary gland*, New York, 1987, Plenum.

**TABLE 2-2** Stages of Mammary Development

Developmental Stage	Hormonal Regulation	Local Factors	Description
Embryogenesis	???	Fat pad necessary for ductal extension	Epithelial bud develops in 18- to 19-week fetus, extending a short distance into mammary fat pad with blind ducts that become canalized; some milk secretion may be present at birth
Pubertal development before onset of menses	Estrogen, GH	IGF-1, HGF, TGF- $\beta$ , ???	Ductal extension into the mammary fat pad; branching morphogenesis
After onset of menses	Estrogen, progesterone, PRL?		Lobular development with formation of terminal duct lobular unit
Development in pregnancy	Progesterone, PRL, placental lactogen	HER, ???	Alveolus formation; partial cellular differentiation
Transition: lactogenesis	Progesterone withdrawal, PRL, glucocorticoid	Unknown	Onset of milk secretion: stage I, midpregnancy; stage II, parturition
Lactation	PRL, oxytocin	FIL, stretch	Ongoing milk secretion, milk ejection
Involution	Withdrawal of prolactin	Milk stasis (FIL??)	Alveolar epithelium undergoes apoptosis and remodeling and gland reverts to prepregnant state

? and ??, Possibly; ???, unknown; FIL, Feedback inhibitor of lactation; GH, growth hormone; HER, herregulin; HGF, human growth factor; IGF-1, insulin-like growth factor-1; PRL, prolactin; TGF- $\beta$ , transforming growth factor- $\beta$ .

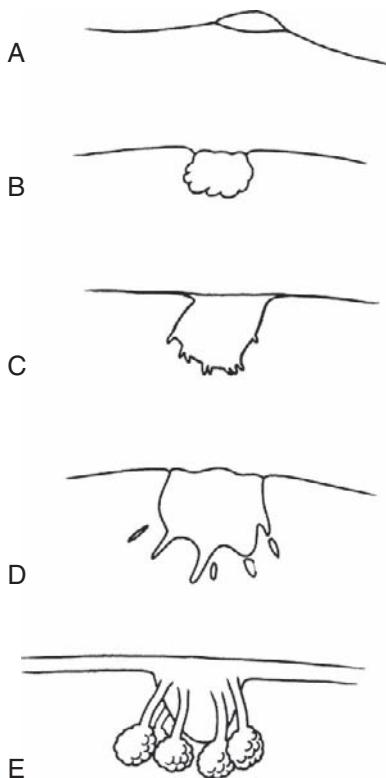

From Neville MC: Breastfeeding, part I: the evidence for breastfeeding. Anatomy and physiology of lactation. *Pediatr Clin North Am* 48:13, 2001.

known as the mammary pit. The pit becomes elevated as a result of the mesenchymal proliferation forming the nipple and areola. An inverted nipple is a result of the failure of the pit to elevate.<sup>3</sup> A lumen is formed in each part of the branching system of cellular processes after 32 weeks' gestation. Near term, about 15 to 25 mammary ducts form the fetal mammary gland (Figure 2-1). Duct and sebaceous glands coalesce near the epidermis. Parenchymal differentiation occurs with the development of lobular-alveolar structures that contain colostrum. This

change occurs at 32 to 40 weeks and is called the end-vesicle stage.

## Fetal and Prepubertal Development

The mammary glands of male and female fetuses of 13 to 40 weeks' gestation were studied ultrastructurally by Tobon and Salazar.<sup>43</sup> This work confirms morphologic developments in the fetal breast tissue in response to hormonal stimuli that are similar to

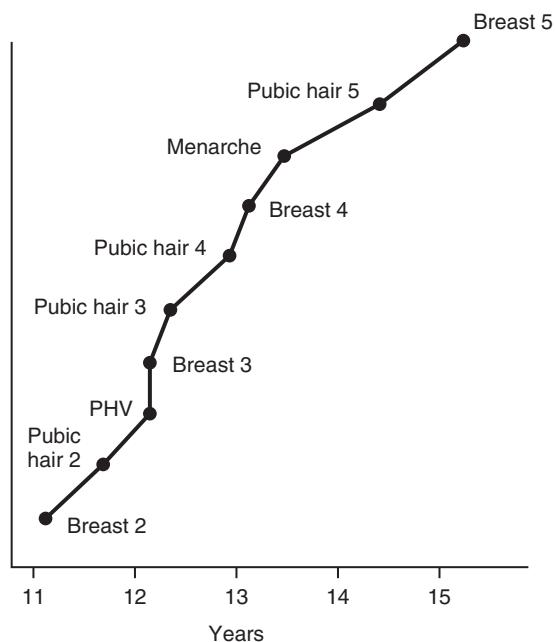

**Figure 2-1.** Evolution of nipple. **A**, Thickening of epidermis with formation of primary bud. **B**, Growth of bud into mesenchyma. **C**, Formation of solid secondary buds. **D**, Formation of mammary pit and vacuolation of buds to form epithelial-lined ducts. **E**, Lactiferous ducts proliferate. Areola is formed. Nipple is inverted initially. (Modified from Weatherly-White RCA: *Plastic surgery of the female breast*, Hagerstown, Md., 1980, Harper & Row.)

those in the maternal breast. The Golgi system and abundant reticula with dilated cisternae filled with fine granular material are present in the cellular structure. Abundant mitochondria and lipid droplets are observed. Proliferation and conditioning of the epithelial cells are evident, and, in the last trimester, microvilli along the ductal lumen are accompanied by large cytoplasmic protrusions (see Table 2-2).

Study of the ultrastructure of the fetal breast may help in understanding the functional lactating breast. The secretion of a fluid resembling milk may take place at birth as a result of maternal hormones that have passed across the placenta into the fetal circulation. The lactiferous sinuses appear before birth as swellings of the developing ducts.

An extensive anatomic and histologic study of the human infant breast revealed an epithelial differentiation that followed a chronologic pattern, starting with secretory changes and apparently going through a period of apocrine metaplasia before the postsecretory changes and involution.<sup>2</sup> The embryonic fat probably plays a role in growth

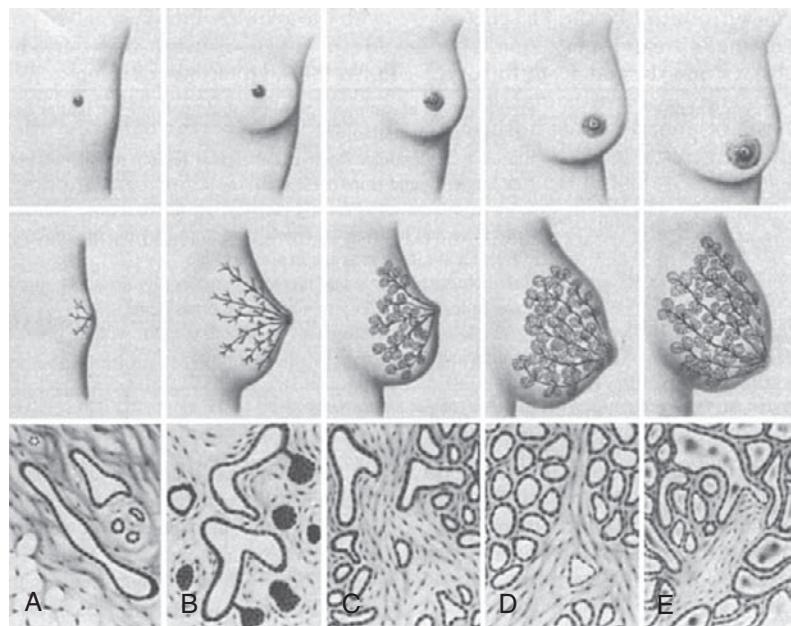

**Figure 2-2.** Pubertal development in the female. The sequence and mean ages of pubertal events in females, adapted from the data of Marshall and Tanner. PHV, Peak height velocity. (From Root AW: Endocrinology of puberty, *J Pediatr* 83:1, 1973.)

and morphogenesis of the ductal system. No distinguishing features were found between the breasts of female and male infants,<sup>2</sup> however.

The terminal end buds, lateral buds, and lobules of three to five alveolar buds predominate in prepubertal tissue. Lobules of alveolar buds and lobules of up to 60 ductules predominate in pubertal females. In prepuberty, these epithelium-lined ducts will bud out to form alveoli when stimulated by hormones of menarche (see Figure 2-1).

The breast is made up of glandular tissue, supporting connective tissue, and protective fatty tissue. Immediately after birth, the newborn's breast may even be swollen and secreting a small amount of milk, often termed witch's milk. This phenomenon, common among both male and female infants, is caused by the stimulation of the infant's mammary glands by the same hormones produced by the placenta to prepare the mother's breast for lactation. This secretory activity subsides within 3 to 4 weeks, and then the mammary glands are inactive until shortly before the onset of puberty, when hormones begin to stimulate growth again. During childhood (prepuberty), the gland merely keeps pace with physical growth<sup>42</sup> (Figures 2-2 and 2-3).

The molecular biology of mammary gland development depends on a combination of systemic mammotrophic hormones plus local cell-to-cell interactions.<sup>42</sup> A variety of growth factors mediate the local cell interactions. These factors

**Figure 2-3.** Female breast from infancy to lactation with corresponding cross section and duct structure. **A, B, and C,** Gradual development of well-differentiated ductular and peripheral lobular-alveolar system. **D,** Ductular sprouting and intensified peripheral lobular-alveolar development in pregnancy. Glandular luminal cells begin actively synthesizing milk fat and proteins near term; only small amounts are released into lumen. **E,** With postpartum withdrawal of luteal and placental sex steroids and placental lactogen, prolactin is able to induce full secretory activity of alveolar cells and release of milk into alveoli and smaller ducts.

include the epidermal growth factor (EGF), transforming growth factor- $\beta$  (TGF- $\beta$ ), fibroblast growth factor (FGF), and the *Wnt* gene families. In the developing breast these factors are thought to act in concert with systemic hormones.<sup>19</sup>

In a longitudinal cohort of 6 to 8 years of age, girls were followed from 2004 to 2011 in three geographic areas in the United States. Using Tanner staging, the age at onset of breast maturation was documented. Stage 2 onset varied by race/ethnicity, BMI at baseline, and site. Mean onset was 8.8, 9.3, 9.7, and 9.7 years for black, Hispanic, white and non-Hispanic, and Asian, respectively. The greater the BMI, the younger the age of maturation. This study confirmed earlier maturation in girls in the last decade.

## Pubertal Development

Puberty stimulates rapid breast growth activated by ovulation and establishment of menses. The development of the human breast involves two distinct processes: organogenesis and milk production.<sup>7</sup> Organogenesis involves ductal and lobular growth and begins before and continues through puberty, resulting in growth of the breast parenchyma with its surrounding fat pad. When a girl is between 10 and 12 years of age, just before puberty, the ductal tree extends and generates its branching pattern, lengthening the existing ducts, dichotomously branching the growing ductal tips, and monopodially branching, with the growth of the lateral buds at the sides of the ducts<sup>18</sup> (Tables 2-2 and 2-3).

**TABLE 2-3** Phases of Breast Development

Phase	Age (yr)	Developmental Characteristics
I	Puberty	Preadolescent elevation of nipple with no palpable glandular tissue or areolar pigmentation
II	$11.1 \pm 1.1$	Presence of glandular tissue in subareolar region; nipple and breast project as single mound from chest wall
III	$12.2 \pm 1.09$	Increase in amount of readily palpable glandular tissue, with enlargement of breast and increased diameter and pigmentation of areola; contour of breast and nipple remains in single plane
IV	$13.1 \pm 1.15$	Enlargement of areola and increased areolar pigmentation; nipple and areola form secondary mound above breast level
V	$15.3 \pm 1.7$	Final adolescent development of smooth contour with no projection of areola and nipple

Modified from Tanner JM: *Wachstum und Reifung des Menschen*, Stuttgart, 1962, Thieme-Verlag.

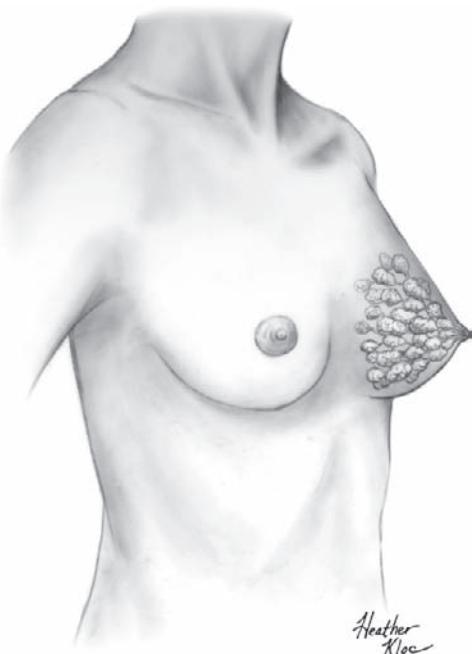

During this period of rapid growth, the ducts can develop bulbous terminal end buds. The formation of alveolar buds begins within a year or two of the onset of menses.<sup>15</sup> During the menstrual cycle, the breast changes, beginning with the follicular phase of days 3 to 14. The stroma becomes less dense. Lumina expansion takes place in the ducts.

Occasionally mitosis occurs, but no secretion has been seen. In days 15 to 28, or the luteal phase, the density of the stroma progresses, and the ducts have a lumen and some secretion. From days 26 to 28 epithelial cells are reduced as apoptosis occurs, and blood flow is greatest in midcycle.<sup>40</sup> The sprouting of new alveolar buds continues for several years, producing alveolar lobes.<sup>32</sup> Mammary stem cell (MaSC) populations from the basal ductal layer are driven by the ovarian hormonal circuit, and changes in epithelial and stromal development result. The mammary mini-remodeling with each cycle does not fully regress at the end of the cycle.

## Anatomic Location

The breast is located in the superficial fascia between the second rib and sixth intercostal cartilage and upon the deep pectoral fascia that is superficial to the pectoralis major muscle.<sup>19</sup> It tends to overlap this muscle inferiorly to become superficial to the external oblique and serratus anterior muscles. The loose connective tissue between the breast and deep fascia forms the "submammary space," which allows some movement.<sup>23</sup> It measures 10 to 12 cm in diameter. It is located horizontally from the parasternal to midaxillary line. The central thickness of the breast is 5 to 7 cm (Figure 2-4).

At puberty, the breasts of a girl enlarge to their adult size, with the left frequently slightly larger than the right.<sup>46</sup> In a nonpregnant woman the

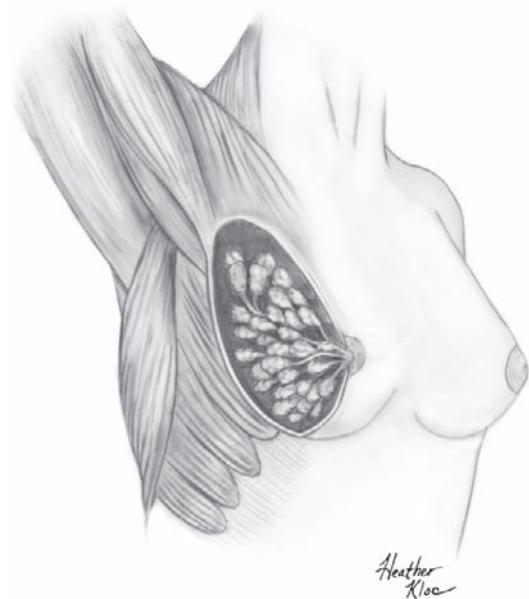

**Figure 2-4.** Mammary gland in longitudinal cross section showing mature, nonlactating duct system.

mature breast weighs approximately 200 g. During pregnancy, breast size and weight increase; thus when a pregnant woman is near term, the breast weighs 400 to 600 g. During lactation the breast weighs 600 to 800 g (see Figure 2-3).

The shape of breasts varies from woman to woman, just as body build and facial characteristics do. Genetic, racial, and dietary variations may be associated with discoidal, hemispheric, pear-shaped, or conical forms.<sup>23</sup> Typically, the breast is dome-shaped or conic in adolescence, becoming more hemispheric and finally pendulous in a parous woman. Mammary glandular tissue projects somewhat into the axillary region. This is known as the tail of Spence (Figure 2-5). Mammary tissue in the axilla, which is connected to the central duct system, becomes more obvious during pregnancy and produces milk during lactation, when it may cause various symptoms (see Chapter 8).<sup>1</sup> The tail of Spence is distinguished from a supernumerary gland because it connects to the normal duct system. Occasionally, in normal women, small masses of breast tissue may grow through the deep fascia to the muscle below. This may explain some pain distribution when the breast is engorged.

The three major structures of the breast are skin, subcutaneous tissue, and corpus mammae. The corpus mammae is the breast mass that remains after freeing the breast from the deep attachments and

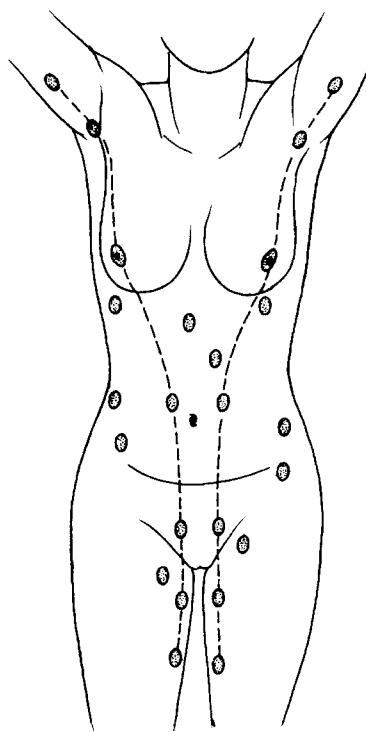

**Figure 2-5.** Ramification of lactiferous ducts and mammary tissue. Ducts extend onto upper medial aspect of arm, to midline, and into epigastrium. Composite drawing from mammographic studies. (Modified from Hicken NF: Mastectomy: pathologic study demonstrating why most mastectomies result in incomplete removal of the mammary gland, *Arch Surg* 40:6, 1940.)

removing the skin, subcutaneous connective tissue, and adipose tissue.

The breasts of an adult woman are always paired and develop from a line of glandular tissue found in the fetus and known as the milk line. This milk streak, or galactic band, develops from the axilla to the groin during the fifth week of embryonic life.<sup>26</sup> In the thoracic region, the band develops into a ridge, and the rest of the band regresses (Figure 2-6).

## Abnormalities

In some women, additional residual tissue of the galactic band remains as mammary tissue, which can develop anywhere along this line. Hypermastia is the presence of accessory mammary glands, which are phylogenetic remnants of the embryonic mammary ridge resulting from incomplete regression or dispersion of the primitive galactic band (see Figure 2-6). Because of this origin, accessory nipples and glandular tissue may be found along these lines, which extend from the clavicular to the inguinal regions. Occasionally, supernumerary glands are found in the urogenital region, on the

**Figure 2-6.** Sites of supernumerary nipples along milk line. Ectopic nipples, areolae, or breast tissue can develop from groin to axilla and upper inner arm. They can lactate or undergo malignant change. (Modified from Weatherly-White RCA: *Plastic surgery of the female breast*, Hagerstown, Md., 1980, Harper & Row.)

buttocks, or on the back.<sup>47</sup> The glands are derived from the ectoderm, whereas the connective tissue stroma is mesodermal in origin.

The accessory tissue may involve the corpus mammae, the areola, and the nipple.<sup>27</sup> Hypermastia occurs in 2% to 6% of women. The response of hypermastia to pregnancy and lactation depends on the tissue present.

**Box 2-1** defines other selected breast abnormalities. Symmastia is a webbing across the midline between the breasts, which are usually symmetric.<sup>3</sup> A more common variation is the presternal confluence representing blending of breast tissue associated with large breasts. These abnormalities are ectodermal in origin and have many variations, from an empty skin web to the presence of significant glandular tissue. Little is known about their function, but several procedures exist for their surgical amelioration.<sup>3</sup>

Congenital absence of the breast is called amastia, which is rare. When a nipple is present but no breast tissue, the condition is called amazia. Another term for this condition when it occurs in addition to a normal breast is hyperthelia.

Some have suggested a relationship between polythelia (supernumerary nipple) and renal defect. Polythelia has also been associated with renal agenesis, renal cell carcinoma,<sup>28</sup> obstructive disease, and supernumerary kidneys.<sup>29</sup> Others have described associations with congenital cardiac anomalies, pyloric stenosis, ear abnormalities, and arthrogryposis multiplex congenita.<sup>3</sup> After careful study of 65 patients with a supernumerary nipple, Hersh et al.<sup>15</sup> found 7 individuals (11%) who had significant renal lesions, somewhat less than the incidence reported originally. Apparently no association exists in black patients.

Poland syndrome, first described in 1841 (**Box 2-2**), includes absence of the pectoral muscle, chest wall deformity, and breast anomalies.<sup>26</sup> It is now known also to include symbrachydactyly, with hypoplasia of the middle phalanges and central skin webbing. Breast hypoplasia is underdevelopment of the breast. Although 90%

### BOX 2-1. Breast Abnormalities

- **Accessory breast:** Any tissue outside the two major glands
- **Amastia:** Congenital absence of breast and nipple
- **Amazia:** Nipple without breast tissue
- **Hyperadenia:** Mammary tissue without nipple
- **Hypoplasia:** Underdevelopment of breast
- **Polythelia:** Supernumerary nipple(s) (also hyperthelia)
- **Symmastia:** Webbing between breasts

**BOX 2-2. Types of Breast Hypoplasia, Hyperplasia, and Acquired Abnormalities**

- Unilateral hypoplasia, contralateral breast normal
- Bilateral hypoplasia with asymmetry
- Unilateral hyperplasia, contralateral breast normal
- Bilateral hyperplasia with asymmetry
- Unilateral hypoplasia, contralateral breast hyperplasia
- Unilateral hypoplasia of breast, thorax, and pectoral muscles (Poland syndrome)
- Acquired abnormalities caused by trauma, burns, radiation treatment for hemangioma or intrathoracic disease, chest tube insertion in infancy, and preadolescent biopsy

of cases of breast hypoplasia are associated with hypoplasia of the pectoral muscles, 92% of women with pectoral muscle abnormalities have normal breasts. **Box 2-2** lists types of breast hypoplasia, hyperplasia (overdevelopment), and acquired breast abnormalities.

Hyperadenia is the presence of mammary tissue without nipples. The swelling and secretion of this tissue may produce pain during lactation. Occasionally, aberrant breast tissue can cause discomfort or embarrassment in adolescence and during menses, especially when located in the axilla.<sup>16</sup> Mammographic features of normal accessory axillary breast tissue were reviewed by Adler et al.<sup>1</sup> in 13 women who were diagnosed on routine mammography. Seven of these women had a mass or fullness on physical examination; one was seen postpartum because of pain; nine were asymptomatic. They ranged in age from 31 to 67 years. On radiographics, the accessory tissue resembled the rest of the normal glandular tissue but was separate from it. It occurred on the right in 11 of the 13 women. The accessory tissue was recognized as a normal developmental variant, distinguishable from the frequent axillary tail of Spence, which represents a direct extension from the outer margin of the main mass of glandular tissue.

On mammography, accessory tissue is best visualized on oblique and exaggerated craniocaudal views and by ultrasound. In rare cases, it may be appropriate to remove the tissue surgically, a treatment well known to experienced plastic surgeons. If treatment is not initiated before pregnancy and lactation in these women, pain and swelling will be intensified and may progress to mastitis or the necessity to terminate lactation.

Apart from physiologic variations, other conditions of abnormal anatomy include hypomastia (abnormally small breasts), hypertrophy, and inequality.

**Acquired Abnormalities**

The most common cause of acquired breast abnormality is iatrogenic and is most commonly caused by chest wall trauma in premature infants when chest tubes are inserted. Biopsy in prepubertal girls may remove vital tissues. Cutaneous burns to the chest wall may result in scarring and breast deformity. Such findings do not automatically prevent breastfeeding. The lactation center at the University of Rochester has been consulted about several such women who have been able to breastfeed with assistance and encouragement in spite of scarring and seeming deformity.

***Corpus Mammæ***

The mammary gland is an orderly conglomeration of a variable number of independent glands. It undergoes a series of changes that can be divided into developmental and differentiation phases. Surgical dissection of many postoperative specimens has contributed more precise information about the anatomic structure of the breast. The ramifications of the lactiferous ducts and stroma were carefully studied by Weatherly-White,<sup>47</sup> who reported that in 95% of women the ducts ascend into the axilla, occasionally following the brachial plexus and axillary vessels into the apex of the axilla. Ducts are found in the epigastric region in 15% of women. In rare cases, ducts cross the midline (see **Figure 2-6**).

The morphology of the corpus mammæ includes two major divisions, the parenchyma and the stroma.<sup>1</sup> The parenchyma includes the ductular-lobular-alveolar structures. It is composed of the alveolar gland with treelike ductular branching alveoli, which are approximately 0.12 mm in diameter. The ducts are approximately 2 mm in diameter. The lobi, which are arranged like spokes converging on the central nipple, are 15 to 25 in number. Each lobe is divided again into 20 to 40 lobuli, and each lobulus is again subdivided into 10 to 100 alveoli, or tubulosaccular secretory units. The stroma includes the connective tissue, fat tissue, blood vessels, nerves, and lymphatics.<sup>19</sup>

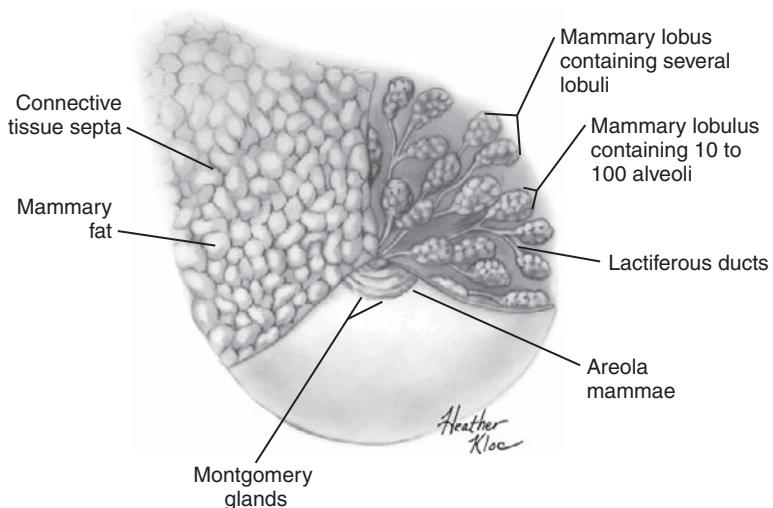

The mass of tissue in the breast consists of the tubuloalveolar glands embedded in fat (the adipose tissue), giving the gland its smooth, rounded contour. The mammary fat pad is essential for the proliferation and differentiation of the mammary epithelium, providing the necessary space, support, and local control for duct elongation and, ultimately, lobuloalveolar proliferation. Each gland forms a lobe of the breast, and the lobes are separated by connective tissue septa. These septa attach

to the skin. Each tubuloalveolar gland opens into a lactiferous duct, which leads into a more elastic duct. A slight constriction occurs before the duct opens onto the surface of the nipple (Figure 2-7). Extension of ducts within the fat pad is orderly. The fat pad is critical to the development of the arborization.<sup>24</sup> Fat is distributed throughout the gland buffering the alveolae and ducts. An inhibitory zone into which other ducts cannot penetrate exists around each duct, and development does not normally proceed beyond the duct end-bud stage before puberty.<sup>2</sup>

## Nipple and Areola

The skin of the breast includes the nipple, areola, and general skin. The skin is the thin, flexible, elastic cover of the breast and is adherent to the fat-laden subcutaneous tissue. It contains hair, sebaceous glands, and apocrine sweat glands. The nipple, or papilla mammae, is a conic elevation located in the center of the areola at about the fourth intercostal space, slightly below the midpoint of the breast. Although very different in size, the nipples and areolae of women and men are qualitatively identical.<sup>21</sup> The nipple contains 23 to 27 milk ducts on average, with a range of 11 to 48. Each of the tubuloalveolar glands that make up the breast opens onto the nipple by a separate opening. The precise anatomy of the nipple has drawn little attention since the work of Sir Ashley Cooper in 1839.<sup>20</sup> Cancer scientists are exploring the anatomy of the breast in detail to determine how cancers grow and how they spread, not to determine how the breast functions. Studies of autopsies and breasts removed for cancer in young vital women are used.<sup>33</sup> Data from mastectomy breasts have shown that collecting duct numbers

in the nipple averaging 25 to 27 are greater in number than the number of nipple duct openings (6 to 8) identifiable on the nipple surface. A 3-D model of the nipple from a mastectomy specimen showed three distinct populations of ducts. The largest lobe was 23% of breast volume. Half the breast was drained by three ducts and 75% by the six largest ducts. Eight small ducts drained about 1.6% of the breast volume. Seven ducts the authors called type A maintained a wide lumen up to the skin surface, 20 ducts (type B) tapered to a minute lumen in the vicinity of the skin on the apex of the nipple, and a minor duct population (type C) arose around the base of the nipple. These distinctions are not distinguishable on microscopic examination except for type C ducts.<sup>12</sup> Using similar 3-D technology, Rusby et al.<sup>33</sup> sought clinical relevance for diagnostic techniques by accessing by cannulation of the ducts. They describe a central duct bundle narrowing to form a "waist" as the ducts enter the breast parenchyma. In a single sample 29 ducts arose from 15 orifices. At skin level, ducts are narrow, becoming larger deeper within the nipple. Many ducts share a few common openings, confirming the apparent discrepancy between number of ducts and number of orifices. Duct diameter does not predict the penetrance of the duct deeper into the breast. Rusby et al.<sup>33</sup> demonstrated that a shared opening of many ducts on the surface of the nipple and the narrow caliber of the ducts closest to the nipple lip changes the clinical interpretation of ductography, ductal lavage, and ductoscopy. In early anatomic studies of the breast, which were done on autopsy specimens, the duct system was identified by pushing dye into the duct under pressure.<sup>6</sup> The duct, being elastic, stretched to suggest ductal sinuses leading to the impression—the ducts had sinuses that collected milk in the areola. This has been shown to be incorrect.<sup>45</sup>

**Figure 2-7.** Morphology of mature breast with dissection to reveal mammary fat and duct system.

The nipple also contains smooth muscle fibers and is richly innervated with sensory nerve endings and Meissner corpuscles in the dermal papillae; it is well supplied with sebaceous and apocrine sweat glands but no hair.

The nipple is surrounded by the areola, or areola mammae, a circular pigmented area. It is usually faintly darker before pregnancy, becoming reddish brown during pregnancy, and always maintaining some darker pigmentation thereafter. The average areola measures 15 to 16 mm in diameter, although the range is great, enlarging during pregnancy and lactation.<sup>20</sup> The pigmentation results from many melanocytes distributed throughout the skin and glands. The understructure of the epidermis of the areola is not as elaborate as that of the nipple but is intermediate to that of the surrounding skin. The nipple and areola are extremely elastic.

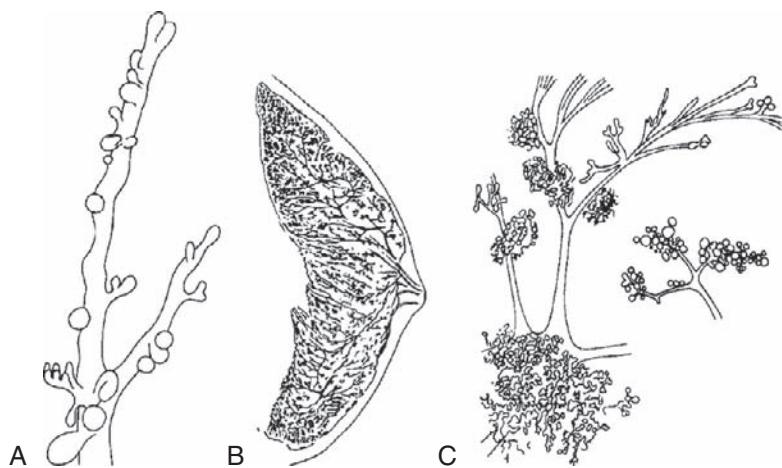

Little or no true lobuloalveolar development occurs before the first pregnancy. A framework is laid down, within which the specialized secretory cells will proliferate (Figure 2-8).<sup>6</sup> The framework forms a vital part of the gland's overall developmental course, and maldevelopment or trauma during fetal or juvenile life can seriously reduce the size and secretory potential of the mature gland.

Montgomery tubercles, containing the ductular openings of sebaceous and lactiferous glands, are present in the areola,<sup>39</sup> as are sweat glands and smaller, free sebaceous glands. The Montgomery glands become enlarged and look like small pimples

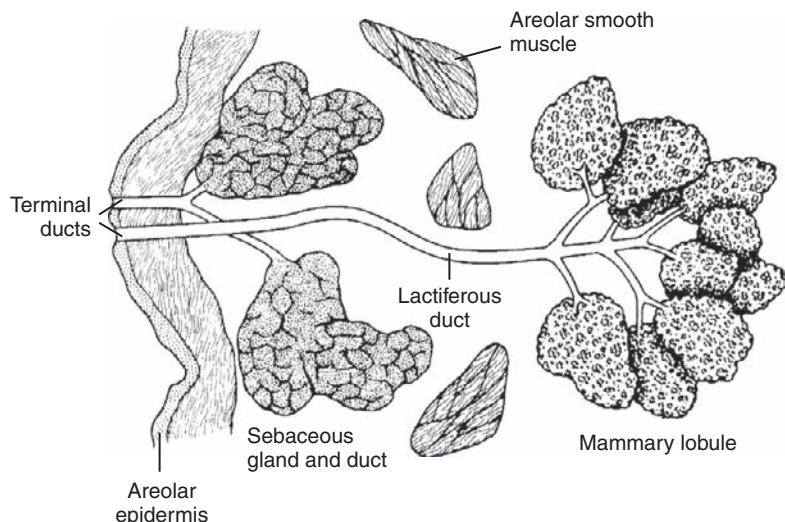

during pregnancy and lactation (Figure 2-9). They secrete a substance that lubricates and protects the nipples and areolae during pregnancy and lactation. A small amount of milk is also secreted from these tubercles. After lactation, these glands recede again to their former unobtrusive state.

Light microscopy has shown that Morgagni was correct in 1719 when he first described the 12 to 20 areolar glands and noted them to be sebaceous and to include lactiferous structures as well. Building on the original work, in 1837 Montgomery prepared a more detailed treatise on the tubercle itself and named it after himself. Serial sections of 35 tubercles also showed that lactiferous ducts from the deeper breast parenchyma ascended into the sebaceous glands of the tubercle (see Figure 2-9).<sup>39</sup> The sebaceous gland itself was no different from those of the skin or those associated with the terminal lactiferous ducts of the nipple. The mammary duct was lined with two layers of cuboidal to columnar cells. They arose from the underlying mammary lobules through the subcutaneous tissues and into the region of the sebaceous gland. The terminal portion of the mammary duct in some cases joined the duct to the sebaceous gland and in other cases opened separately but close to it. The ducts appear to be a miniature of the major mammary system. Sebaceous and mammary ductal components underlie the areolar tubercle.<sup>20</sup>

The areola and nipple are darker than the rest of the breast, ranging from light pink in fair-skinned

**Figure 2-8.** **A**, Duct end from a 15-year-old nulligravida adolescent on second day of menstruation showing typical form of puberty: a coarsely diversified system of thick, mostly well-filled ducts with round, often ball-shaped or half-ball-shaped ends. Note use of connective tissue as guiding tracts, circumvention of fat tissue, and paucity of secretory alveoli. **B**, Sagittal section through milk gland of a nulligravida 19-year-old woman between menses (died of skull fracture). Note massive body of connective tissue without preserved lobes of fatty tissue and richness of connective tissue with respective richness of parenchyma. Note also the distribution of larger ducts in superficial parallel connective tissue septum of former subcutaneous fat tissue and smaller ducts in vertical septa. Thin section; drawing with Busch magnifying glasses. **C**, Gland of a nulligravida 19-year-old woman (part of a 4-mm-thick section). Bushy short sprout and duct build long sprout, with the latter in acute angled bifurcation, often lying very close to each other. This demonstrates development of ductal and secretory elements during menstrual cycle; however, connective tissue and fat are predominant. (From Dabelow A: Die Milchdrüse. In *Handbuch der Mikroskopischen Anatomie des Menschen*, vol 3, part 3, Berlin, 1957, Springer-Verlag.)

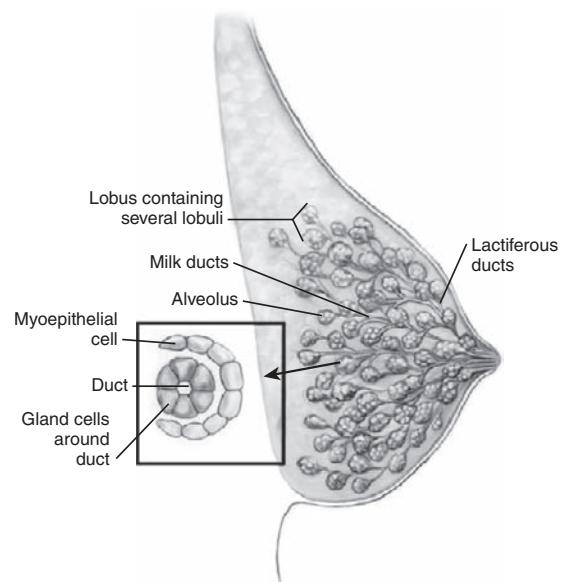

**Figure 2-9.** Tubercle of Montgomery and underlying structures. Lactiferous duct may join sebaceous gland ducts and terminate at common opening in areolar epidermis as shown. (Modified from Smith DM, Peters TG, Donegan WL: Montgomery's areolar tubercle: a light microscopic study, *Arch Pathol Lab Med* 106:62, 1982.)

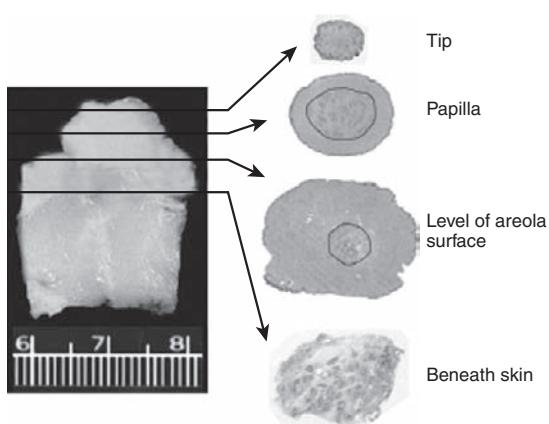

women to dark brown in others. The areola's darker color may be a visual signal to newborns so that they will close their mouth on the areola, not on the nipple alone, to obtain milk. Nipple erection is induced by tactile, sensory, and autonomic sympathetic stimuli. The corium (dermis) of the areola lacks fat but contains smooth muscle and collagenous and elastic connective tissue fibers in radial and circular arrangements. The dermis of the nipple and the areola contains many multibranched, free nerve fiber endings. Local venostasis and hyperemia occur to enhance the process of erection of the nipple because the nipple and areola are rich in arteriovenous anastomoses. The glabrous skin of the nipple is wrinkled, containing large papillae of the corium.

Each nipple contains 15 to 25 lactiferous ducts surrounded by fibromuscular tissue<sup>12</sup> (Figures 2-10 through 2-13). This number has often been challenged but was finally confirmed by Taneri et al.<sup>41</sup> and also Rusby et al.<sup>33</sup> to be a mean of 23. These ducts end as small orifices near the tip of the nipple. Within the nipple, the lactiferous ducts may merge. The ductular orifices, therefore, are sometimes fewer in number than the respective breast lobi. The ampullae function as temporary milk containers during a feeding but contain only epithelial debris in the nonlactating state. The use of ultrasound imagery of the contralateral breast while the infant is nursing on the other breast or the other breast is being pumped has shown that the profound elasticity of the ductal system allows for an acute increase in milk duct diameter during let-down and milk production (see Figure 2-10). Contrary to the sketches of the breast in many professional and lay journals, the ducts do not form sinuses just before the nipple.<sup>13</sup> The concept of lactiferous

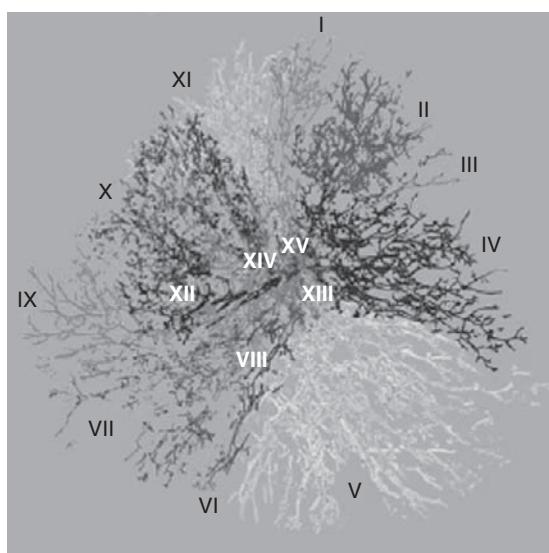

sinuses was described when postmortem specimens were injected with solidifying liquid under pressure causing a ballooning of the duct. The lining of the infundibular and ampullar parts of the lactiferous ducts consists of an 8- to 10-cell layered squamous epithelium. The bulk of the nipple is composed of smooth musculature, which represents a closing mechanism for the milk ducts of the nipple. The milk ducts in the nipple are embedded in stretchable and mobile connective tissue. The inner longitudinal muscular arrangements and the outer, more circular and radial arrangements do not obstruct the milk

**Figure 2-10.** Simplified schematic drawing of duct system with cross section of myoepithelial cells around duct opening. Myoepithelial cells contract to eject milk.

**Figure 2-11.** Photograph of a sagittal section through a nipple with coronal block sections from a different nipple. The sagittal section illustrates the approximate location of tissue sections. Block sections from a coronally sectioned nipple show differences in morphology with depth. The duct bundle is outlined in black. The beginnings of the waist can be seen at the level of the areola. (From Rushby J, et al: Breast duct anatomy in the human nipple: 3-dimensional patterns and clinical implications, *Breast Cancer Res Treat* 106:171, 2006.)

**Figure 2-12.** All ducts and their branches in an autopsy breast, viewed en face. Each Roman numeral refers to a different independent duct system. (From Going JJ, Moffat DF: Escaping from flatland: clinical and biological aspects of human mammary duct anatomy in three dimensions, *J Pathology* 203:538, 2004.)

ducts. Tangential fibers also branch off from the more circular muscular fibers of the nipple bases to the outer circular muscular range.

The functions of the muscular fibroelastic system of the areola and nipple include decreasing the surface area of the areola, producing nipple erection, and emptying the swollen ducts during

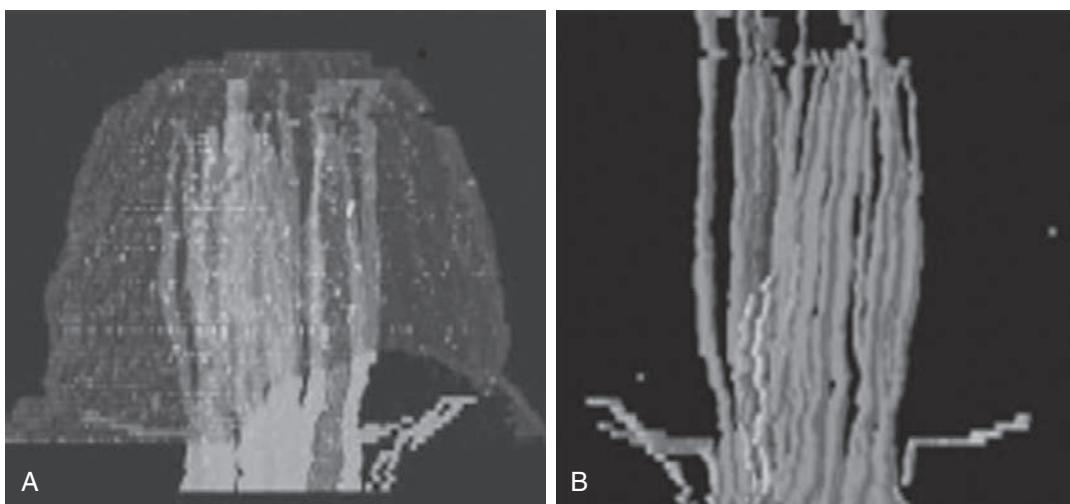

nursing. When the nipple erects because of tactile, thermal, or sexual stimulation, the system causes the nipple to become smaller, firmer, everted, and more prominent.<sup>30</sup>

The mammary tissues are enveloped by the superficial pectoral fascia, and the breast is fixed by fibrous bands to the overlying skin and the underlying pectoral fascia, which are known as ligaments of Cooper. The glandular part of the breast is surrounded by a fat layer that seldom extends beyond the lower border of the pectoralis major muscle. The breast is attached to the muscles between the ribs, the clavicle, and the bones of the upper arm near the shoulder. The breast itself contains no supporting muscles and relies on ligaments to sustain its shape. The measurement of the glandular tissue compared to the amount of intermingling fat tissue has been estimated by Ramsey et al.<sup>31</sup> using ultrasound in 21 lactating white women. The ratio was variable, ranging from 50% to 100% of the breast, proving again that size of the breast does not predict milk production. Ethnicity has little impact on breast size and production but the density of the breast is measurably less in Asian women than white or black women according to work by Chen et al.<sup>4</sup> (Figures 2-14 and 2-15).

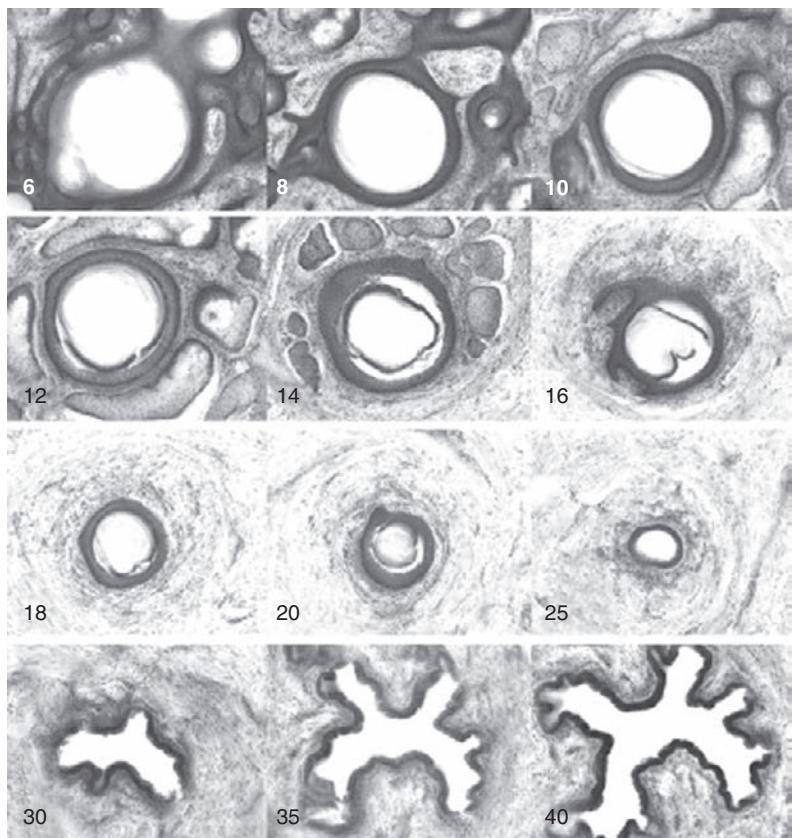

## Blood Supply

The blood supply to the breast is from branches of the intercostal arteries and the perforating branches of the internal thoracic artery; the third, fourth, and fifth are usually most prominent. The major blood supply to the breast is provided by the internal mammary artery and the lateral thoracic artery. A small supply is obtained from the intercostal arteries and the arterial branches of the axillary and subclavian arteries, but this contribution is minimal; 60% of the total breast tissue, especially the medial and central part, receives blood from the internal mammary artery. All the mammary branches of this artery lead transversely to the nipple and anastomoses, with branches coming from the lateral thoracic artery.<sup>40</sup> Anastomoses with intercostal arteries are less common, but the blood supply to the nipple is extensive and close to the surface, contributing to the richer color. Many areas of the breast are supplied by two or three arterial sources (Figure 2-16).

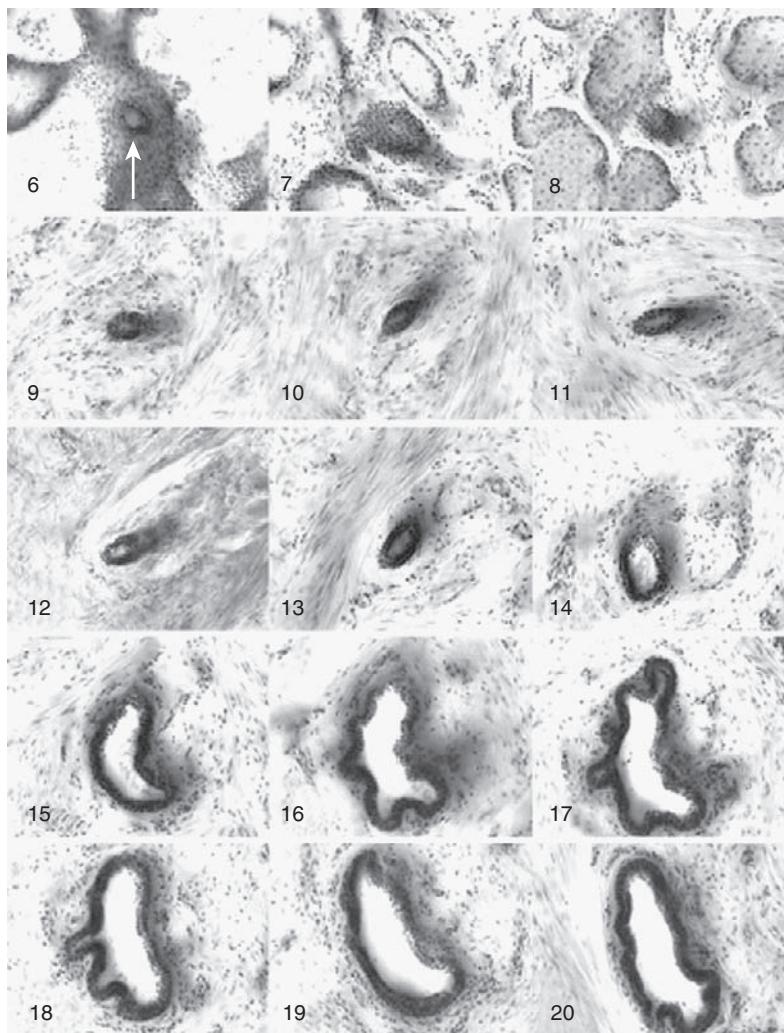

The venous supply parallels the arterial supply and bears similar names. The veins drain the breast and enter the fascia, muscle layers, and intercostal spaces at the same point. The veins end in the internal thoracic and the axillary veins. Some veins may reach the external jugular vein. The veins create an anastomotic circle around the base of the papilla, called the circulus venosus.<sup>40</sup> Individual variation is common.

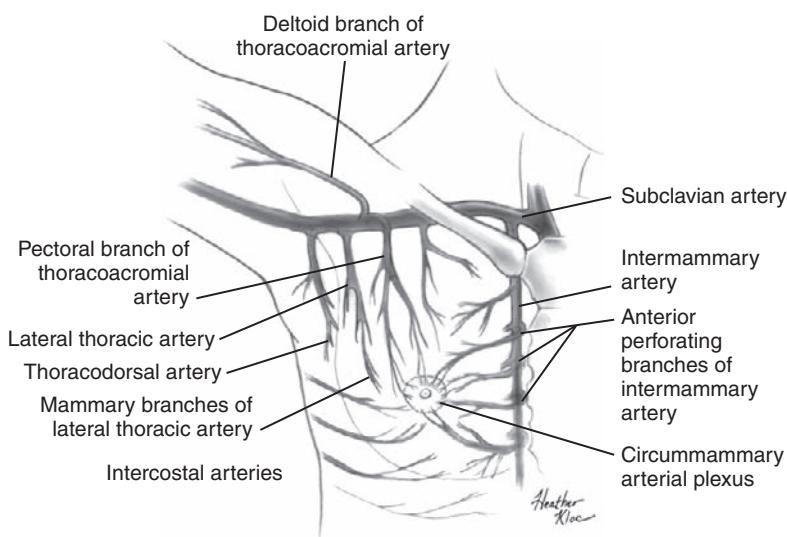

**Figure 2-13.** Digital model of nipple duct anatomy. **A**, Relationship of nipple duct bundle (*inner fibers*) to skin of the papilla (*outer film*). **B**, Lateral view of duct bundle. Seven ducts of varying caliber extend up to the surface of the nipple (population A); 20 other ducts (population B) diminish in caliber and terminate 0.8 to 1.0 mm beneath the surface, close to skin appendages. Seven accessory ducts (population C) are shown as short fibers at base. (From Going JJ, Moffat DF: Escaping from flatland: clinical and biological aspects of human mammary duct anatomy in three dimensions, *J Pathology* 203:538, 2004.)

**Figure 2-14.** A typical “population A” nipple duct: selected sections between 6 and 40. The duct has a wide, funnel-shaped opening onto the surface of the nipple. The lumen tapers moderately before opening out into the characteristically convoluted profile of the collecting ducts in the nipple. The lumen is plugged by keratin in section 20.<sup>17</sup> (From Going JJ, Moffat DF: Escaping from flatland: clinical and biological aspects of human mammary duct anatomy in three dimensions, *J Pathology* 203:544, 2004.)

**Figure 2-15.** A typical “population B” nipple duct: consecutive serial sections from 6 to 20. The duct takes origin from the deep aspect of the nipple epidermis in close proximity to skin appendages (arrow, section 6, top left). It retains a minute lumen over about eight sections (800 µm) before the lumen begins to widen in sections 14 to 20. Such a duct will be difficult to cannulate.

**Figure 2-16.** Blood supply to mammary gland. Major blood supply is from anterior perforating branches of internal mammary artery.

## Lymphatic Drainage

The lymphatic drainage of the breast has been the subject of considerable study because of the frequency of breast cancer, but it has significance for lactating breasts as well. The lymphatic drainage can be extensive. The main drainage is to axillary nodes and to the parasternal nodes along the internal thoracic artery inside the thoracic cavity. The lymphatics of the breast originate in the lymph capillaries of the mammary connective tissue, which surrounds the mammary structures, and drain through the deep substance of the breast. The subepithelial or papillary plexus of the lymphatics of the breast is confluent with the subepithelial lymphatics over the surface of the body. These valveless lymphatics communicate with subdermal lymphatic vessels and merge with the subareolar plexus.<sup>26</sup>

The lymph drainage of the breast consists of the superficial or cutaneous section, the areola, and the glandular or deep-tissue section. More than 75% of the lymph from the breast goes to the axillary nodes. Other points of drainage are to pectoral nodes between the pectoralis major and minor muscles and to the subclavicular nodes in the neck deep to the clavicle. Flow from the deep subcutaneous and intramammary lymphatic vessels travels centrifugally toward the axilla and the internal mammary lymph nodes. The recent physiologic studies have disproved the former hypothesis of centripetal flow toward the subareolar plexus; 97% of lymph flow is into the axillary nodes.<sup>26</sup> Some transmammary lymph drainage occurs to the opposite breast as well as to subdiaphragmatic lymphatics that lead ultimately to the liver and intraabdominal nodes (Figure 2-17). There

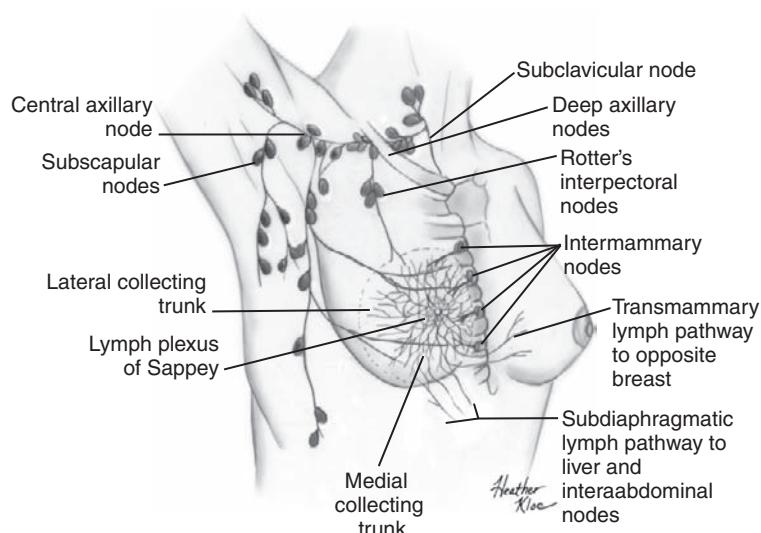

has been minimal study of lymphatic drainage of the lactating breast in spite of its importance in engorgement and mastitis.

## Innervation

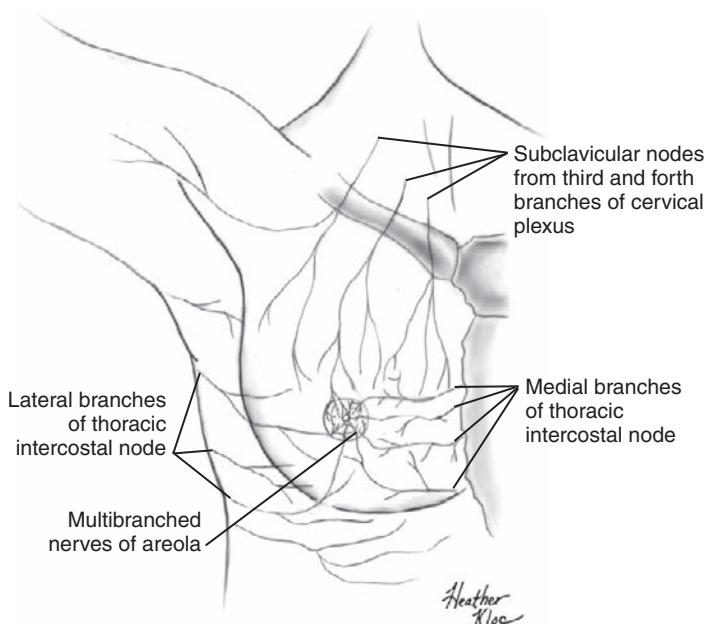

The nerves of the breast are from branches of the fourth, fifth, and sixth intercostal nerves and consist of sensory fibers innervating the smooth muscles in the nipple and blood vessels. The sensory innervation of the nipple and areola is extensive and consists of both autonomic and sensory nerves. A detailed anatomic and clinical study of the nipple-areola complex showed that it is innervated from the lateral cutaneous branch of the fourth intercostal nerve, which penetrates the posterior aspect of the breast at the intersection of the fourth intercostal space and the pectoralis major muscle (4 o'clock on the left breast and 8 o'clock on the right breast).<sup>8</sup> The nerve divides into five fasciculi, one central to the nipple, two upper, and two lower branches (always at 5 and 7 o'clock, left and right side, respectively) (Figures 2-18 and 2-19).

The innervation of the corpus mammariae is minimal by comparison and predominantly autonomic. No parasympathetic or cholinergic fibers supply any part of the breast. No ganglia are found in mammary tissue. Norepinephrine-containing nerve fibers are abundant among the smooth muscle cells of the nipple and at the interface between the media and adventitia of the breast arteries. Physiologic observations demonstrate that the efferent nerves to these structures are sympathetic adrenergic.

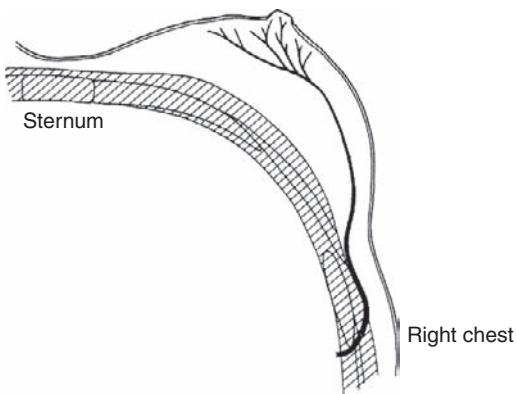

The majority of the mammary nerves follow the arteries and arterioles and supply these structures. A few fibers from the perivascular networks course

**Figure 2-17.** Lymphatic drainage of mammary gland. Major drainage is toward axilla.

**Figure 2-18.** Innervation of mammary gland. Supraclavicular nerves and lateral and medial branches of intercostal nerves provide sensory innervation. Sympathetic and motor nerves are provided by supracervical and intercostal nerves.

**Figure 2-19.** Cross section of nerve supply of breast and nipple. Cutaneous nerves run close to deep fascia before turning outward toward skin.

along the walls of the ducts. They may correspond to sensory fibers for sensing milk pressure. No innervation of mammary myoepithelial cells has been identified. It can, therefore, be concluded that secretory activities of the acinar epithelium depend on hormonal stimulation, such as that of oxytocin and other hormones, and are not stimulated via the nervous system directly. The nipple and areola are reportedly always innervated by the anterior and lateral cutaneous branches of the third to fifth intercostal nerves,<sup>38</sup> which lie along the ducts to the nipple.

Stimulation of the sensory nerve fibers or sensory receptors does induce the release of adenohypophyseal prolactin and neurohypophyseal oxytocin via an

afferent sensory reflex pathway whereby stimuli reach the hypothalamus. Sympathetic mammary stimulation causes the contraction of the small myoepithelial cells of the areola and the nipple. The locally released norepinephrine induces stimulation of the myoepithelial adrenergic receptors, causing muscular relaxation. In the absence of parasympathetic activity, a minor physiologic catecholamine inhibitory effect on the mammary myoepithelium may exist. This is overcome by oxytocin release during suckling, inducing myoepithelial contraction.

The supraclavicular nerves supply the sensory fibers for innervation of the upper cutaneous parts of the breast. Branches of the intercostal nerves provide the major sensory innervation of the mammary gland. The sympathetic sensory and motor fibers are derived from the supraclavicular and intercostal nerves, respectively. Sympathetic fibers run only along the mammary gland—supplying arteries to innervate the glandular body. There is relatively restricted innervation to the epidermal parts of the nipple and areola, leading to lack of superficial sensory acuity.

Courtiss and Goldwyn<sup>5</sup> measured breast sensation in a large number of women using a device that emitted a variable current producing a burning sensation when the threshold was exceeded. The areola was shown to be the most sensitive and the nipple the least sensitive, with the skin of the breast intermediate. The nipple and areola are sparsely innervated with neural elements at the base of the nipple and almost none in the areola.<sup>10</sup> A study of lactating women showed marked increase in areola and nipple sensitivity within 24 hours of birth.<sup>29</sup>

After 1 to 6 months of breastfeeding, women were noted to have minimal two-point discrimination of the skin of the breast.<sup>10</sup> Thus the skin in these areas responds only to major stimuli, such as sucking. The relatively large number of dermal nerve endings provides a high mammary responsiveness toward stimuli for elicitation of the sucking reflex. The neuroreflex induces adequate release of both prolactin and oxytocin. It appears that, in addition to the hormonal actions, breast nerves can also influence the mammary blood supply and milk secretion. Abnormalities of sensory or autonomic nerve distributions in the areola and nipple, therefore, could impair adequate lactation, especially in the functioning of the let-down reflex and the secretion of prolactin and oxytocin.

In summary, the somatic sensory cutaneous nerve supply of the breast includes the supraclavicular nerves and the thoracic intercostal nerves. The autonomic motor nerve supply of the breast is derived from the sympathetic fibers of the intercostal nerves, which supply the smooth musculature of the areola and the nipple. The autonomic supply is also derived from sympathetic fibers of the accompanying arteries, which innervate the smooth musculature of the inner glandular blood vessel walls to produce constriction. The nerve supply to the area of the areola and the nipple includes free sensory nerve endings, tactile corpuscles to the papillae of the corium of the nipple and areola, and the fibers around the larger lactiferous duct and in the dermis of the areola and peripheral breast. All cutaneous nerves run radially to the glandular body toward the nipple. The nerve supply to the inner gland is sparse and contains only sympathetic nerves accompanying blood vessels (see Figure 2-19). Twenty-four hours postpartum, the nipple and areola sensitivity is markedly heightened but decreases in the next few days. The skin of the breast, areola, and nipple showed reduced two-point discrimination when lactation is well established. Clinical evidence supports the observation of limited nerve distribution in the breast.<sup>14</sup>

## Microscopic Anatomy

After many decades of neglect since the phylogenetic studies of the mammary gland in the 1800s and early 1900s, the mammary gland has become one of the most studied organs because of its usefulness as a tool in developmental biology, biochemistry, endocrinology and biology, histology, oncology, toxicology, virology, and molecular biology.<sup>37</sup> No cell can exist independent of its surrounding cells. All cells have relations with neighboring

cells and with cells at distant sites. The interactions of the epithelial parenchyma and mesenchymal stroma are most important in primary and secondary induction in organogenesis. The microstructure of nonlactating mature breasts varies with age, the phase of the menstrual cycle, pregnancy, and lactation. The ducts are lined with columnar epithelium of two cells thick in larger ducts and single layers in the smaller ones. Myoepithelial cells are numerous, creating a distinct layer around ducts and potential alveola.<sup>37</sup>

The mammary gland consists of a branching system of excretory ducts embedded in connective tissue.<sup>11</sup> The gland is composed of two layers of epithelial cells: luminal epithelium and basal layer epithelium, along with a few basal (stem) cells. The whole structure is surrounded by a basement membrane. In the ducts, elongated myoepithelial cells make up a continuous sheath. The luminal cell interaction with the extracellular matrix is mediated by the myoepithelium.

The integrity of the normal mammary gland is maintained by several adhesion systems.<sup>11</sup> The mammary gland is composed of epithelial parenchyma and two types of mesenchymal stroma: dense mammary mesenchyma and fatty stroma. The dense mammary mesenchyma is present in the embryonic stage, in end buds of puberty, and in cancers. It determines mammary epithelium and fixes the ability of the epithelium to interact with the fatty stroma. The fatty stroma is essential for typical mammary gland morphogenesis.<sup>37</sup>

The two types of mammary stroma synthesize different extracellular matrix proteins. Dense mesenchyma makes fibronectin and tenascin. Fatty stroma makes laminin, proteoglycans, and fibronectin.

In their structure and mode of development, the mammary glands somewhat resemble the sweat glands.<sup>9</sup> During embryonic life, their differentiation is similar in the two sexes. Male humans experience little additional development postnatally. Female humans, in contrast, experience extensive structural change paralleling age and the functional state of the reproductive system.

Vogel et al.<sup>45</sup> studied histologic changes in the normal human mammary gland in association with the menstrual cycle. They describe five phases: proliferative (days 3 to 7), follicular phase of differentiation (days 8 to 14), luteal phase of differentiation (days 15 to 20), secretory (days 21 to 27), and menstrual (days 28 to 2). Table 2-4 outlines the morphologic criteria for these phases. These findings illustrate the correlation of morphologic response to hormonal stimulus of the mammary gland during normal cycling.

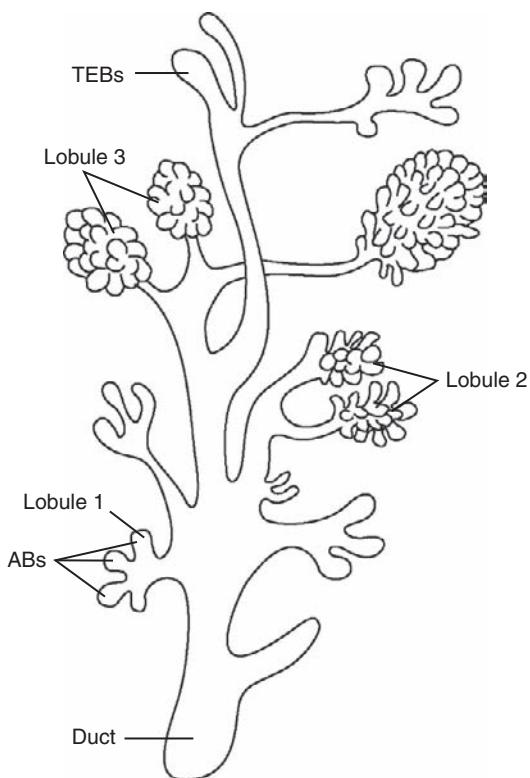

The greatest development in girls is reached by the twentieth year. Gradual changes are correlated with the menstrual cycle, and major changes

**TABLE 2-4** Morphologic Criteria for Phase Assignment in Menstrual Cycle

Phase	Stroma	Lumen	Cell Types	Epithelium		
				Orientation of Epithelial Cells	Mitoses	Active Secretion
Phase I (days 3-7)	Dense, cellular	Tight	Single predominant pale eosinophilic cell	No stratification apparent	Present, average 4/10 HPF	None
Phase II (days 8-14)	Dense, cellular-collagenous	Defined	1. Luminal columnar basophilic cell 2. Intermediate pale cell 3. Basal clear cell with hyperchromatic nucleus (myoepithelial)	Radial around lumen	Rare	None
Phase III (days 15-20)	Loose, broken	Open with some secretion	1. Luminal basophilic cell 2. Intermediate pale cell 3. Prominent vacuolization of basal clear cell (myoepithelial)	Radial around lumen	Absent	None
Phase IV (days 21-27)	Loose, edematous	Open with secretion	1. Luminal basophilic cell 2. Intermediate pale cell 3. Prominent vacuolization of basal clear cell (myoepithelial)	Radial around lumen	Absent	Active apocrine secretion from luminal cell
Phase V (days 28-2)	Dense, cellular	Distended with secretion	1. Luminal basophilic cell with scant cytoplasm 2. Extensive vacuolization of basal cells	Radial around lumen	Absent	Rare

**Figure 2-20.** Schematic representation depicting various topographic compartments of human mammary gland: terminal end buds (TEBs); alveolar buds (ABs); lobules types 1, 2, and 3; and ducts. (Modified from Russo J, Russo IH: Development of human mammary gland. In Neville MC, Daniel CW, editors: *The mammary gland*. New York, 1987, Plenum.)

accompany pregnancy and lactation<sup>34,36</sup> (see Figure 2-8).

Russo and Russo<sup>35</sup> describe the development of the mammary gland as "an asynchronous process of progressive invasion of the mammary stroma by a parenchyma composed of ductal elements in which the advancing ends are the club-shaped terminal end buds (TEBs) that progressively differentiate into alveolar buds (ABs) or regress to terminal ducts (TDs)" (Figure 2-20).

## Mature Mammary Gland

The mammary gland is a compound tubuloalveolar gland containing 15 to 25 irregular lobes radiating from the nipple. Each lobe has a lactiferous duct (2 to 4 mm in diameter) lined by stratified squamous epithelium. The duct opens on the nipple and has an irregular angular outline. Beneath the areola, each duct finally emerges at the end of the nipple as a 0.4- to 0.7-mm opening. Each lobe is subdivided into lobules of various orders; the smallest are

elongated tubules, the alveolar ducts, covered by small saccular evaginations, the alveoli. The interlobular connective tissue is dense; however, it is more cellular, has fewer collagenous fibers, and contains almost no fat. Greater distensibility is permitted by the looser connective tissue.

The ducts and ductules of mature women consist chiefly of two cell types: the inner lining of epithelial cells and the outer lining of myoepithelial cells. A basement membrane separates these structures from the stroma. Histochemical and immunocytochemical reagents can distinguish these elements, their positions, and their infrastructures. Rudland<sup>32</sup> has reported on the histochemical organization and cellular composition of ductal buds in the developing human breast. This work suggests that cytochemical intermediates occur between epithelial and myoepithelial cells. The undifferentiated peripheral cap cells may be transitional forms of the cortical epithelial cells that will line the lumina and of the myoepithelial cells of the subtending duct.

Transforming growth factors (TGF- $\beta$ 1, 2, and 3) are potent inhibitors of cell proliferation but play an important role in mammary gland development. They exhibit overlapping patterns of expression within the epithelium of the developing gland. TGF- $\beta$ 3 is detected in the myoepithelial progenitor cells of the growing end buds and the myoepithelial cells in the mature duct.<sup>28</sup>

The secretory portions of the gland, the alveolar ducts and the alveoli, have cuboidal or low-columnar secretory cells, resting on basal laminae and myoepithelial cells. These myoepithelial cells enclose the alveoli in a loosely meshed network with their many starlike branchings. The myoepithelial cells are stimulated by oxytocin and sex steroids. The presence of myoepithelial cells has been used as evidence that the mammary gland is related to the sweat gland.

In the at rest phase, epithelial structures consist of the ducts and their branches. The presence of a few alveoli budding from the ends of ducts is still under investigation. This variance may be caused by the effect of the menstrual cycle. The swelling and engorgement accompanying the menstrual cycle are associated with hyperemia and some edema of the connective tissue. Most significant is that the gland does not have a single duct but many. Each lobe is a separate compound alveolar gland in which primary ducts join into larger and larger ducts. These ducts drain into a lactiferous duct. Each lactiferous duct drains separately at the tip of the nipple.

The epidermis of the nipple and areola is invaded by unusually long dermal papillae in which capillaries richly vascularize the surface and impart the richer hue. Bundles of smooth muscle, placed

longitudinally along the lactiferous ducts and circumferentially within the nipple and at its base, permit the erection of the nipple. In the areola are the areolar Montgomery glands, which are intermediate in their microscopic structure between sweat glands and true mammary glands. The periphery of the areola also has sweat glands and sebaceous glands (see Figure 2-9).

## Mammary Gland in Pregnancy

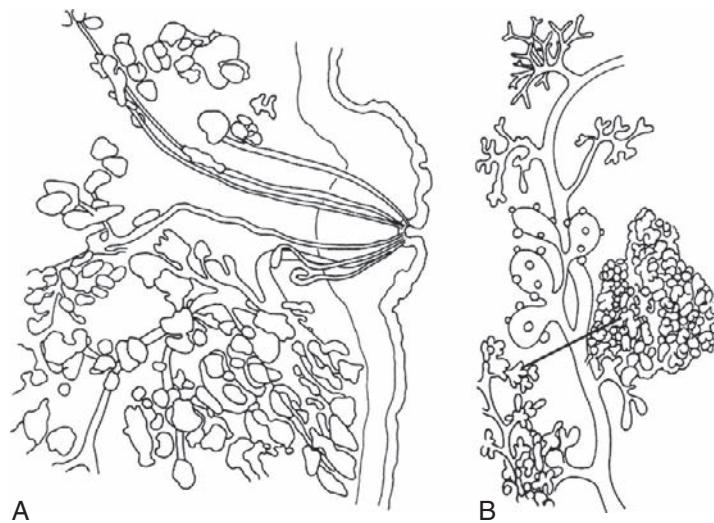

Although mini-remodeling of the breast occurs at each menstrual cycle, it is not until pregnancy that complete remodeling occurs. It is transformed into a mature functional organ. The MaSC population is activated by the ovarian hormonal circuit. The levels of estrogen, progesterone, and prolactin are increased. Other hormones and growth factors regulate the mammary expansion.

The first 3 to 4 weeks of pregnancy has marked ductular sprouting with some branching and lobular formation, stimulated by estrogenic release. By 5 to 8 weeks, the breast changes are physically notable with dilation of the superficial veins, heaviness, and increased pigmentation of the nipple and areola. Changes in levels of circulating hormones result in profound changes in the ductular-lobular-alveolar growth during pregnancy (Figure 2-21). During the first trimester, growth and branching from the terminal portion of the duct system into the adipose tissue is rapid.<sup>43</sup> As the epithelial structures proliferate, the adipose tissue seems to diminish. During this time, increasing infiltration of the interstitial tissue

occurs with lymphocytes, plasma cells, and eosinophils. The rate of hyperplasia levels off. In the last trimester, any enlargement is the result of parenchymal cell growth and distention of the alveoli with early colostrum, which is rich in protein and relatively low in lipid. Fat droplets gradually accumulate in the secretory alveolar cells. The interlobular connective tissue is noticeably decreased, and alveolar proliferation is extensive. In experimental studies, these effects can be duplicated when estrogen and progesterone stimulate a release of prolactin-inhibiting factor (PIF). Prolactin is released in humans during pregnancy, thus stimulating epithelial growth and secretion. Prolactin levels increase over time during pregnancy.

Pregnancy induced changes are important clinical observations usually completed by 22 weeks. The size varies markedly. Although important, breast size during pregnancy is not an accurate indicator of lactation potential. The lactation potential of women who deliver prematurely may be diminished and result in delayed secretory initiation.

The histologic appearance of the gland varies. The functional state appears to vary from dilated, thin-walled lumen to narrow-lumened, thick-walled glandular tissue. Epithelial cells vary, being flat to low columnar in shape with indistinct boundaries. Some cells protrude into the lumen of the alveoli, others are short and smooth. The lumen of the alveolus is crowded with fine granular material and lipid droplets similar to those protruding from the cells. The mammary alveoli but not the

**Figure 2-21.** **A**, Milk gland of 21-year-old primigravida woman in second month of pregnancy. Development of small lobes has protruded almost to mammilla. Very regular development is shown over whole range of this thick section. Natural dimensions:  $2.6 \times 2.1$  cm. **B**, Milk gland of same 21-year-old primigravida woman. Note very different forms of sprouting. Partly atypical sprouts above diagonal line are composed from same section; bifurcations below line are in natural position. Alveoli are beginning to resemble mature gland. (From Dabelow A: Die Milchdrüse. In *Handbuch der Mikroskopischen Anatomie des Menschen*, vol 3, part 3, Berlin, 1957, Springer-Verlag.)

milk ducts lose the superficial layer of cells in the second trimester. The monolayer differentiates into a cell layer that accumulates eosinophilic cells, plasma cells, and leukocytes around the alveoli. Lymphocytes, round cells, and desquamated phagocytic alveolar cells are also found in the lumen. The resting breast consists of ductal epithelial tissue with a fibrous stroma. The duct wall is lined with layers of epithelial cells. The inner layer encapsulates the ductal lumen, which is made up of cuboidal epithelial cells, some of which can actually further differentiate into milk secretory cells (lactocytes) during lactation. The outer layer, or basal layer, is made up of contractile myoepithelial cells that encircle the luminal layer and behave like smooth muscle cells (see Figure 2-21). The basal layer lies on the basement membrane and is believed to contain MaSCs.

More recent studies have identified stem cells in the breast that are related to the breast's ability to expand and regress repeatedly throughout adult life. The presence of self-renewing bipotent MaSCs as well as unipotent progenitors have been identified in the resting epithelium. Most of the observations have been made in mice whose mammary stroma differ. Human mammary stroma is highly dense fibrous connective tissue which embeds in the adipose tissue. The intralobular stroma consists of mesenchymal cells. These cells are very responsive to the hormonal microenvironmental cues. They initiate and promote the various stages of mammary development as they interact with the mammary epithelium. The cellular hierarchy of the lactating breast is found in the milk itself. It includes early stage stem cells and more differentiated myoepithelial and milk secreting cells.

By the end of pregnancy, lobular, highly branched epithelial tissue separated by some fibrous stroma is the predominant structure. Secretory differentiation has occurred in some luminal cells of the alveoli. Fat globules are visible with the cells, and alveoli are formed at the end of the duct termini, which contain the lactocytes. The lactocyte is a cuboidal polarized cell. Polarization promotes the movement of milk toward the lumen. The milk moves through the duct containing the biochemical factors secreted by lactocytes and some cells from the epithelium.

## Lactating Mammary Gland

The lactating mammary gland is characterized by a large number of alveoli (Figure 2-22). The alveoli of the lactating gland are made up of cuboidal epithelial and myoepithelial cells.<sup>34</sup> Only a small amount of connective tissue separates the neighboring alveoli. Under special preparations, lipid can be seen as

**Figure 2-22.** Part of a mammary gland with significant milk obstruction in a 26-year-old woman who died from food poisoning after ingesting spoiled fish 3 weeks postpartum and who had not breastfed for 48 hours before death. In upper half, formed duct and lobes are located on alternating sides. This form results from different development of two parts of a dichotomized bifurcation: one takes over production of small lobes, while the other continues the stem. Thick section; very primitive, undeveloped sprouts (arrow). (From Dabelow A: Die Milchdrüse. In *Handbuch der Mikroskopischen Anatomie des Menschen*, vol 3, part 3, Berlin, 1957, Springer-Verlag.)

small droplets within the cells. These droplets become larger and are discharged into the lumen.

The functioning of the mammary gland depends on the interplay of multiple and complex nervous system and endocrine factors.<sup>44</sup> Some factors are involved in the development of the mammary glands to a functional state (mammogenesis), others in the establishment of milk secretion (lactogenesis), and others in the maintenance of lactation (galactopoiesis).<sup>43</sup>

The division and differentiation of mammary epithelial cells and presecretory alveolar cells into secretory milk-releasing alveolar cells take place in the third trimester. Stimulation of ribonucleic acid (RNA) synthesis promotes galactopoiesis and apocrine milk secretion into the alveoli. The deoxyribonucleic acid (DNA) and RNA content of the cellular nuclei increases during pregnancy and is highest at lactation (see Figure 2-3).

The former concepts of mammary gland secretion indicated that the mode of release was apocrine secretion. Apocrine secretion is the process by which the cell undergoes partial disintegration. A fat-filled portion projects into the lumen; the fat globule constricts at the base, and the cell replaces itself. Electron microscopy has shown that the cell has two distinct secretory products, formed and released by different mechanisms. The protein constituents of milk are formed and released identically to those of other protein-secreting glands, classified as merocrine glands. Secretory materials are passed out through the cell apex without appreciable loss of cytoplasm in merocrine glands.

The fatty components of milk arise as lipid droplets free in the cytoplasmic matrix. The droplets increase in size and move into the apex of the cell. They project into the lumen, covered by a thin layer of cytoplasm. The droplets are ultimately cast off, enveloped by a detached portion of the cell membrane and a thin rim of subjacent cytoplasm (see [Figure 2-3](#) and [Chapter 3](#) for further discussion).

The ultrastructure of the human mammary gland during lactogenesis was studied by Tobon and Salazar,<sup>43</sup> who reviewed surgical specimens from seven lactating women 1 day to 5½ months postpartum. They noted widespread hypertrophy and hyperplasia of the acini accompanied by dilatation and engorgement of the lumen by milk. The vascular channels were engorged. The lactogenic epithelial cells had rich cytoplasm, prominent layers of reticulum, and enlarged oval mitochondria. The Golgi apparatus was hypertrophied. The myoepithelium was stretched and thinned to contain the filled acini.

The ratio of glandular tissue to fat tissue changes during lactation from a 1:1 ration in the nonlactating breast to 2:1 during lactation.

The least well studied and, therefore, understood is the adipose cell, which has been recognized as important by Geddes.<sup>10</sup> Adipocytes have been observed to be transformed into lactocytes during pregnancy by Morroni et al.<sup>22</sup> using the mouse model. They then returned to adipocytes during the involuntary phase. Breast milk contains a cellular hierarchy from early stage stem cells with embryonic-like features and multilineage differentiation potential to MaSCs from the resting breasts, cells with progenitor characteristics to the mature myoepithelial and milk secreting cells (see [Figure 2-3](#) and [Chapter 3](#) for further discussion).

Not all alveoli are at the same development stage; there are some nonfunctioning ducts at any given time during lactation. The signaling cascade that influences alveoli is development and differentiation patterns between different lobules. The role of vascularization may be significant in the functional heterogeneity of the lactating breast.

## *Postlactation Regression of Mammary Gland*

If milk is not removed from the breast, the glands become greatly distended and milk production gradually ceases. Part of the decrease results from the lack of stimulation of sucking, which initiates the neurohormonal reflex for maintenance of prolactin secretion. Perhaps a stronger effect is the engorgement of the breast with compression of blood vessels, causing diminished flow. The diminished blood flow results in decreased oxytocin to the myoepithelium. The alveoli are greatly distended and the epithelium flattened. The secretion remaining in the alveolar spaces and ducts is absorbed. The alveoli gradually collapse, with an increase in perialveolar connective tissue. The glandular elements gradually return to the at rest state. Adipose tissue and macrophages increase. The gland does not return completely to the prepregnancy state in that the alveoli formed do not totally involute. Some appear as scattered, solid cords of epithelial cells.

Microscopically, increased autophagic and heterophagic processes occur in the first few days after weaning. Lysosomal enzymes increase, whereas nonlysosomal enzymes decrease. The gland undergoes alveolar epithelium apoptosis and remodeling, reverting back to the prepregnant state with the loss of prolactin.

Although the process of regression has been studied carefully in animals, little study has been done in humans. Slow weaning, which usually takes 3 months, probably has a very different timetable from abrupt weaning, in which marked involution has been intense and rapid over days or weeks. At the conclusion of weaning or involution the breast returns to a resting or nonlactating state. The structure and morphology is not the same as it was in the nulliparous stage. Some lobular structures remain in the parous gland. Some partially differentiated epithelial cells escape the involution and act as "memory precursor cells" in the next pregnancy. The cell types that actually phagocytose the apoptotic epithelial cells are still unsettled (nonhuman research on the subject varies). Apoptotic cells may be phagocytosed by neighboring nonhematopoietic cells. The mechanisms through which involution is initiated and the gene networks involved remain under investigation.

## CHAPTER 3

# *Physiology of Lactation*

---

Lactation is the physiologic completion of the reproductive cycle.\*<sup>23,53,62,63,66,103</sup> Human infants at birth are the most immature and dependent of all mammals, except for marsupials. The marsupial joey is promptly attached to the teat of a mammary gland in an external pouch. The gland changes as the offspring develops, and the joey remains there until able to survive outside the pouch. In humans, throughout pregnancy the breast develops and prepares to take over the role of fully nourishing the infant when the placenta is expelled.

There are two stages in the initiation of lactation: secretory differentiation and secretory activation. Pang and Hartman<sup>66</sup> said it best: "Secretory differentiation represents the stage of pregnancy when the mammary epithelial cells differentiate into lactocytes with the capacity to synthesize unique milk constituents such as lactose." They further explain that this requires the presence of a "lactogenic hormone complex." This complex of reproductive hormones includes estrogen, progesterone, prolactin, and some other metabolic hormones. Secretory activation, they note, is the initiation of copious milk secretion associated with major changes in the concentrations of many milk constituents. With the withdrawal of progesterone, secretory activation is triggered. This requires prolactin as well as insulin and cortisol.

The breast is prepared for full lactation from 16 weeks' gestation without any active intervention from the mother. It is kept inactive by a balance of inhibiting hormones that suppress target cell response. In the first few hours and days postpartum, the breast responds to changes in the hormonal milieu and to the stimulus of the newborn infant's suckling to produce and release milk.<sup>50,59,61,63</sup> The existence of mammary stem cells has been speculated because the mammary gland has been regenerated by transplanting epithelial fragments in mice.

Transplanted cells contributed to both luminal and myoepithelial lineages. From these were generated functional lobuloalveolar units during pregnancy. The cells had self-renewing properties. The serial transplantsations of Shackleton et al.<sup>78</sup> have established that single cells are multipotent and self-renewing and can generate a functional mammary gland. The potential for further understanding of the mammary gland is unlimited.

The energy expenditure during lactation has suggested an efficiency of human milk synthesis greater than the 80% value previously hypothesized by investigators. From work in Gambian women and extensive review of other studies, Frijerio et al.<sup>25</sup> suggest that the energy cost of human lactation is minimal and the process functions at 95% efficiency.

This chapter provides a review of the physiologic adaptation of the mammary gland to its role in infant survival. Several major reviews that include substantial bibliographies for readers who need the detailed reports of the original investigators are referenced. Newer scientific techniques in the study of human lactation provide more precise, more detailed, and more integrated data on which the clinician can base a physiologic approach to lactation management.

**Box 3-1** lists the abbreviations for the hormones that are involved in lactation and are discussed in this chapter.\*

### *Apoptosis in the Mammary Gland*

---

Epithelial apoptosis has a key role in the development and function of the mammary gland. It begins with the formation of the ducts in the embryonic

\*<sup>13,14,16,44,54,92</sup>

**BOX 3-1. Hormone Abbreviations**

Adrenocorticotrophic hormone	ACTH
Epidermal growth factor	EGF
Feedback inhibitor of lactation	FIL
Follicle-stimulating hormone	FSH

Heregulin	HER
Human growth factor	hGF, HGF
Human placental lactogen	hPL
Insulin-like growth factor-1	IGF-1
Prolactin	PRL
Prolactin-inhibiting factor	PIF
Thyroid-stimulating hormone	TSH
Thyrotropin-releasing hormone	TRH
Transforming growth factor beta	TGF-β

phase and occurs again at puberty and with a stage of menses. Regulated apoptosis occurs at several stages of mammary development. In the embryo, epithelial buds emerge from ectoderm into mammary mesenchyme, which is the origin of the ductal tree. When the ducts later hollow out in puberty, extensive apoptosis occurs within the terminal bud.<sup>27</sup>

Deregulated apoptosis contributes to the malignant progression in the genesis of breast cancer. Research in apoptosis continues because it may lead to new cancer treatments, but the knowledge itself will be valuable.

When suckling ceases during weaning, the alveolar component of the gland involutes by both

apoptosis and tissue remodeling, which rebuilds the gland to the prepregnancy state.

Much is being learned about mammary development and function through the intense study of the breast as an experimental system. The use of novel "knockout" mouse models has been employed to study nursing failure. The apoptosis control mechanism from the angle of the signaling pathways has been studied. Further work at the level of the cell is underway, including extensive genetic analysis.<sup>27</sup>

## Hormonal Control of Lactation

In contrast to most organs, which are fully developed at birth, the mammary gland undergoes most of its morphogenesis postnatally, in adolescence, and in adulthood.<sup>57</sup> Lactation is an integral part of the reproductive cycle of all mammals, including humans. The hormonal control of lactation can be described in relation to the five major stages in the development of the mammary gland: (1) embryogenesis; (2) mammogenesis, or mammary growth; (3) lactogenesis, or initiation of milk secretion; (4) lactation (stage III lactogenesis), or full milk secretion; and (5) involution (Table 3-1).<sup>57</sup>

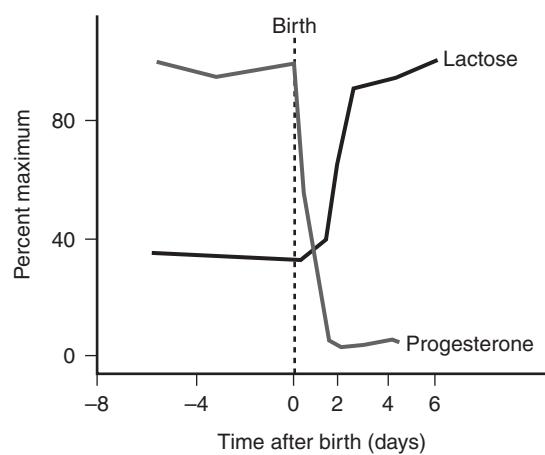

Current terminology divides lactogenesis into two stages.<sup>32</sup> Stage I takes place during pregnancy when the gland is sufficiently developed to actually produce milk. It begins about midpregnancy (approximately 16 weeks). It can be identified by measuring the levels of plasma lactose and α-lactalbumin.<sup>2</sup> Should the mother deliver at this point, milk would be produced. Some mothers can express

**TABLE 3-1** Stages of Mammary Development\*

Developmental Stage	Hormonal Regulation	Local Factors	Description
Embryogenesis	?	Fat pad necessary for ductal extension	Epithelial bud develops in 18- to 19-week-old fetus, extending short distance into mammary fat pad with blind ducts that become canalized; some milk secretion may be present at birth
Puberty Before onset of menses After onset of menses	Estrogen, GH Estrogen, progesterone ? PRL	IGF-1, hGF, TGF-β, ? others	Ductal extension into mammary pad; branching morphogenesis Lobular development with formation of terminal duct lobular unit (TDLU) Anatomic development
Mammogenesis			
Pregnancy	Progesterone, PRL, hPL	HER, ? others	Alveolus formation; partial cellular differentiation
Lactogenesis	Progesterone withdrawal, PRL, glucocorticoid	Not known	Onset of milk secretion Stage I: midpregnancy Stage II: parturition
Lactation	PRL, oxytocin	FIL	Ongoing milk secretion
Involution	PRL withdrawal	Milk stasis, ? FIL	Alveolar epithelium undergoes apoptosis and remodeling; gland reverts to prepregnant state

\*See Box 3-1 for abbreviations.

Modified from Neville MC: Mammary gland biology and lactation: a short course. Presented at biannual meeting of the International Society for Research on Human Milk and Lactation, Plymouth, Mass., 1997.

**Figure 3-1.** Progesterone withdrawal initiates lactogenesis II in women. The increase in lactose concentrations associated with increased synthesis of milk components coincides with a rapid decrease in progesterone concentration when the placenta is removed at parturition. (From Czan KC, Henderson JJ, Kent JC, et al: Hormonal control of the lactation cycle. In Hale TW, Hartmann PE, editors: *Textbook of human lactation*, Amarillo, Tex., 2007, Hale Publishing LP.)

colostrum during this time. As the pregnancy proceeds, milk production is inhibited by high levels of circulating progesterone in most mammals and estrogen as well in humans.

Stage II of lactogenesis is the onset of copious milk production at delivery. In all mammals, it is associated with the drop in progesterone levels (Figure 3-1). This drop occurs to herald delivery in some species so that milk is copious when the young are born. In humans, these levels drop during the first 4 days postpartum, which is reflected by the milk "coming in" during this time. The drop in progesterone is accompanied by the transformation of the mammary epithelium to produce volumes of milk by the fifth day. This change includes a change in permeability of the paracellular pathway and changes in secretion of protective factors (i.e., lactoferrin, immunoglobulins), as well as increases in all milk components that parallel increased glucose production.

During the next 10 days, the composition of the milk slowly changes to mature milk. Composition then changes slowly over the months of full exclusive breastfeeding.

## Embryogenesis

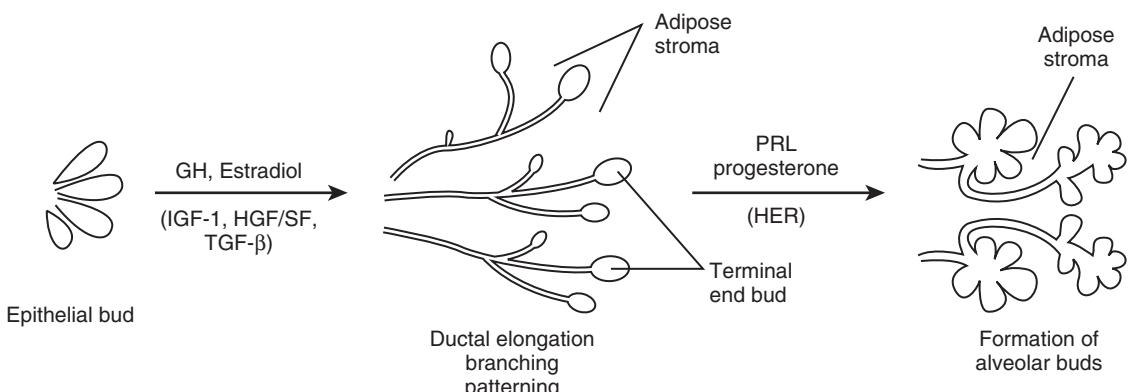

Embryogenesis begins with the mammary band, which develops about the 35th embryonic day and progresses to a bud at the 49th day (see Chapter 2). Ducts continue to elongate to form a mammary sprout, which invades the fat pad, branches, and canalizes, forming the rudimentary

mammary ductal system present at birth. After birth, growth of this set of small branching ducts parallels the child's linear growth but remains limited, probably controlled by growth hormone (GH) before onset of ovarian activity.

Under the influence of sex steroids, especially the estrogens, the mammary glandular epithelium proliferates, becoming multilayered. Buds and papillae then form. The growth of the mammary gland is a gradual process that starts during puberty. The process depends on pituitary hormones. Lobuloalveolar development and ductal proliferation also depend on an intact pituitary gland.

The following six well-documented factors help explain the organization of mammary growth. Much of this work has resulted since the availability of "knockout" studies in mice and associated techniques.

1. Mammary ducts must grow into an adipose tissue pad if morphogenesis is to continue. Only adipose stroma supports ductal elongation. The mammary epithelium is closely associated with the adipocyte-containing stroma in all phases of development. In midgestation during human fetal development, a fat pad is laid down as a separate condensation of mesenchyma. Rudimentary ducts expand into the fat pad but do not progress.<sup>57</sup> At puberty, the ducts elongate to fill the entire fat pad, terminating growth as they reach the margins of the fat pad.
2. Estrogen is essential to mammary growth.<sup>100</sup> Ductal growth does not occur in the absence of ovaries but can be stimulated when estrogen is provided. In the ovariectomized (oophorectomized) mouse, an estrogen pellet placed in the mammary tissue stimulates growth in that gland but not in the opposite gland. When the estrogen receptor is "knocked out" in the mouse, no mammary development occurs. The increase in estrogen at puberty results in mammary development. Although estrogen is essential, it is not adequate alone.<sup>6</sup>
3. The exact location of the estrogen receptors in human breasts is unclear. Estrogen receptors are not in the proliferating cells and have not been located in the stroma. Cells with estrogen receptors, however, secrete a paracrine factor that is responsible for the proliferation of ductal cells. This paracrine factor may hold the key to understanding both normal and abnormal breast development.
4. In addition to estrogen, the pituitary gland is necessary for breast development. Kleinberg<sup>39</sup> has identified GH as important to pubertal development and development of the terminal end buds in the breast. Prolactin could not replace GH in these experiments, but insulin-like

**Figure 3-2.** Scheme for regulation of mammary development in the mouse. (From Neville MC: Mammary gland biology and lactation: a short course. Presented at the annual meeting of the International Society for Research on Human Milk and Lactation, Plymouth, Mass., 1997.)

growth factor-1 (IGF-1) could. It is produced in the stromal compartment of the mammary gland under stimulation by GH, and together with estradiol from the ovaries, IGF-1 brings about ductal development at puberty.

5. Transforming growth factor beta (TGF- $\beta$ ) maintains the spacing of the mammary ducts as they branch and elongate.<sup>57</sup> These ducts exhibit unique behavior during growth, turning away to avoid other ducts and end buds. This avoidance behavior accounts for the orderly development of the duct system in the breast and the absence of ductal entanglements. This pattern provides ample space between ducts for later development of alveoli. TGF- $\beta$  has been identified as the negative regulator and is found in many tissues, including breast tissue produced by an epithelial element. The pattern formation in ductal development depends on the localized expression of TGF- $\beta$ .<sup>18</sup>
6. Progesterone secretion brings about the side branching of the mammary ducts.<sup>35</sup> The presence of progesterone receptors in the epithelial cells has been confirmed by studies in knockout mice in which mammary glands develop to the ductal stage but not to alveolar morphogenesis. Ormandy et al.<sup>66</sup> established that prolactin is necessary for full alveolar development through prolactin receptor studies in knockout mice in which mammary glands do not develop beyond the ductal stage. This was further confirmed in murine mammary cultures in which full development of the alveoli depends on prolactin. Further, when prolactin is withdrawn, apoptosis of the alveolar cells occurs.<sup>95</sup>

The coordination of epithelial and stromal activity in the mammary gland is complex. Hepatocyte growth and scatter factor has been associated with the process during puberty.<sup>64</sup> Another growth

factor, heregulin, a member of the epidermal growth factor (EGF) family, has been identified in the stroma of mammary ducts during pregnancy.

Neville<sup>57</sup> has diagrammed the regulation of mammary development (Figure 3-2). She notes that the concentrations of estrogen, progesterone, and lactogenic hormone in the form of prolactin or placental lactogen (PL) greatly increase, enhance alveolar development, and result in the differentiation of alveolar cells. Although many investigators have contributed pieces to the puzzle of mammogenesis, Neville succeeded in creating the current visualization.<sup>57</sup>

## Mammogenesis: Mammary Growth

### PREPUBERTAL GROWTH

Mammogenesis occurs in two phases as the gland responds to the hormones of puberty and later of pregnancy.<sup>54</sup> During the prepubertal phase, the primary and secondary ducts that develop in the fetus in utero continue to grow in both boys and girls in proportion to growth in general. Shortly before puberty, a more rapid expansion of the duct system begins in girls. The growth of the duct system seems to depend predominantly on estrogen and does not occur in the absence of ovaries. The complete growth of the alveoli requires stimulation by progesterone as well.

Studies of hypophysectomized animals have shown failure of full mammary growth even with adequate estrogen and progesterone. Secretion of prolactin and somatotropin by the pituitary gland results in mammary growth. Adrenocorticotropic hormone (ACTH) and thyroid-stimulating hormone (TSH) acting on the adrenal and thyroid glands also play a minor role in the growth of the mammary gland.

Growth and development during organogenesis involve the interaction of cells with extracellular

matrices and neighboring cells.<sup>76</sup> Necropsy breast specimens from six male and eight female infants ranging in age from 1 day to 9 months were studied to determine the process of organogenesis in humans.<sup>1</sup> Integrins were expressed in a pattern that correlates with morphologic and functional differentiation of the normal mammary gland. Integrins are transmembrane glycoproteins that form receptors for extracellular matrix proteins, such as fibronectin, laminin, and collagen. Integrins are widely expressed in normal tissue and are considered critical to the control of cell growth and differentiation. This suggests integrin involvement in the functional characterization of the adhesion molecules in the breast.

## PUBERTAL GROWTH

When the hypophyseal-ovarian-uterine cycle is established, a new phase of mammary growth, which includes extensive branching of the system of ducts and proliferation and canalization of the lobuloalveolar units at the distal tips of the branches, begins. Organization of the stromal connective tissue forms the interlobular septa. The ducts, ductules (terminal intralobular ducts), and alveolar structures are formed by double layers of cells. One layer, the epithelial cells, circumscribes the lumen. The second layer, the myoepithelial cells, surrounds the inner epithelial cells and is bordered by a basement lamina.

## MENSTRUAL CYCLE GROWTH

The cyclic changes of the adult mammary gland can be associated with the menstrual cycle and the hormonal changes that control that cycle. Estrogens stimulate parenchymal proliferation, with formation of epithelial sprouts. This hyperplasia continues into the secretory phase of the cycle. Anatomically, when the corpus luteum provides increased amounts of estrogens and progesterone, there is lobular edema, thickening of the epithelial basal membrane, and secretory material in the alveolar lumen. Lymphoid and plasma cells infiltrate the stroma. Clinically, mammary blood flow increases in this luteal phase. This increased flow is experienced by women as fullness, heaviness, and turgescence. The breast may become nodular because of interlobular edema and ductular-acinar growth.

After onset of menstruation and reduction of sex steroid levels, milk-secretory prolactin action is limited. Postmenstrual changes occur rapidly, with degeneration of glandular cells and proliferation tissue, loss of edema, and decrease in breast size. The ovulatory cycle actually enhances mammary growth in the early years of menstruation (until

about age 30 years) because the postmenstrual regression of the glandular-alveolar growth after each cycle is not complete. These changes of ductal and lobular proliferation, which occur during the follicular phase before ovulation, continue in the luteal phase and regress after the menstrual phase, exemplifying the sensitivity of this target organ to variations in the balance of hormones.

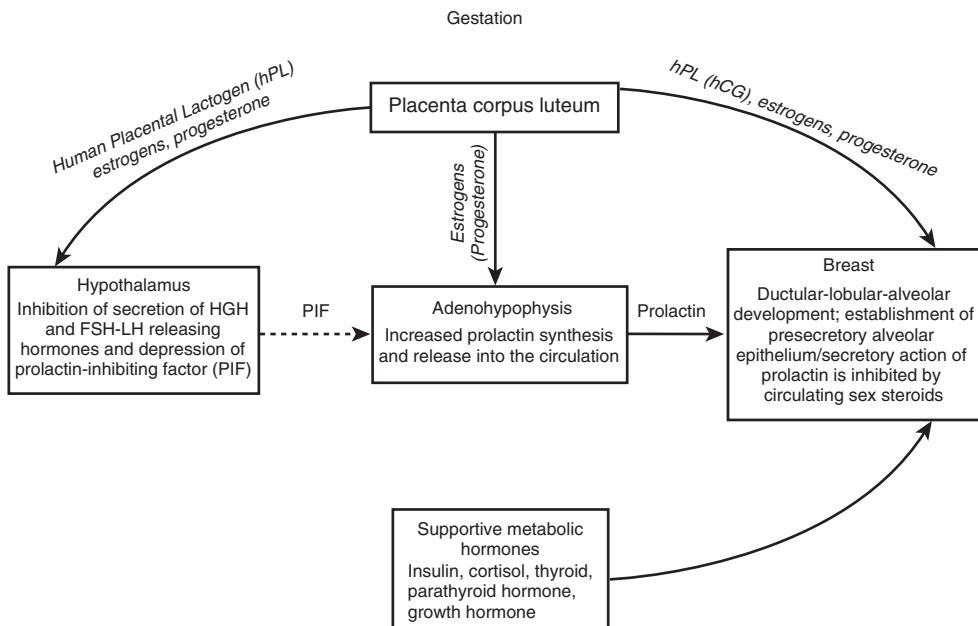

Fowler et al.<sup>21</sup> measured cyclic changes in composition and volume of the breast during the menstrual cycle using nuclear magnetic resonance T1-weighted imaging. The T1 relaxation time (spin-lattice T1 relaxation) is a measure of the rate of energy loss from tissues after T1 excitation. This energy loss depends on the biophysical environment of the excited protons. A short T1, therefore, indicates the presence of lipids and organic structures that bind water tightly. A longer T1 occurs with greater hydration and with the greatest amount of cellular water. This study revealed the lowest total breast volume and parenchymal volume. T1 and water content occurred between days 6 and 15 of the cycle. Between days 16 and 28, T1 rose sharply and it peaked on the 25th day. The rise in parenchymal volume in the second half of the cycle resulted from not only increased tissue water but also from growth and increased tissue fluid, according to Fowler et al.<sup>21</sup>

## Growth During Pregnancy

Hormonal influences on the breast cause profound changes during pregnancy (Figures 3-3 and 3-4). Early in pregnancy, a marked increase in ductular sprouting, branching, and lobular formation is evoked by luteal and placental hormones.<sup>99</sup> PL, prolactin, and chorionic gonadotropin have been identified as contributors to the accelerated growth (Figure 3-4). The dichorionic ductular sprouting has been attributed to estrogen and lobular formation to progesterone.

Prolactin is essential for complete lobular-alveolar development of the gland. Almost complete growth of the mammary lobular-alveolar system can be obtained experimentally in the hypophysectomized-adrenalectomized rat if the animal receives estrogen, progesterone, and prolactin.<sup>42</sup> Prolactin, as with other protein hormones, exerts its effect through receptors for the initiation of milk secretion located on the alveolar cell surfaces. The induction of milk synthesis requires insulin-induced cell division and the presence of cortisol. Prolactin is secreted by the pituitary, which is negatively controlled by prolactin-inhibiting factor (PIF) from the hypothalamus.<sup>42</sup>

From the third month of gestation, secretory material that resembles colostrum appears in the acini. Prolactin from the anterior pituitary gland

**Figure 3-3.** Hormonal preparation of breast during pregnancy for lactation. (Modified from Vorherr H: *The breast: morphology, physiology and lactation*, New York, 1974, Academic Press.)

stimulates the glandular production of colostrum. By the second trimester, PL begins to stimulate the secretion of colostrum. A mother who delivers after 16 weeks' gestation will secrete colostrum, even though she has had a nonviable infant. This demonstrates the effectiveness of hormonal stimulation on lactation.

An estrogen-mediated increase in prolactin secretion in pregnancy may produce as much as a tenfold to twentyfold increase in plasma prolactin. This effect may be partially controlled by lactogen from the placenta, which inhibits the production of prolactin. Hormonal regulation of the growth and proliferation of the mammary gland cells has been carefully studied in many species.

Studies of mice in which receptors for each of the hormones have been ablated demonstrate that progesterone and prolactin (or possibly placenta lactogen) are key to alveolar development in pregnancy. The major inhibitor of milk production during pregnancy has been shown to be progesterone.<sup>35</sup>

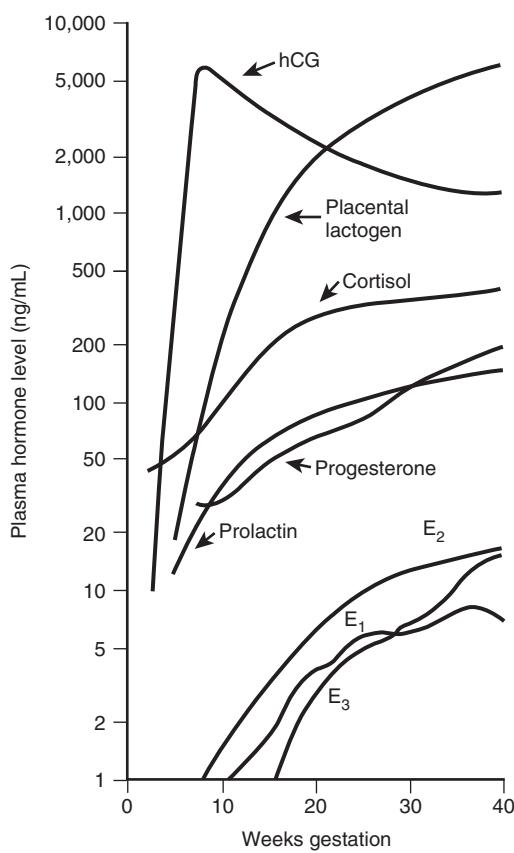

A complex sequence of events, governed by hormonal action, prepares the breast for lactation (see Figure 3-3). During pregnancy, 17 $\beta$ -Estradiol stimulates the ductal system of epithelial cells to elongate. In contrast to puberty, however, when estrogens appear to directly and indirectly stimulate breast development, estrogens have no indispensable role in mammary development during pregnancy except as a prolactin potentiator: according to Neville,<sup>54</sup> when estrogen levels are low in pregnancy, the breast still develops.

Estrogen levels are normally high in pregnancy, but not for mammogenesis. Induced lactation in the cow is dependably reproduced with 7 days of estrogen and progesterone treatment. Progesterone, in turn, induces the specific epithelial cells of the tubular invaginations to produce distinct ducts, which branch from the main tubules.<sup>35</sup>

The end result of the combined actions of estrogen and progesterone is a richly branched arborization of the gland. Highly differentiated secretory alveolar cells develop at the ends of these ducts under the influence of prolactin (Figure 3-5).

Serum growth factor, which is present in normal human serum, and insulin can stimulate the stem cells of the gland to proliferate. These dividing cells are further directed to the formation of alveoli by corticosteroid hormones. At least two types of cells are identified in the epithelial layer of the gland: stem cells and secretory alveolar cells. At this point in the pregnancy, prolactin influences the production of the constituents of milk.

TGF- $\beta$  influences pattern formation in the developing mammary gland and may negatively regulate ductal growth as well.<sup>18</sup> The pattern of mammary ductal development varies widely among species and is a function of both genotype and hormonal status. Normal human breast cells secrete TGF- $\beta$  and are themselves inhibited by it, suggesting an autoregulatory feedback circuit that may be modulated by estradiol. Growth and patterning of the ductal tree are regulated in part by TGF- $\beta$  operating through an autocrine feedback mechanism

**Figure 3-4.** Plasma hormone levels during pregnancy.  $E_1$ , estrone;  $E_2$ , estradiol;  $E_3$ , estriol; hCG, human chorionic gonadotropin. (From Neville MC, Morton J, Umemura S: The evidence for breastfeeding, *Pediatr Clin North Am* 48:42, 2001.)

and by paracrine circuits associated with epithelial-stromal interactions.<sup>18</sup>

The high circulating levels of prolactin in pregnancy are not associated with milk production partly because of the progesterone antagonism of the stimulatory action of prolactin on casein messenger ribonucleic acid (mRNA) synthesis. During late pregnancy, the lactogenic receptors, which have similar affinities for both prolactin and human placental lactogen (hPL), are predominantly occupied by hPL. High doses of estradiol impair the incorporation of prolactin into milk secretory cells.

Prolactin is prevented from exerting its effect on milk excretion by the elevated levels of progesterone. Following the drop in progesterone and estrogen at delivery, copious milk secretion begins. The key hormone requirements for lactation to begin are prolactin, insulin, and hydrocortisone. A high level of plasma prolactin is essential to lactogenesis in humans as well. There is a question as to whether it is a surge in prolactin that is necessary for lactogenesis at parturition. Prolactin levels are now described as biphasic in humans for the initiation of lactogenesis at birth.<sup>56</sup> Prolactin stabilizes and

promotes transcription of casein mRNA and stimulates synthesis of a lactalbumin that is the regulatory protein of the lactose-synthetase enzyme system.<sup>65</sup> Prolactin further increases the lipoprotein lipase activity in the mammary gland. Prolactin exists in three heterogenic forms of varying biologic activity. The monomer is in greatest quantity and is the most active form.

### Lactogenesis: Initiation of Milk Secretion

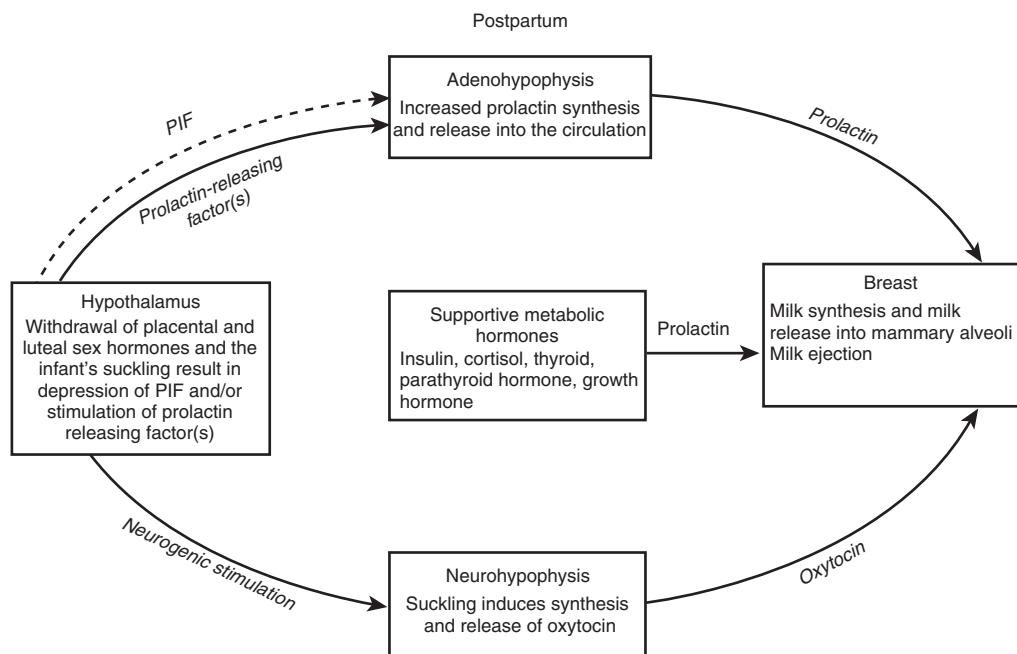

Stage I lactogenesis starts approximately 12 weeks before parturition and is heralded by significant increases in lactose, total proteins, and immunoglobulin and by decreases in sodium and chloride, and the gathering of substrate for milk production. The composition of prepartum secretion is fairly constant until delivery, as monitored by the milk protein  $\alpha$ -lactalbumin.

Lactogenesis is initiated in the postpartum period by a fall in plasma progesterone, but prolactin levels remain high (Figure 3-6). The initiation of the process does not depend on suckling by the infant until the third or fourth day, when the secretion declines if milk is not removed from the breast.<sup>98</sup>

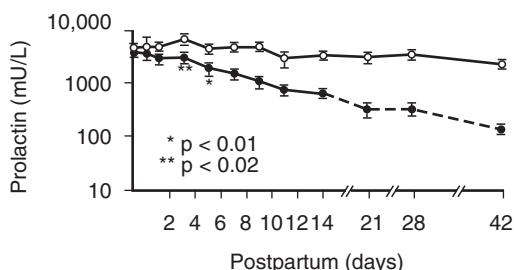

Stage II lactogenesis includes the increase in blood flow and oxygen and glucose uptake as well as the sharp increase in citrate concentration, considered a reliable marker for lactogenesis stage II. Stage II at 2 to 3 days postpartum begins clinically when the secretion of milk is copious and biochemically when plasma  $\alpha$ -lactalbumin levels peak (paralleling the period when "the milk comes in"). The major changes in milk composition continue for 10 days, when "mature milk" is established. The establishment of the mature milk supply, once called galactopoiesis, is now referred to as stage III of lactogenesis (Figures 19-2 to 19-4 and 3-6).<sup>98,99</sup>

The profound changes in milk composition have been established for the period of transition to mature milk in relationship to increase in milk volume.<sup>55</sup> Detailed studies of successfully lactating women were performed by Neville et al.,<sup>58</sup> who report that a significant fall in sodium, chloride, and protein and a rise in lactose precede the major increase in milk volume during early lactogenesis. At 46 to 96 hours postpartum, copious milk production is accompanied by an increase in citrate, glucose, free phosphate, and calcium concentrations and a decrease in pH.

The breast, one of the most complex endocrine target organs, has been prepared during pregnancy and responds to the release of prolactin by producing the constituents of milk (see Figure 3-5). The

**Figure 3-5.** Hormonal preparation of breast for lactation postpartum. PIF, prolactin-inhibitory factor. (Modified from Vorherr H: *The breast: morphology, physiology and lactation*, New York, 1974, Academic Press.)

**Figure 3-6.** Prolactin levels in the postpartum period in women who are lactating (open circles) and nonlactating (dots). Levels in lactating women vary with intensity of suckling. (From Neville MC, Morton J, Umemura S: The evidence for breastfeeding, *Pediatr Clin North Am* 48:44, 2001.)

lactogenic effects of prolactin are modulated by the complex interplay of pituitary, ovarian, thyroid, adrenal, and pancreatic hormones (Figure 3-7).

## Prolactin

Stricker and Grueter<sup>86</sup> discovered the pituitary hormone prolactin in 1928. They observed that extracts of the pituitary gland induced lactation in rabbits.

Human prolactin is a significant hormone in pregnancy and lactation.<sup>22</sup> Prolactin also has a range of actions in various species that is greater than any other known hormone. Prolactin has been identified in many animal species whether they nurse their young or not. Because of the original

association with lactation, the term describes its action, "support or stimulation of lactation." Prolactin, however, has been shown to control nonlactating responses in other species and has been identified with more than 300 different physiologic processes, unrelated to lactation. Study of prolactin was hampered until 1970, when it became possible to separate prolactin from human growth hormone (hGH) and to isolate and characterize prolactin from human pituitary glands.

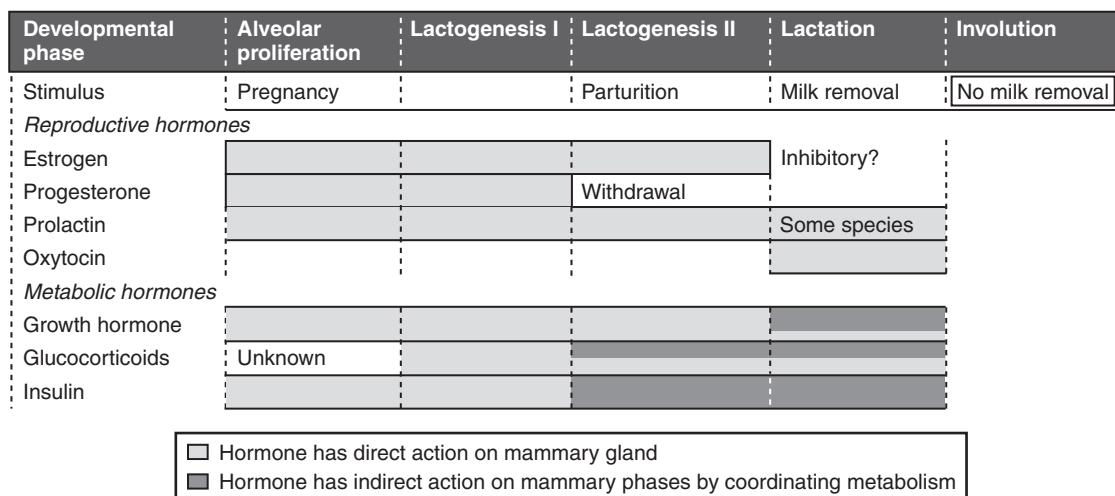

Before 1971, hGH and prolactin in humans were considered the same hormone. Until 1971, in fact, it was thought that prolactin did not exist in humans. However, hGH is present in the human pituitary gland in an amount 100 times that of prolactin.<sup>43</sup>

Although prolactin is secreted by the anterior pituitary gland, the brain is exposed to it. Prolactin is found in the cerebrospinal fluid and may even be produced by neurons in the portal vessels of the hypothalamus. Prolactin increases the activity of tuberoinfundibular neurons, which control dopamine.<sup>96</sup>

Prolactin, the lactogenic hormone, is essential for glucocorticoid stimulation of the milk-protein genes.<sup>84</sup> Little is known about the biochemical pathway of action of this important polypeptide hormone, which is required for both morphogenesis and expression of functional differentiation of the parenchyma of the breast (see Figures 3-8 and 3-9).<sup>3</sup>

Synthesis and secretion is not restricted to the anterior pituitary gland, but includes multiple sites

## Hormonal control of the lactation cycle

**Figure 3-7.** Hormonal action necessary for phases of the lactation cycle. (From Czank C, Henderson JJ, Kent JC, et al: Hormonal control of lactation cycle. In Hale TW, Hartmann PE, editors: *Textbook of human lactation*, Amarillo, Tex., 2007, Hale Publishing LP, p 91.)

in the brain (cerebral cortex, hippocampus, amygdala, cerebellum, brainstem, and spinal cord). It is also produced in the placenta, amnion, decidua, and uterus. Evidence suggests that lymphocytes from the immune system, thymus, and spleen release bioactive prolactin. Prolactin is found in epithelial cells of the lactating mammary gland and the milk itself. Prolactin reaches the milk by crossing the mammary epithelial cell basement membrane, attaches to a specific prolactin binding protein, and ultimately moves by exostosis through the apical membranes into the alveolar lumen. Prolactin mRNA in milk contains more prolactin variants than serum. Milk prolactin participates in the maturation of the neuroendocrine and immune systems.

The information generated by the use of knock-out mice with prolactin knockouts or prolactin receptor knockouts has refined the understanding of mammary morphogenesis and subsequent lactogenesis.<sup>16</sup> It has been confirmed that prolactin does not operate alone but depends on estrogen, progesterone, and glucocorticoids, as well as insulin, thyroid hormone, parathyroid hormone, and even oxytocin. Prolactin also stimulates uptake of some amino acids, uptake of glucose, and synthesis of milk sugar and milk fats (see Figure 3-7).<sup>23</sup>

Plasma prolactin varies in relation to psychosocial stress. Utilizing four different real-life stress studies in a longitudinal design, Theorell<sup>89</sup> found that changing situations associated with passive coping are accompanied by increased plasma prolactin levels. Changing situations associated with active coping are associated with unchanged or even lowered prolactin levels. The regulation of

plasma prolactin is part of a dopaminergic system (see the list of pharmacologic suppressors in the next section).

In vitro, prolactin stimulates the synthesis of the mRNA of specific milk proteins by binding to membrane receptors of the mammary epithelial cells. Prolactin has been demonstrated to penetrate the cytoplasm of these cells and even their nuclei. These specific actions in the gland require the presence of extracellular calcium ions. Some prolactin actually appears in the milk substrate itself, the functional significance of which is uncertain, although it is thought to influence fluid and ion absorption from the neonatal jejunum.

The effect of the stimulation of protein synthesis by allowing the expression of milk protein genes is not a direct effect of the hormone, but rather the consequence of the activation of sodium/potassium adenosinetriphosphatase (Na/K ATPase) in the plasma membrane.<sup>16</sup> The intracellular concentration of potassium is kept high and that of sodium low compared with the concentrations in extracellular fluid. As a result, the Na/K ratio is high both in the milk and in the intracellular fluid. Further action of prolactin has been identified in the development of the immune system in the mammary gland and, possibly more directly, in the lymphoid tissue. In conjunction with estrogen and progesterone, prolactin attracts and retains immunoglobulin A (IgA) immunoblasts from the gut-associated lymphoid tissue for the development of the immune system for the mammary gland. A very sensitive bioassay has been developed using the in vitro biologic effect of prolactin to stimulate the growth of cell cultures for malignant niobium rat lymphomas.

**TABLE 3-2** Prolactin Levels\*

	Range (ng/mL)	Average (ng/mL)
Males and prepubertal and postmenopausal females	2-8	-
Females' menstrual life	8-14	10
Term pregnancy	200-500	200
Amniotic fluid	Up to 10,000	-
<b>Lactating women</b>	<b>Response to breastfeeding</b>	
First 10 days	Baseline 200	Rise to 400
10-90 days	60-110	70-220
90-180 days	50	100
180 days to 1 year	30-40	45-80

\*Collation of values from multiple studies and sources.

The baseline levels of prolactin are essentially the same in normal male and female humans (Table 3-2). Moreover, both men and women experience a rise in prolactin levels during sleep.<sup>84</sup> There is also a normal diurnal variation in levels in both men and women. At puberty, the increase in estrogens causes a slight but measurable increase in prolactin. Prolactin increases during the proliferative phase of the menstrual cycle but not during the secretory phase. A number of factors, including some that are significant for the nursing mother, such as psychogenic influence and stress, increase prolactin levels. Anesthesia, surgery, exercise, nipple stimulation, and sexual intercourse also produce increased amounts in both lactating and nonlactating women. Prolactin levels increase as serum osmolality increases.

Although prolactin levels in maternal serum are well established, less is known about prolactin levels in the milk and their role in the newborn. Prolactin in milk is known to be biologically potent and is absorbed by the newborn. In the intestine, prolactin influences fluid, sodium, potassium, and calcium transport. Prolactin content is highest in the early transitional milk just after the colostrum in the first postpartum week (levels of  $43.1 \pm 4$  ng/mL). Levels drop to  $11.0 \pm 1.4$  ng/mL in mature milk over time until approximately 40 weeks postpartum.<sup>16</sup>

## Prolactin-Inhibiting Factor

PIF controls the secretion of prolactin from the hypothalamus. Prolactin is unusual among the pituitary hormones because it is inhibited by a hypothalamic substance. Catecholamine levels in the hypothalamus control the inhibiting factor, which is poured into the circulation as a result of

dopaminergic impulses. Drugs and events that decrease catecholamines also decrease the inhibiting factor, causing a rise in prolactin. Dopamine itself can act directly on the pituitary gland to decrease prolactin secretion. Agents that increase prolactin by decreasing catecholamines, and thus the PIF level include the phenothiazines and reserpine.

Thyrotropin-releasing hormone (TRH) is a strong stimulator of prolactin secretion, but its physiologic role is not clear, because thyrotropin levels do not rise during normal nursing. In the postpartum period, a dose of TRH will cause a marked increase in prolactin. Even a nonnursing postpartum mother will experience engorgement and milk release when stimulated with TRH. Ergot, which is frequently prescribed for postpartum patients, inhibits prolactin secretion either by direct inhibition or by its effect on the hypothalamus.

Prolactin response to breast stimulation in lactating women is not mediated by endogenous opioids. Neither baseline nor stimulated prolactin values were affected by naloxone.<sup>9</sup>

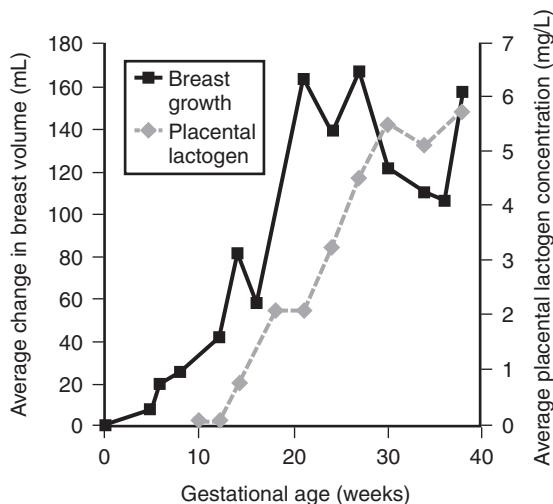

The following factors affect prolactin release in normal humans:

- Physiologic stimuli
- Nursing in postpartum women: breast stimulation
- Sleep
- Stress
- Sexual intercourse
- Pregnancy
- Pharmacologic stimuli
- Neuroleptic drugs
- TRH
- Metoclopramide (procainamide derivative)
- Estrogens
- Hypoglycemia
- Phenothiazines, butyrophenones
- Norepinephrine
- Histamine
- Acetylcholine
- Pharmacologic suppressors
- Apomorphine, bromocriptine, cabergoline
- L-Dopa
- Ergot preparations (2-Br- $\alpha$ -ergocryptine)
- Clomiphene citrate
- Large amounts of pyridoxine
- Monoamine oxidase inhibitors
- Pramipexole
- Prostaglandins E and F<sub>2</sub> $\alpha$
- Ropinirole, rotigotine, selegiline

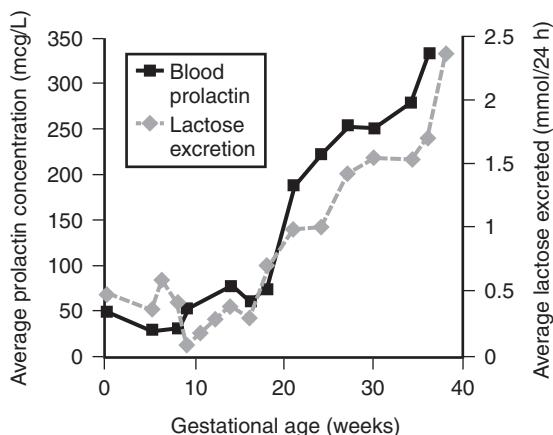

In pregnancy, prolactin levels begin to rise in the first trimester and continue to rise throughout gestation. In a nonnursing mother, prolactin levels drop to normal in 2 weeks, independent of therapy to suppress lactation.

At delivery, with the expulsion of the placenta, levels of PL, estrogens, and progesterone abruptly decline (Figure 3-8 and 3-9).

PL disappears within hours.<sup>55</sup> Progesterone drops over several days, and estrogens fall to baseline levels in 5 to 6 days (see Figures 3-6 and 19-2 to 19-4). Prolactin in nonlactating women requires 14 days to reach baseline. Progesterone is considered the key inhibiting hormone, and decline in plasma progesterone levels is considered the lactogenic trigger for stage II lactogenesis.<sup>51</sup> However, progesterone does not inhibit established lactation because breast tissue does not contain progesterone-binding sites. Estrogens enhance the effect of prolactin on mamlogenesis but antagonize prolactin by inhibiting secretion of milk. After delivery, there are low

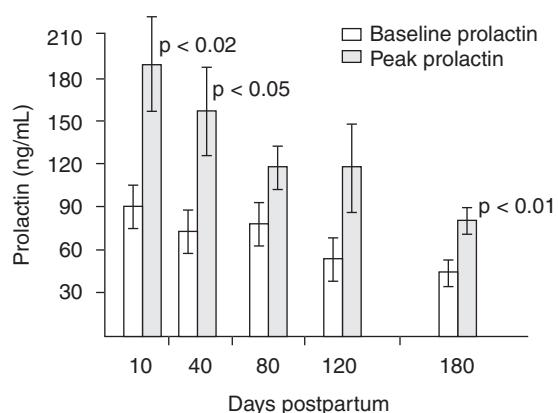

**Figure 3-8.** Breast growth and placental growth are closely associated. (Modified from Cox DB, Kent JC, Casey TM, et al: Breast growth, *Exp Physiol* 84:421-434, 1999.)

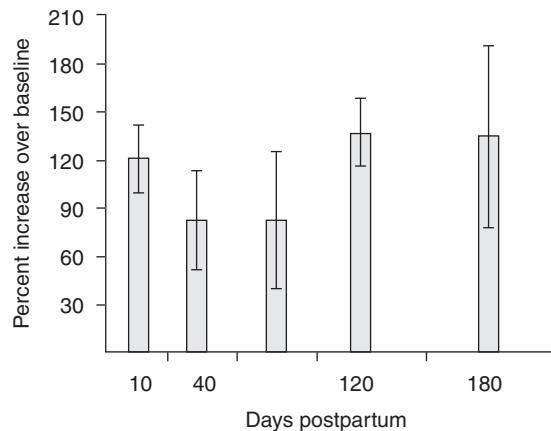

**Figure 3-9.** Relationship between lactose excretion into urine and prolactin concentration in the blood during pregnancy. (Modified from Cox DB, Kent JC, Casey TM, et al: Breast growth, *Exp Physiol* 84:421-434, 1999.)

estrogen and high prolactin levels. Suckling provides a continued stimulus for prolactin release. If prolactin, essential for lactation, is diminished by hypophysectomy or medication, lactation ceases. Baseline prolactin levels do eventually diminish to more normal levels months after parturition, although lactation may continue.<sup>37</sup>

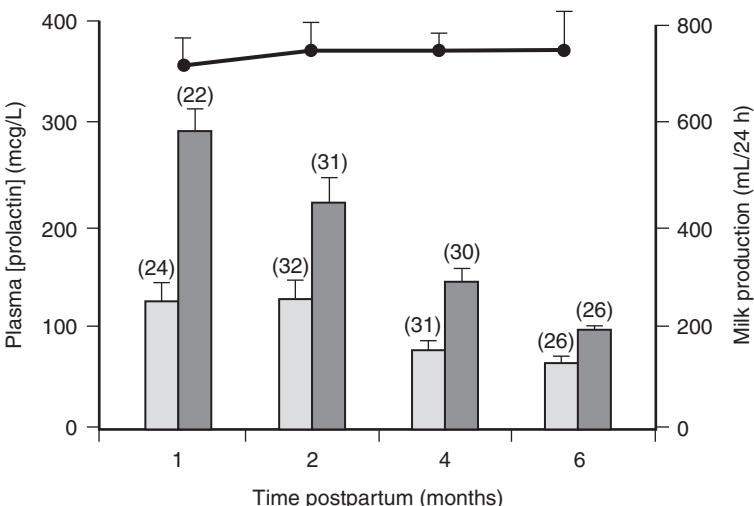

The surge in prolactin over baseline levels, however, is critical to milk production, not the baseline levels (Figures 3-6, 3-10, and 3-11). Although prolactin is necessary for milk secretion, the volume of milk secreted is not directly related to the concentration of prolactin in the plasma. Local mechanisms within the mammary gland that depend on the amount of milk removed by the infant are responsible for the day-to-day regulation of milk volume.<sup>84</sup> Suckling stimulates the release of adenohypophyseal prolactin and neurohypophyseal oxytocin. These

**Figure 3-10.** Prolactin levels after suckling. (From Battin DA, Marrs RP, Fleiss PM, et al: Effect of suckling on serum prolactin, luteinizing hormone, follicle-stimulating hormone, and estradiol during prolonged lactation, *Obstet Gynecol* 65:785, 1985.)

**Figure 3-11.** Percent increase in prolactin over baseline after suckling. (From Battin DA, Marrs RP, Fleiss PM, et al: Effect of suckling on serum prolactin, luteinizing hormone, follicle-stimulating hormone, and estradiol during prolonged lactation, *Obstet Gynecol* 65:785, 1985.)

**Figure 3-12.** Immunoreactive prolactin determined in plasma samples collected from 11 mothers (at 1, 2, and 4 months) and from nine mothers (at 6 months), immediately before suckling (□) and 45 minutes after the commencement of suckling (●). Number of observations is shown in parenthesis. Twenty-four hour milk production (mL/24 h) of the same mothers determined by test weighing. Results are mean values + SEM. (From Cox DB, Owens RH, Hartman PE: Prolactin and milk synthesis in women, *Exp Physiol* 81:1007–1020, 1996.)

hormones stimulate milk synthesis and production of milk-ejection metabolic hormones, which are also necessary in the process of milk synthesis.<sup>51</sup> Thus suckling, emptying the breast, and receiving adequate precursor nutrients are essential to effective lactation (Figures 3-12 and 3-13).

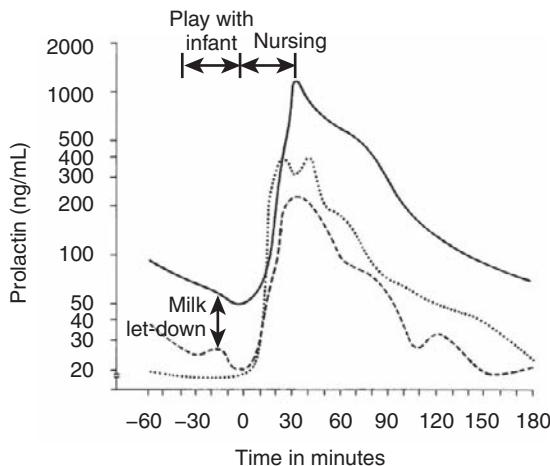

When milk is not removed, secretion ceases in a few days, and the composition of the mammary secretion returns to a colostrum-like fluid. When the composition of the breast secretion of breastfeeding and nonbreastfeeding women was followed

by Kulski and Hartmann,<sup>41</sup> it was the same for 3 to 4 days. Thereafter, the sodium and chloride concentrations in the nonbreastfeeding women increased rapidly.

The regulation of milk production in full lactation is based primarily on infant demand.<sup>60</sup> Maternal nutrition, age, body composition, and parity have only secondary impact. Suckling is a powerful stimulus to prolactin synthesis and secretion, and prolactin is necessary for milk secretion.<sup>89</sup> The pulsatile nature of prolactin secretion makes it difficult to measure over time. Milk yield is not directly correlated to prolactin levels.

Two local mechanisms have been associated with milk volume control. An inhibitor of milk secretion builds up as milk accumulates. The actual volume of milk secreted may be reduced if the breast is not drained adequately. Distention or stretching of the alveoli also affects production and secretion of milk. Evidence indicates that a proteinaceous factor in milk itself actually inhibits milk production and is associated with residual milk in the breast. This has been identified as a feedback inhibitor of lactation (FIL).

It has been assumed that prolactin levels control the rate of milk synthesis. When 24-hour milk production was measured by Cox et al.,<sup>13</sup> however, the results were different. The short-term rates of milk synthesis (i.e., between feeds) and the concentration of prolactin in the blood and in the milk were measured from 1 to 6 months in 11 women. The 24-hour milk production remained constant ( $708 \pm 54.7$  g per 24 hours at 1 month and  $742 \pm 79.4$  g per 24 hours at 6 months). Marked variation in short-term milk synthesis between breasts was observed. The baseline and

**Figure 3-13.** Plasma prolactin measured by radioimmunoassay before, during, and after a period of nursing in three mothers, 22 to 26 days postpartum. Prolactin levels rose with suckling and not with infant contact. (Modified from Josimovich JB, Reynolds M, Cobo E: Lactogenic hormones, fetal nutrition, and lactation. In Josimovich JB, Reynolds M, Cobo E, editors: *Problems of human reproduction*, vol 2, New York, 1974, John Wiley & Sons.)

suckling-stimulated prolactin levels declined over time but the peak over base remained. The concentration of prolactin in milk was related to the fullness of the breasts, being highest when the breasts were full. Cox et al.<sup>13</sup> found no relationship between the concentration of prolactin in the plasma and the rate of milk synthesis in either the short or long term.

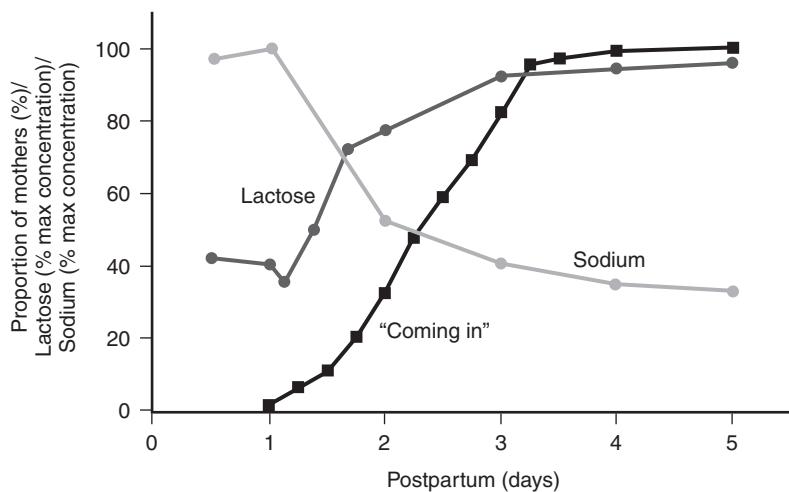

Evidence indicates that a proteinaceous factor in milk itself actually inhibits milk production and is associated with residual milk in the breast. This has been identified as a FIL. Prolactin circadian rhythm persists throughout lactation. Prolactin levels are notably higher at night than during the day, despite greater nursing times during the day. The highest levels in the study by Stern and Reichlin<sup>34</sup> were when the least nursing occurred.

The most effective and specific stimulus to prolactin release is nursing. The stimulation is a result of nipple or breast manipulation, especially suckling, not a psychologic effect of the presence of the infant (see Figures 3-13 and 3-14). The prolactin-release reflex during nipple stimulation is suppressed in some adult women, being evidenced only during pregnancy and lactation.<sup>48</sup>

During human pregnancy, when serum prolactin rises steadily to 150 to 200 ng/mL at term, there is a brief drop in levels hours before delivery and then a rise again as soon as the neonate is suckled.<sup>46,48</sup> The response to nipple stimulation can be abolished by applying local anesthetic.<sup>53</sup> On the other hand, trauma or surgery to the chest wall can initiate a prolactin rise and, in some reported cases, milk production.

Although it was initially reported that the high levels of prolactin measured in the first days and weeks of lactation dwindled to normal baseline by 6 months and showed no response to suckling stimulus, later studies clearly showed a different picture with more sensitive assays.<sup>46</sup> Prolactin does not drop to normal, but further stimulus causes a doubling of levels over baseline at all stages of lactation through the second year (see Table 3-2).

Acute prolactin and oxytocin responses were measured by Zinaman et al.,<sup>104</sup> who compared various mechanical pumping devices with manual expression and infant suckling. Prolactin response to mechanical expression in quantity and duration depended on the device used, with a full-size pulsatile electric pump eliciting the greatest response. This compared equally with infant suckling. There was no difference seen in oxytocin response with various devices. These data confirm that results in studies of milk production and release in humans also depend on the equipment used to stimulate the breast.<sup>104</sup> Eight fully lactating women were followed through the first 6 months postpartum at 10, 40, 80, 120, and 180 days, recording serum prolactin, luteinizing hormone, follicle-stimulating hormone, and estradiol (zero time only) obtained just before the initiation of suckling and during the next 120 minutes.<sup>3</sup> Samples were obtained at 0, +15, +30, +60, and +120 minutes. Prolactin levels were high the first 10 days (90.1 ng/mL) but slowly declined over 180 days (44.3 ng/mL). The stimulus of suckling doubled the baseline values. Mean estradiol levels were low at 10 days (7.2 pg/mL), then gradually rose to a mean of 47.3 pg/mL at 180 days

**Figure 3-14.** The sense of milk coming in. Secretory activation precedes the sense of milk “coming in.” The distribution of the times when women first sensed the “coming in” of milk after normal delivery is compared with the changes in lactose and sodium concentrations of breast milk over the first postpartum days. The number of women for each time point was expressed as a cumulative percentage of the total number ( $n=107$ ) of women. Lactose and sodium concentrations obtained from left and right breasts for each woman were averaged and presented as percentages of the maximum lactose and sodium concentrations over the 5 days. (From Pang WW, Hartman PL: Initiation of human lactation: secretory differentiation and secretory activation, *J Mammary Gland Biol* 12:211–221, 2007.)

postpartum in the subjects whose menses had resumed. In the amenorrheic subjects the estradiol levels remained low (4.25 pg/mL), whereas baseline prolactin remained high (63.6 ng/mL). The subjects were breastfeeding on demand, averaging 11 feedings (range 8 to 16) per day at 10 days and 8 feedings (range 5 to 12) at 120 and 180 days. All infants had stopped one night feeding, and two infants had started some solids between the third and fourth months.

When specific binding sites for prolactin were looked for in the tammar wallaby, many sites were demonstrated in the lactating mammary gland but not the inactive gland. Mammary prolactin receptors were also identified in the rabbit. Thus the increased binding capacity would enhance tissue responsiveness, which may explain the maintenance of full lactation in the face of falling concentrations of prolactin. Prolactin also plays a critical role in increasing maternal bile secretory function postpartum.<sup>48</sup>

## *Human Placental Lactogen and Human Growth Hormone*

Three main hormones are recognized in the lactogenic process: hPL, hGH, and prolactin. The progressive rise in prolactin during pregnancy parallels the rise in hPL, becoming measurable at 6 weeks' gestation and increasing to 6000 ng/mL at term (see Figure 3-4). This parallel action contributed to the belief that prolactin and hPL were the same. Although the principal function of hPL and prolactin in humans is a lactogenic one, no lactation ordinarily appears before delivery,<sup>81</sup> although some women report being able to express a few drops of colostrum.

First described in 1962, hPL has been studied more than lactogens from any other species.<sup>53</sup> Extensive immunologic and structural homology exists between hGH and hPL, which probably explains their similar biologic activities. Concentrations of hPL increase steadily during gestation and decrease abruptly with the delivery of the placenta. A large-molecular-weight substance, hPL is derived from the chorion. Receptor sites that bind lactogen also bind protein and hGH.<sup>94</sup> hPL has been associated with mobilization of free fatty acid and inhibition of peripheral glucose utilization and lactogenic action.

hGH is secreted from the anterior pituitary eosinophilic cells. These cells have been identified by staining techniques that distinguish them from those that produce prolactin. Toward the end of pregnancy, the cells that produce prolactin are noticeably more numerous, whereas those that produce hGH are "crowded out." The role of

hGH in the maintenance of lactation is poorly defined and may be synergistic with prolactin and glucocorticoids.

Prolactin, hGH, PL, and chorionic somatotropin form a family of polypeptide hormones from the same ancestral gene, even though prolactin and hGH are produced by the pituitary and PL and chorionic somatotropin by the placenta.<sup>100</sup> The suckling stimulus in postpartum lactation causes a rapid increase in serum hGH and prolactin. hGH and prolactin evolve from the same precursor, and, although the hormones are distinct, the acute interruption of hGH secretion does not interfere with the milk secretion.

The possible role of TSH as a physiologic prolactin-releasing factor has been disproved by Gehlbach et al.,<sup>26</sup> who state that TSH is not responsible for the brisk release of prolactin with suckling. Normal lactation is possible in women with ateliotic dwarfism in the absence of detectable quantities of hGH. For any hormone to exert its biologic effects, however, specific receptors for the hormone must be present in the target tissue. Changes in serum concentration have no effect if receptors are not present in the mammary gland to bind the hormone.

Oxytocin was the first hormone studied in relation to breastfeeding and to the let-down reflex. Studies first explored its role in the initiation and progression of labor. Because it was measurable, isolated in the laboratory, and finally manufactured synthetically, our knowledge of oxytocin was more extensive than it was for prolactin until the last two decades.

Oxytocin is not just a female hormone; it is produced by both male and female humans, and it is increased not just during reproduction in women. It is now credited with producing increased responsiveness to receptivity, closeness, openness to relationships, and nurturing. The oxytocin circulating during breastfeeding has been credited with producing calm, lack of stress, and an enhanced ability to interact with infants. The calm and connectedness system is part of a system of nerves and hormones that together trigger these effects.

Oxytocin is a polypeptide found in all mammalian species and works through a mechanism through which it activates receptors on the outer surface of the cell membrane.<sup>19</sup> Oxytocin is produced in the supraoptic and paraventricular nuclei of the hypothalamus. Receptors have been identified for oxytocin in the uterus and the breast as well as the brain. It acts via the bloodstream and as a signaling substance in the nervous system. Substances that act to stimulate the release of oxytocin include serotonin, dopamine, noradrenaline, and glutamate. Other substances, such as opiates, enkephalin, and  $\beta$ -endorphin, inhibit its release. Spinal anesthesia has been associated with the inhibition of oxytocin release after childbirth.<sup>37</sup> Estrogen can increase

the number of receptors and stimulate the production of oxytocin. The release of oxytocin by repetitive soothing touches or when given via injection produces a calming reaction and lowers blood pressure and pulse rate. Uvnäs Moberg<sup>91</sup> has studied oxytocin extensively and calls it the hormone of calm, love, and healing.

### **Stage III Lactogenesis (Galactopoiesis): Maintenance of Established Lactation**

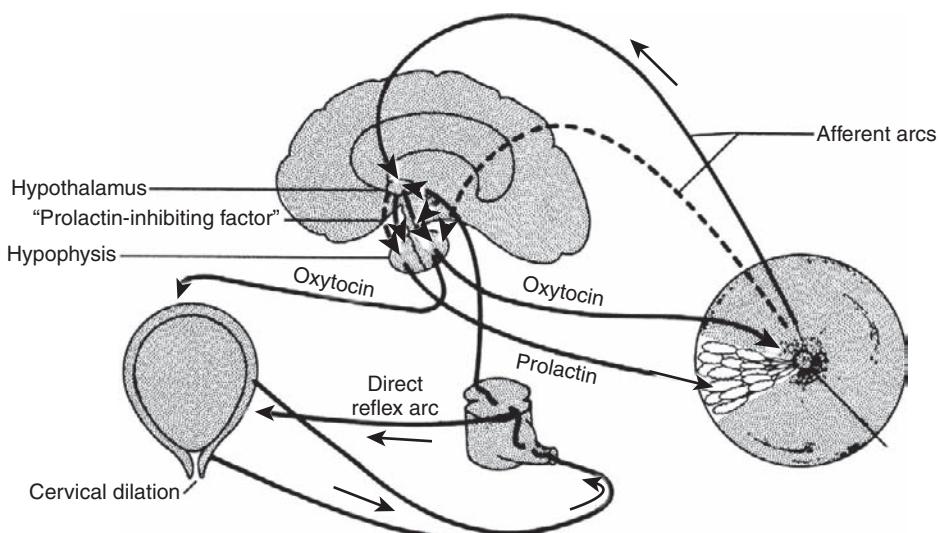

Early studies in the past 100 years established that milk was synthesized in the mammary gland from substances removed from the maternal arterial blood supply. Then it was confirmed that milk ejection was the removal of stored milk and not from the rapid synthesis of milk. The enzymes and hormones involved have been identified. Understanding the molecular biochemistry and physiology of the gland has revealed the details of the production of milk. A number of genes encode for components that are part of the intricate signaling pathways. Complex interactions of signaling molecules with epigenetic factors interact at the level of gene expression. Intracellular signaling is basic to understanding normal human mammary development.

The basic features of milk production are the identification of the cell surface and intracellular receptors for extra cellular signals (12 hormones autocrine and paracrine factors according to Martin and Czank).<sup>52</sup> Chain reactions convey the signal to

a site of action. A class of compounds that regulate gene expression depend on modification to their structures and the nature of their binding to the genetic material.

The maintenance of established milk secretion, originally called galactopoiesis, is now labeled stage III lactogenesis, or simply lactation. An intact hypothalamic-pituitary axis regulating prolactin and oxytocin levels is essential to the initiation and maintenance of lactation.<sup>38</sup> The process of lactation requires milk synthesis and milk release into the alveoli and the lactiferous sinuses. When the milk is not removed, the increased pressure lessens capillary blood flow and inhibits the lactation process. Lack of sucking stimulation means lack of prolactin release from the pituitary gland. Basal prolactin levels that are enhanced by the spurts that result from sucking are necessary to maintain lactation in the first postpartum weeks. Without oxytocin, however, a pregnancy can be carried to term, but the woman will fail to lactate because she will fail to let-down.

Sensory nerve endings, located mainly in the areola and nipple, are stimulated by suckling. The afferent neural reflex pathway, via the spinal cord to the mesencephalon and then to the hypothalamus, produces secretion and release of prolactin and oxytocin. Hypothalamic suppression of earlier PIF secretion causes adrenohypophyseal prolactin release. When prolactin is released into the circulation, it stimulates milk synthesis and secretion. A conditioned milk ejection can occur in lactating women without a concomitant release of prolactin, so that indeed the releases are independent, which may be significant in treating apparent lactation failure (Figure 3-15).

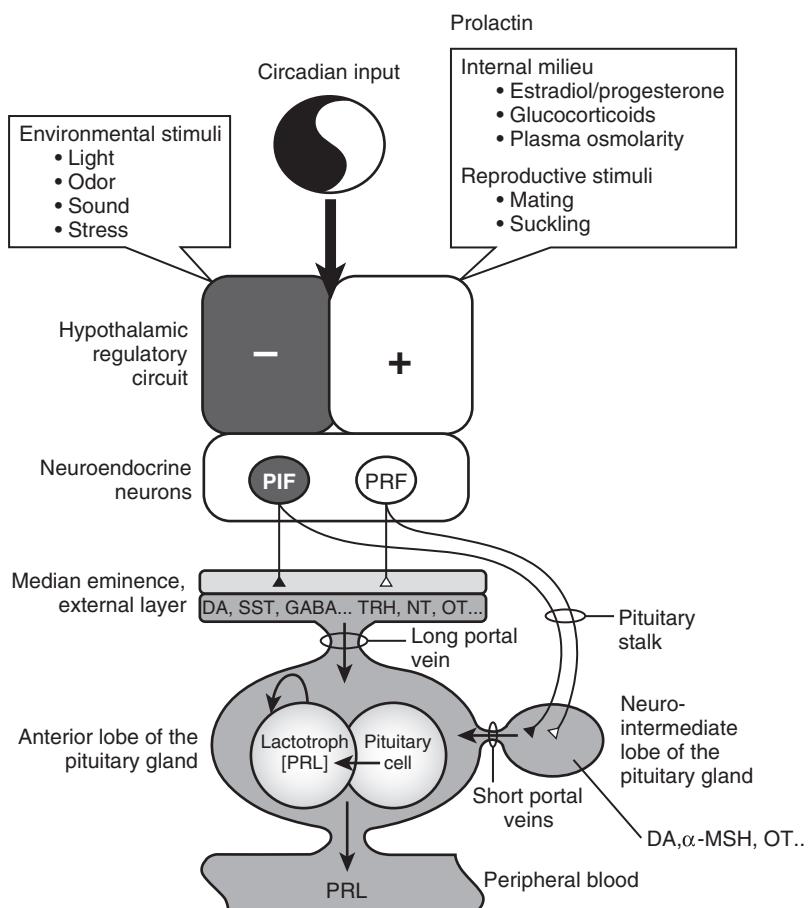

**Figure 3-15.** Neuroendocrine control of milk ejection. (Modified from Vorherr H: *The breast: morphology, physiology and lactation*, New York, 1974, Academic Press.)

## Hormonal Regulation of Prolactin and Oxytocin

The release of prolactin is inhibited by PIF.<sup>44</sup> The PIF has not been described but is closely associated with dopamine. There is also evidence of either serotonin release or prolactin or catecholamine-serotonin control of prolactin release. TSH has also been shown to stimulate the release of prolactin. The amount of prolactin is proportional to the amount of nipple stimulation during early stages of lactation after the first 4 days. Milk synthesis proceeds for the first 4 days whether or not the breast is stimulated. At this time, prolactin levels

are the same for lactators and nonlactators<sup>56</sup> (Figure 3-16).

Although both oxytocin and prolactin release are stimulated by nipple stimulation, some oxytocin is released by other sensory pathways, such as visual, tactile, olfactory, and auditory.<sup>60</sup> Thus a woman may release milk on seeing, touching, hearing, smelling, or thinking about her infant. Prolactin, however, is released only on nipple stimulation so that milk production is not initiated by other sensory pathways. Oxytocin is also released under physical stress, such as pain, exercise, cold, heat, changes in plasma osmolality, or hypovolemia, but these responses are blunted or reversed during lactation.<sup>15,60</sup>

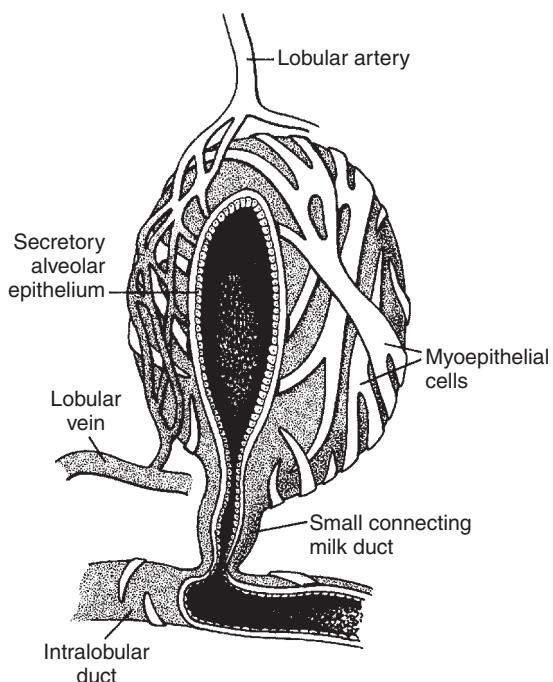

**Figure 3-16.** An overview of the regulation of prolactin secretion. Prolactin secretion is paced by a light-entrained circadian rhythm, which is modified by environmental input, with the internal milieu and reproductive stimuli affecting the inhibitory or stimulatory elements of the hypothalamic regulatory circuit. The final common pathways of the central stimulatory and inhibitory control of prolactin secretion are the neuroendocrine neurons producing prolactin-inhibiting factors (PIF), such as dopamine (DA), somatostatin (SST), and  $\gamma$ -aminobutyric acid (GABA), or prolactin-releasing factors (PRF), such as thyrotropin-releasing hormone (TRH), oxytocin (OT), and neuropeptides (NT). PIF and PRF from the neuroendocrine neurons can be released either at the median eminence into the long portal veins or at the neurointermediate lobe, which is connected to the anterior lobe of the pituitary gland by the short portal vessels. Thus lactotrophs are regulated by bloodborne agents of central nervous system or pituitary origin ( $\alpha$ -melanocyte stimulating hormone) delivered to the anterior lobe by the long or short portal veins. Lactotrophs are also influenced by PRF and PIF released from neighboring cells (paracrine regulation) or from the lactotrophs themselves (autocrine regulation). (From Freeman ME, Kanyicska B, Lerant A, Nagy G: Prolactin: structure, function and regulation of secretion, *Physiol Rev* 80:1523–1630, 2000.)

When suckling occurs, oxytocin is released.<sup>12</sup> It enters the circulation and rapidly causes ejection of milk from alveoli and smaller milk ducts into larger lactiferous ducts and sinuses. This is the pathway of the let-down, or ejection, reflex. Oxytocin also causes contraction of the myometrium and involution of the uterus (Figure 3-17).

The polypeptide oxytocin is a messenger molecule with diverse physiologic actions as well as modes of delivery to its target sites. Oxytocin exerts effects as a hormone carried by the systemic circulation to distant targets in the uterus and the breast.<sup>15</sup> Oxytocin also serves as a hypophysiotropic factor, released from nerve terminals in the median eminence into the pituitary portal vasculature to affect anterior pituitary secretion. Its action here is as a peptidergic neurotransmitter or neuromodulator within the central nervous system, influencing a variety of neuroendocrine, behavioral, and autonomic functions. Its well-known role is related to reproduction and lactation, but it has other, less well explored physical and metabolic roles.<sup>15</sup>

After suckling is initiated, the oxytocin response is transient and intermittent rather than sustained.

**Figure 3-17.** Fundamental mammary unit at lactation, with arrangement of secretory alveoli, myoepithelial cells, and vasculature. The secretory alveolar epithelium is monolayered, and the epithelial lining of milk ducts consists of two layers. Between bases of glandular epithelial cells and tunica propria, starlike myoepithelial mammary cells surround alveolus in a basketlike arrangement. (Modified from Vorherr H: *The breast: morphology, physiology and lactation*, New York, 1974, Academic Press.)

Plasma levels often return to basal between milk ejections, even though suckling continues. Ejection can be measured by placing a microcatheter in the mammary duct or can be noted subjectively by the mother as tingling or turgescence. The contractions last about 1 minute, with about 4 to 10 occurring in a 10-minute period. Corresponding pulses of oxytocin can be measured in the maternal bloodstream. The controls of oxytocin release are complex and are extensively described by Crowley and Armstrong.<sup>15</sup> That centrally released oxytocin is in control of the milk-ejection reflex was established in 1981 by Freund-Mercier and Richard.<sup>24</sup> They demonstrated in rats that intracerebroventricular administration of oxytocin greatly increased the frequency and amplitude of pulsatile oxytocin release during suckling. Administration of oxytocin antagonists produced the opposite effect and suppressed responses.<sup>24</sup>

The human pituitary has an excessive storage capacity and contains 3000 to 9000 mU of oxytocin, but the reflex milk ejection involves the release of only 50 to 100 mU.<sup>101</sup> Except in extreme cases (Sheehan syndrome), hormone depletion is rarely an issue, but hormone release and target-organ sensitivity are. Opiate and β-endorphin released during stress are known to block stimulus-secretion coupling by dissociating electrical activity at the terminal. This inhibition is naloxone reversible.

The mammary gland, from platypus to human, has an identical fine structure consisting of alveolar tissue that has increased its surface area 10,000-fold during gestation compared with the size of the gland.<sup>47</sup> It continuously produces milk throughout lactation, but the most complex issue is the release of milk. Because of the substantial surface tension forces opposing the movement of fluid in the small ducts, simple suction applied by suckling is relatively ineffective, especially in early lactation. Thus the alveolus is enveloped in a basketlike network of myoepithelial cells that respond to oxytocin by contracting and expelling the milk into larger and larger ductules until it can be removed by the infant (see Figure 3-17). This is a classic example of a neuroendocrine reflex, a process that is remarkably uniform in all mammals.<sup>61</sup>

## Changes in Breast Hemodynamics in Breastfeeding Mothers

The tissue concentrations of oxyhemoglobin, deoxyhemoglobin, and total hemoglobin and the hemoglobin oxygen saturation while breastfeeding have been measured by near infrared time resolved spectroscopy because it is a noninvasive method of assessment during breastfeeding.<sup>63</sup> When both the

breast being suckled and the contralateral breast were measured, both sides showed a significant decrease compared with the presuckling values. During the breastfeeding, values from both breasts fluctuated cyclically. Thus it was documented that blood volume decreases and fluctuates during breastfeeding as does oxygenation. The investigators speculate that this is a result of changes in pressure and resistance in blood vessels accompanying the milk-ejection reflex.<sup>63</sup>

Milk ejection involves both neural and endocrinologic stimulation and response. A neural afferent pathway and an endocrinologic efferent pathway are required.<sup>53</sup>

The ejection reflex depends on receptors located in the canalicular system of the breast. When the canalliculi are dilated or stretched, the reflex release of oxytocin is triggered. Tactile receptors for both oxytocin and reflex prolactin release are in the nipple. Neither the negative and positive pressures exerted by suckling nor the thermal changes trigger the milk-ejection reflex. Negative pressures have a minor effect, but tactile stimulation is the most important factor in milk ejection.

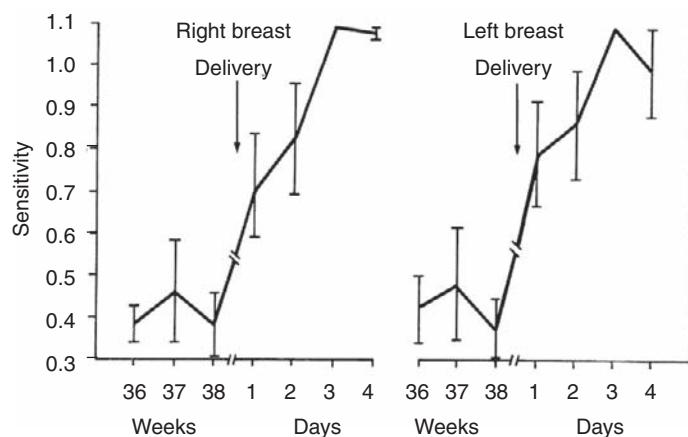

Studies in tactile stimulation show changes in sensitivity at puberty, during the menstrual cycle, and at parturition.<sup>74</sup> No difference exists in sensitivity between the sexes before puberty. In girls, tactile sensitivity increases after puberty and is increased at midcycle and during menstruation. (Midcycle peak is absent in women taking oral contraceptives, probably due to the suppression of ovulation.) Dramatic changes occur within 24 hours of delivery after several weeks of complete insensitivity. The nipple is the most sensitive area to both touch and pain, followed by the areola; the least sensitive area is the cutaneous breast tissue. The increased sensitivity of the breast continues several days postpartum, even when a woman does not breastfeed. Estrogen treatment suppresses the

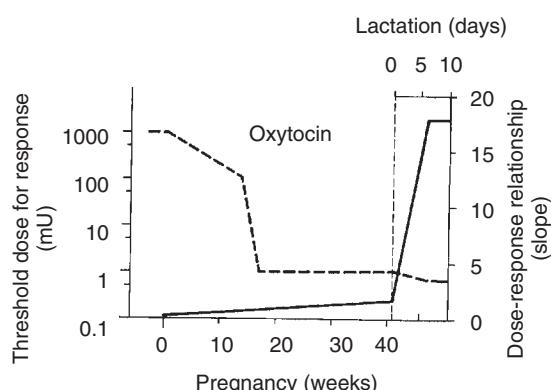

induction of prolactin release on nipple stimulation; on withdrawal of estrogen the prolactin response returns. Increased tactile sensitivity may be the key event activating the suckling-induced release of oxytocin and prolactin at delivery (Figures 3-18 and 3-19).

The clinical study of oxytocin challenge tests for use in measuring the viability of the fetus has led to the study of breast stimulus on the uterus. Numerous studies have confirmed that oxytocin levels rise significantly during nipple stimulation, with short bursts of oxytocin during accompanying uterine contractions.<sup>10</sup> When the effect of breast stimulation on prostaglandin secretion was tested at 38 to 40 weeks' gestation, uterine contractions occurred and prostaglandin metabolite levels increased in all cases. Shalev et al.<sup>79</sup> suggest that the principal action of oxytocin is to stimulate prostaglandin synthesis in uterine tissues, which then becomes the primary cause of the uterine contractions.

The oxytocin-binding sites are located within the basement membrane of the mammary alveolus and along the interlobular ducts. A gradual tenfold increase occurs in the concentration of oxytocin receptor sites in the mammary gland during pregnancy.<sup>47</sup> This contrasts sharply with the sudden fortyfold increase in oxytocin receptors in the uterus in the hours before delivery that then rapidly disappear. These changes in receptor availability may be why copious milk does not occur until shortly after delivery, because oxytocin first facilitates delivery and then promotes milk ejection sequentially. When the increase in intramammary pressure obtained with varying doses of oxytocin in nonpregnant, pregnant, and lactating women was recorded by Caldeyro-Barcia, the amount of oxytocin required for a response dropped from 1000 mU in nonpregnancy to about 1 mU in late pregnancy and to 0.5 mU in lactation (see Figure 3-19).<sup>51</sup> The maximum intramammary

**Figure 3-18.** Changes in tactile sensitivity of cutaneous breast tissue in perinatal period. Sensitivity was calculated from two-point discrimination according to the formula  $K - \log(e)$ . K is an arbitrary figure employed to portray a low two-point discrimination value as peak of sensitivity. Dramatic increase in tactile sensitivity at delivery enhances response to suckling of newborn. (From Robinson JE, Short RV: Changes in breast sensitivity at puberty, during the menstrual cycle, and at parturition, *Br Med J* 1:1188, 1977.)

**Figure 3-19.** Sensitivity of human mammary epithelium to oxytocin during pregnancy and lactation. Scale at left shows threshold dose necessary to evoke increase in intramammary pressure; scale at right shows maximum intramammary pressure obtained. (Modified from Caldeyro-Barcia R: Milk ejection in women. In Reynolds M, Folley SJ, editors: *Lactogenesis: the initiation of milk secretion at parturition*, Philadelphia, 1969, University of Pennsylvania Press.)

pressure that could be evoked increased from 1 mm Hg early in pregnancy to a peak of 10 mm Hg at 5 days postpartum. Caldeyro-Barcia suggests that not only the sensitivity of the myoepithelial cells but the number of receptor sites also increases during pregnancy.

Conflicting information exists regarding the exact nature of the release of oxytocin from the pituitary. The dose-response curve of the mammary gland has a very limited dynamic range, so that a bolus of 0.1 mU oxytocin (0.2 mg) given intravenously to a lactating rat fails to change intramammary pressure. An injection of 1 mU evokes an increase in pressure that begins after a delay of 10 seconds and peaks in 15 seconds at 8 to 10 mm Hg. A bolus has greater effect than a slow push, suggesting that a pulsatile pattern of hormone release would be the most effective way of utilizing oxytocin to produce milk ejection.<sup>48</sup>

Plasma oxytocin levels measured by Lucas et al.<sup>50</sup> with continuous sampling every 20 seconds revealed the hormone was released in surges and persisted in the circulation for less than 1 minute. The multiparas had a greater total response than primiparas, but with no difference between early (1 to 3 days postpartum) and late (5 to 7 days). When a similar study was done by Dawood et al.,<sup>19</sup> collecting samples only every 3 minutes, no pulsing was identified. Oxytocin was measurable within 2 minutes of suckling, peaked at 10 minutes, and had a bimodal curve dropping to a mean at 20 minutes, comparable with that before suckling, which followed the burping and changing of breasts at approximately 15 minutes. A secondary peak occurred at 25 minutes. They found maximum response of intramammary pressures at the fifth to

seventh day. McNeilly et al. measured release of oxytocin in response to suckling in early and established lactation, drawing samples every 30 seconds. A catheter for blood sampling was placed in the forearm 40 minutes before lactation. Oxytocin levels increased 3 to 10 minutes before suckling in response to the baby crying or becoming restless or the mother preparing herself to feed. There was no prolactin response until suckling began.

Most results clearly showed response before tactile stimuli and then a second surge in response to suckling. The levels were pulsatile during suckling and not related to milk volume, prolactin response, or parity of the mother.

Significant elevations of the maternal oxytocin level occur at 15, 30, and 45 minutes after delivery when the infant is put skin to skin, compared with levels just before delivery during expulsion of the placenta.<sup>62</sup> Levels return to baseline after 60 minutes if the infant does not suckle. When oxytocin levels were measured after initiating breast stimulation with a mechanical breast pump in early lactation (10 to 90 days), midlactation (90 to 190 days), and late lactation (180 days to 12 months), baseline levels were similar in all three periods. The stimulated plasma oxytocin levels were greater in early than late lactation, but there was always a response. Thus the oxytocin secretory reflex appears to continue for at least the first year of lactation.

The release of oxytocin by neurohypophyseal responses during lactation has been evoked both by the infant's suckling and by mechanical dilatation of the mammary ducts. This release of oxytocin was demonstrated to be independent of vasopressin release. Conversely, further study<sup>43,44</sup> demonstrated that there could be stimulation of vasopressin release independent of oxytocin release.

When the levels of hGH, vasopressin, prolactin, calcitonin, gastrin, insulin, epinephrine, norepinephrine, and dopamine were measured in six lactating women during breastfeeding, Widstrom et al.<sup>102</sup> confirmed the rise in prolactin and demonstrated the progressive increase in insulin that may be secondary to prolactin rise and may participate in stimulating milk production. Gastrin level decreased, and there were no consistent findings for calcitonin, hGH, norepinephrine, or epinephrine and no change in dopamine and vasopressin. Vagally stimulated release of insulin and gastrin is antagonized when the tone of the sympathetic nervous system is increased, such as during stress, pain, or anxiety. Increased insulin also is known to stimulate the synthesis of casein and lactalbumin and thus, secondarily, milk production. It should be advantageous to breastfeed after a meal rather than before (practically, many mothers eat while feeding the infant).

Human myoepithelium, the effector tissue, is specifically stimulated by oxytocin, and this sensitivity and specificity increase throughout pregnancy. Suckling can induce milk secretion, which is under control of the adenohypophysis. In this case, oxytocin released by the neurohypophysis because of the suckling stimulus would cause both milk ejection and release of the anterior pituitary hormones responsible for milk secretion.<sup>59</sup> This is probably the mechanism behind relactation and induced lactation in a woman who has never been pregnant. Mammary growth and lactogenesis may be induced by suckling, massage, and breast stimulation in many species.

Oxytocin responsivity in human mothers was studied by Light et al.<sup>43</sup> Responses are well documented in animal models and include facilitating maternal behavior, reducing blood pressure, and reducing stress responses. The relationship of oxytocin responsivity to blood pressure in breastfeeding mothers was compared to bottle feeding mothers. The breastfeeding mothers had higher oxytocin levels but lower blood pressure while feeding, especially during stress. The authors concluded that oxytocin has antistress and blood pressure lowering effects.<sup>43</sup>

Alcohol has a dose-related effect on the central nervous system in inhibiting milk ejection. When intramammary pressure was measured in response to suckling by the infant while the mother received measured doses of alcohol, milk ejection was inhibited in a dose-dependent manner.<sup>9</sup> Doses to a maximum of 0.45 g per kilogram of body weight (blood alcohol less than 0.1%), however, had no effect on intramammary pressure. Mechanical breast stimulation for 10 minutes and concomitant administration of intravenous fluid containing normal saline, naloxone, ethanol, or a combination of ethanol and naloxone were initiated in normal nonlactating women on day 22 of the regular menstrual cycle.<sup>11</sup> Plasma oxytocin levels rose twofold, with breast stimulation peaking at 10 minutes. Responses were unchanged by naloxone but were completely abolished by alcohol taken orally (approximately 110 mL of whiskey). Naloxone partially reversed the inhibiting effects of ethanol. The authors concluded that naloxone-sensitive endogenous opioids do not appear to be involved in the control of the oxytocin rise induced by breast stimulation and that opioid peptides are partly involved in the alcohol action.<sup>11</sup> Alcohol has been used in obstetrics to suppress premature labor in humans.

In a study of women who had received oxytocin for stimulus during labor or postpartum for control of bleeding and/or epidural analgesia compared with women who were untreated, plasma oxytocin and prolactin concentrations were measured during suckling on the second day postpartum. All subjects

showed a pulsatile oxytocin pattern during the first 10 minutes of breastfeeding. When women received both oxytocin and an epidural, the median oxytocin levels were the lowest. The more oxytocin they had received, the lower their endogenous oxytocin. A significant rise of prolactin occurred after 20 minutes in all women except those who had oxytocin, in whom the levels rose in 10 minutes. The rise in prolactin between 0 and 20 minutes correlated significantly with the median oxytocin and prolactin levels. Thus oxytocin infusion was observed to decrease endogenous oxytocin release dose dependently and facilitated the release of prolactin. Epidural analgesia, when combined with oxytocin, resulted in lowered endogenous oxytocin levels. The length of the breastfeeding session was increased by the prolactin levels; that is, the longer the mother breastfed the higher the levels.

Epidural anesthesia has been demonstrated to inhibit the release of oxytocin during labor into the circulation and the brain of sheep and cows. As a consequence, maternal behavior and bonding to the young are inhibited.<sup>37</sup>

In this study, in the women who received only an epidural, oxytocin levels matched controls. But other studies have shown that epidurals decrease oxytocin levels.

Normal, alert newborns have been observed to "crawl" to the nipple and latch on unassisted when placed on the maternal abdomen following a normal delivery and the clamping and severing of the umbilical cord.<sup>73</sup>

Suckling brings about functional changes in the offspring. An infant who sucks on an artificial nipple quickly decreases the amount of body movement, increases mouth activity, and decreases crying. The suckling experience may affect infant behavior and mother-infant interaction. Nonnutritive sucking is observed in many species. In the human infant, nutritive sucking is shown to be a continuous stream of regular sucks with few, if any, pauses. Nonnutritive sucking has bursts of activity alternating with no sucking. Suckling can be altered by extraneous aural, visual, or olfactory stimuli. Response of breasts to different stimulation patterns of an electric breast pump was measured by Kent et al.<sup>38</sup> When cycles were 45 per minute, let-down occurred in  $147 \pm 13$  seconds. In response to breastfeeding, let-down occurred after  $56 \pm 4$  seconds. Volume was a reflection of negative pressure or vacuum applied but not the time for milk ejection.<sup>38</sup>

## *Understanding the Myth of "Milk Coming In"*

Much of lactation physiology in the human has been based on research done in the bovine and

other mammals. This has led to some misinterpretation of human data. An important understanding is that in humans secretory activation occurs after parturition rather than before. Only a small volume of colostrum is available during the first 24 to 48 hours after birth. Today, in newborn nurseries, fixation on technology and measurements have led to determination of blood sugars and strict attention to intake. Human newborns are born with significant stores of energy in body fat and mobilize adequate energy from these sources. This suggests that the concentration of antibodies in the colostrum provides adequate surface protection for the gastrointestinal tract and the respiratory tree. This represents colostrum already secreted in the ducts and not the rapid synthesis and secretion of milk. Thus the awaiting of milk "coming in" has been reported in the first 96 hours. Many women do not experience a sudden change, but a gradual one. When the timing of "milk coming in" is compared with the actual physiologic measurements of increase in lactose and the decrease in sodium, it is noted to lag behind these markers (see Figure 3-4). It is thought<sup>71</sup> that the sensation of "milk coming in" is an "overshoot" seen more commonly in primiparas. The milk supply then has to downregulate to match the infant's needs. Physiologically, it is not a documentable event.

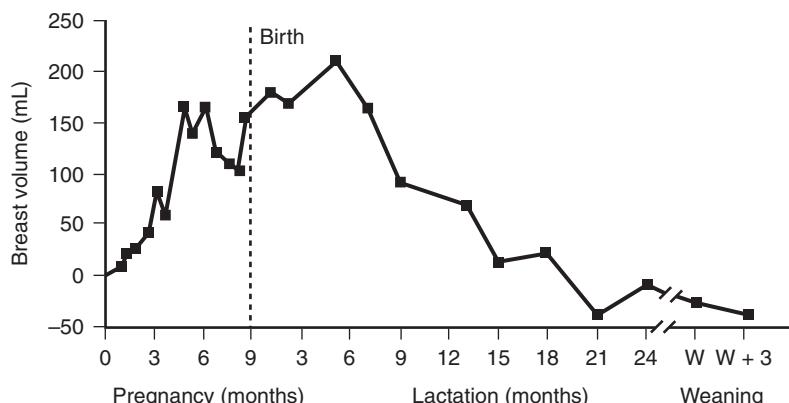

During active lactation the storage time of milk in the alveoli and ducts is about an hour in the human, but much longer in some other species, such as rabbits and sea mammals (to a maximum of 4 days). It is important to point out that the ejection reflex (see Figure 3-15) has been illustrated to imply that there is rapid synthesis and secretion with activation of both oxytocin and prolactin simultaneously. That is not the case. Secretory differentiation is independent of birth; secretory activation is closely associated with birth (see Figures 3-5 and 3-6). Progesterone drop in humans

is associated with the delivery of the placenta; therefore, it is after delivery that secretory activation begins, approximately 30 to 40 hours after delivery.<sup>77</sup>

## Maternal Effects of Suckling

Effects of suckling on the mother include the stimulation of afferent nerves for the removal of milk.<sup>45</sup> Reduction in sucking stimulus produces a reduction in prolactin and in milk synthesis.<sup>59</sup> The lactating glands adjust the milk supply to demand, probably as a result of both a local and an endocrinologic mechanism. Variations in milk secretion are rapidly reflected in anatomic changes in the mammary gland. Mammary tissue shows regression after the first week or so, if unstimulated. Tissue regression proceeds at a rate parallel to the demand for secretory tissue. Thus when a suckling infant signals needs, the breast will respond<sup>75</sup> (Figure 3-20).

Effects on maternal behavior have been attributed to lactation. Maternal behavior is more easily defined in many other species, in which early nursing is initiated by the mother, who stimulates the neonate to suckle by grooming. She then presents her mammary gland to the offspring so that the nipple is located with minimal effort. All species of lactating females have a lessened response to stress. In humans, however, nursing behavior has a strong voluntary nature. When lactating women were stressed with graded treadmill exercise, significant decreases in plasma levels of ACTH, cortisol, and epinephrine were observed compared with a matched group of nonlactating women.<sup>8</sup> Plasma glucose levels did not increase in either group. Oxytocin pulse in the plasma in response to suckling was also accompanied by a decrease in plasma ACTH and cortisol in the lactating women.

**Figure 3-20.** Average change in breast volume during pregnancy, lactation, and after weaning (w) compared to preconception breast volume. (From Kent JC, Mitoulas L, Cox DB, et al: Breast volume and milk production during extended lactation, *Exp Physiol* 84:435–447, 1999.)

Oxytocin administered intraventricularly to virgin rats induces maternal behavior. Local infusion of oxytocin antagonists to appropriate regions of the hypothalamus during parturition blocked the dams from pup retrieval, a measure of maternal behavior in rats. Similar observations have been made in sheep.<sup>71</sup> The neurophysical mechanism is under study in humans. Oxytocin promotes the development of human maternal behavior and mother-infant bonding.<sup>70</sup> Some effects of oxytocin in the nipple and mammary gland appear to be caused by peptides released in the nipple from axon collaterals of somatosensory afferent nerves. Oxytocin is also present in neurons projecting to many areas in the brain and exerts many central actions. In addition to maternal behavior, oxytocin causes more nonspecific behavior changes, such as sedation or antistress effects, and optimizes transfer of energy to the mammary gland.<sup>70</sup>

Investigations of the agile wallaby, *Macropus agilis*, have revealed the let-down reflex because this species displays concurrent asynchronous lactation. The young, weighing 35 g, attach to the teat at birth. The lactating gland continues to grow for 200 days, increasing tenfold in size. At 200 to 220 days, weighing 2500 g, the young first leaves the pouch. Twenty-six days later a second young is born, although the older one continues to suckle intermittently for another 160 days at the original teat. The second young attaches to an unused nipple, which begins to develop, displaying complete autonomy. Measurements of oxytocin during the initial lactation show an increase in intraductal pressure response with a decline in sensitivity over time. This permits milk ejection in response to a small release of oxytocin to be confined to the mammary gland to which the neonate is continuously attached. The release of large quantities of oxytocin in response to the suckling of the juvenile would cause release in both glands.

Mammals have thus evolved diverse strategies for survival. Tandem nursing in the human has not been as carefully studied, but, although the milk reverts to colostrum at the birth of the new infant, no known change occurs in let-down.

The spinothalamic tract is the most likely of the possible spinal and brainstem pathways by which the suckling stimulus reaches the forebrain. The areas of the forebrain influenced by the suckling stimulus include the hypothalamic structures that mediate oxytocin and prolactin release. The inhibition of milk ejection by visual and auditory stimuli, pinealecstasy, and ventrolateral midbrain lesions in lactating rats has been studied to define further the neurohormonal pathways. In these experiments, the pineal gland appeared to mediate an inhibitory visual reflex on both oxytocin release and milk ejection.<sup>30</sup>

A mechanism consisting of smooth muscle and elastic fibers acting as a sphincter at the end of the ducts in the nipple appears to prevent most unwanted loss of milk. Sympathetic control does not appear to be present in humans, although it is demonstrable in most other species.

As the end of pregnancy approaches, the breast is prepared to respond to the suckling offspring.<sup>73</sup> In humans, this is evidenced by increased sensitivity of the breast to tactile stimulation; increased responsiveness of the ductules to oxytocin, thus preparing to eject the milk; and increased response of the breast to signaling the release of prolactin to stimulate milk production. The signal for lactation occurs when the placenta is removed and the end organs in the breast can fully respond to the surge of prolactin resulting from suckling.<sup>92</sup>

## Concentrations of Oxytocin in Milk

Human milk samples obtained by manual expression daily from the first to the fifth postpartum day were collected immediately before and after a feeding as well as 2 hours after nursing.<sup>88</sup> The baseline mean oxytocin concentrations were 3.3 to 4.7 mg/mL, increasing significantly with nursing. Oxytocin in milk is fairly stable compared with that in maternal serum, which is inactivated by oxytocinase in plasma, liver, and kidney. When oxytocin was administered to rat dams, it was also found in the suckling offspring's gastric contents, where it is stable in acid. Some is absorbed into the neonatal blood, where it is unstable. Levels of oxytocin in neonatal serum are produced predominantly by the neonate itself. Whether oxytocin has a physiologic role on the gut or other hormones is unknown.

## Role of Prostaglandins as Milk Ejectors

Because prostaglandins have many physiologic effects and are known to increase mammary duct pressure, Toppozada et al.<sup>90</sup> investigated their role as milk ejectors.<sup>62</sup> Comparison was made among three treatments: intravenous (IV) injections of oxytocin, prostaglandin (PG) E2 (PGE2), and 16-phenoxy-PGE2 given to one group of women on the third to sixth day postpartum; IV oxytocin, 15-methyl-PGF $2\alpha$ , and PGF $2\alpha$  tromethamine salt to a second group; and oxytocin and PGF intranasally to a third group. All combinations had some effect, with the IV route having a shorter latency period than the intranasal. PGF $2\alpha$ , the more potent of the prostaglandin preparations,

was more potent via the nasal route than oxytocin nasally. The response lasted 25 minutes after intranasal instillation of 400 mg. PGE2 and PGF $2\alpha$ , orally administered, reduce prolactin levels and appear to be successful in suppressing lactation in the immediate postpartum period when given in large doses of 2 to 4 mg or in multiple doses to a maximum of 10 times greater. Although they are produced in larger quantities by the mammary gland in vitro and in vivo, the role of prostaglandins is still not clear, because these studies<sup>90</sup> are in conflict with previous results by Vorherr.<sup>99</sup> The practical application of this in-lactation failure has not been reported.

Milk-borne prostaglandins clearly survive in the environment of the infant's gastrointestinal tract and are delivered in an active form to peripheral organs. The significance of this remains under investigation.<sup>40</sup>

## *Production of Hormones by the Mammary Gland*

Hormones synthesized by the mammary gland may have endocrine, autocrine, or paracrine effects within the mother. The chemical mediators known to be synthesized by the mammary gland are EGF, progesterone, prolactin, estrogens, and relaxin. Other hormones are transported to the gland.<sup>68</sup> These bioactive agents could have multiple roles in both mother and recipient infant. Insulin-like growth factors are found in high concentration in colostrum and at lower levels in mature milk. Milk factors other than nutrients are thought to control specific developmental processes in the infant. Because infants survive and grow on formula, this latter point is difficult to prove. Actions of milk regulatory substances are much more important in at-risk infants than in full-term infants.

## *Feedback Inhibitor of Lactation*

The mammary gland is unique because, as an exocrine gland, it stores its secretion extracellularly. Storage within the gland's lumen suggests a local level of control on the rate of secretion.<sup>57</sup>

As stated earlier, milk is produced as long as it is removed from the mammary gland. Further, prolactin and oxytocin are responsible for the production and release of milk, allowing the infant to extract milk by suckling. The rate of milk secretion may differ between breasts if one breast is suckled more frequently or for a longer time. When lactating goats have an extra daily milking, the secretory rate is increased even if the milk is immediately replaced with an inert solution to maintain the gland's

distention. The dilution of stored milk in the gland with an inert isotonic solution results in increased milk secretion, suggesting the dilution of a chemical inhibitor.

Identification of a factor that is produced and functions at the mammary level, FIL, has evolved from multiple studies.<sup>72</sup> Wilde et al.<sup>103</sup> described autocrine regulation of milk secretion by a previously unknown protein in the milk. When this active whey protein, a FIL, was isolated and injected into the mammary gland of lactating goats, milk secretion was decreased temporarily. Similar work by Prentice et al.<sup>72</sup> confirmed the presence of FIL in humans. FIL is able to exert reversible concentration-dependent autocrine inhibition on milk secretion in the lactating gland. It controls secretion of all milk constituents simultaneously; that is, it affects secretion, not composition.

The search for the mechanism that explains regulation of milk supply continues. When goats were studied, it was noted that when milk accumulated in the mammary gland, production decreased. When the milk was removed and replaced with isotonic sucrose solution to volume, the rate of milk produced increased. This finding supports the concept that it is a compound in the milk and not distention of the mammary gland that regulates synthesis. This factor, FIL, is an autocrine mechanism.

FIL cannot be the sole control of milk synthesis, or removal of milk would not stimulate milk production (see Figure 3-20). Cregan and Hartmann speculate that the mechanism of local control of milk synthesis is related to the filling/emptying cycle of the alveoli.<sup>14</sup> Milk accumulation changes the morphology of the lactocytes lining the alveoli. When the luminal volume of mammospheres increased, according to St. Reuli and Edwards, it altered the interaction of the lactocytes with the basement membrane inhibiting prolactin receptors and further milk synthesis.<sup>83</sup>

## *Maternal Adaptation to Lactation*

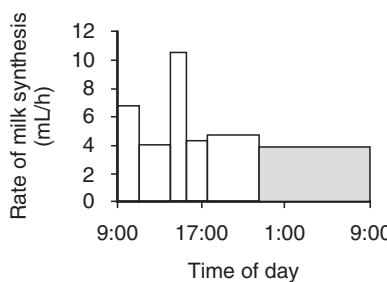

The hormonal trigger for lactogenesis is a decrease in progesterone while prolactin levels are maintained. Postpartum prolactin levels are comparable in breastfeeding and nonbreastfeeding women for a few days (see Figures 19-2 to 19-4 and Figure 3-6). Thus the basic process occurs regardless of whether breastfeeding is initiated. The mammary epithelium must be adequately prepared by the hormones of pregnancy to respond by synthesizing milk.

Each mammalian species has evolved its own lactational strategies to meet the nutritional needs of its offspring, with influences from both genetic and environmental forces. The endocrine signals promote mammary development, inhibit milk

production during gestation, and then promote development of enhanced metabolic and transport functions in adipose tissue, visceral organs, and reproductive organs.<sup>67</sup> Lactational adaptations of adipose tissue metabolism have been recognized in all species and may be most dramatic in seals, hibernating bears, and whales, who produce fat-rich milk from their fat stores while fasting. Lactation results in profound changes in adipose tissue metabolism to provide energy stores, modulate mammary development, affect appetite, and influence the immune system function.<sup>93</sup>

The substantial adaptation of the maternal intestine during lactation is the large increase in its size and complexity, which ensures adequate absorption of nutrients to meet the increased energy demand.<sup>28</sup> A corresponding increase occurs in liver and heart performance. In addition to extra fat demands, calcium concentration must be sufficient to maintain maternal stores while providing for the demands of milk synthesis, which are greater than those of pregnancy.<sup>34</sup> The estimated calcium requirement is 12 mg/kg per day in humans. The elevation in plasma dihydroxycholecalciferol, or 1,25-(OH)2D3, during late gestation continues during early lactation. As lactation progresses beyond 3 months, plasma 1,25-(OH)2D3 levels decline. This results in decreased calcium absorption, which is offset by greater maternal bone losses and reduced urinary calcium. Glucose requirements during lactation require major adjustments in glucose production and utilization in the maternal liver, adipose tissue, bone, muscle, and other tissues. Adaptation of folic acid metabolism is equally important, although less well studied.<sup>67</sup>

The mechanisms by which early pregnancy and lactation decrease the incidence of breast cancer are unclear. Close examination of the more differentiated mammary cell, which is less susceptible to the loss of growth regulation, is a next step, along with inspection of mucin, a glycoprotein and normal differentiation antigen expressed in both milk fat globules and mammary tumors.

**Figure 3-21.** Rate of milk synthesis and volume of milk produced in one breast by an exclusively expressing mother over a 24-hour period. The shaded columns indicate the overnight period that had the lowest rate of milk synthesis but the highest volume expressed. (From Cregan MD, Hartmann PE: Computerized breast measurement from conception to weaning: clinical implications, *J Hum Lact* 15:89, 1999.)

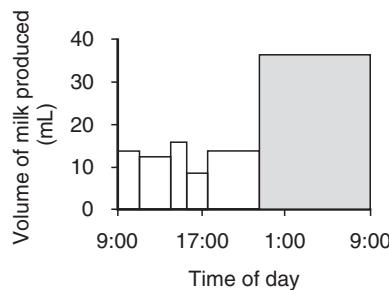

## Delay in the Onset of Lactogenesis

Clinically, it has been observed that delayed lactogenesis occurs in women who have diabetes, are stressed during delivery, and occasionally experience retained placenta. When signs of lactogenesis are absent in the first 72 hours, a cause should be sought. In women with diabetes, extra effort should be made to ensure that the process goes well with good hydration, adequate dietary intake, insulin control, and attention to detail. A study of the impact of cesarean delivery on lactogenesis II found that early pumping did not help and may have interfered with the volume of milk produced.<sup>7</sup> After stressful deliveries, it may be necessary to initiate pumping if the infant is unable to adequately stimulate the breast, but this needs further study. Again, close monitoring is essential before discharge. Retained placenta is discussed in Chapter 16. The treatment, dilatation and curettage, is definitive and dramatically therapeutic.

Anticipating problems and identifying early signals of faltering are key to ultimately improving lactogenesis.

## Synthesis of Human Milk

Computerized breast measurement (CBM) was developed by Hartmann et al.<sup>32</sup> because of the inaccuracy of the established methods for measuring milk synthesis. The three other techniques utilized are (1) weighing either the infant or the mother before and after every feeding for 24 hours; (2) isotope dilution used to estimate production over a 4- or 7-day period; and (3) breast expression in which a mother removes milk from breasts (this technique does not reflect the effect of the infant on milk production by suckling). CBM is designed to measure short-term rates of milk synthesis. This technique allows the appetite of the infant to dictate the amount of milk removed from the breast while also being able to measure the residual (Figure 3-21).

CBM measures changes in breast volume without interfering with the infant's pattern of breastfeeding. CBM allows not only measurement of change in breast volume and volume of milk removed during a feeding but four additional parameters.

The first is the short-term rate of milk synthesis (S) between feedings. The calculation takes the increase in breast volume from the end of one feeding ( $V_{B1}$ ) to the beginning of the next ( $V_{B2}$ ), divided by the time between these two measurements (T).

$$S = \frac{V_{B2} - V_{B1}}{T}$$

The second measures storage capacity (SC), which is defined by the authors as the maximum breast volume ( $V_{\max}$ ) minus the minimum breast volume ( $V_{\min}$ ) observed over a 24-hour period (see [Figure 3-21](#)).

$$SC = V_{\max} - V_{\min}$$

The third measurement is the degree of fullness (F), which is the ratio of any particular breast volume ( $V_B$ ) divided by the storage capacity of the breast (SC).

$$F = \frac{V_B}{SC}$$

The range is from 1 when the breast is full to 0 when it is at minimum volume in a 24-hour period.

In addition, this CBM technology can be used to measure the increase in breast volume during pregnancy, thus measuring breast growth and breast involution after peak lactation.

The storage capacity was measured by Daly et al.<sup>17</sup> and varied from 80 to 600 mL. The rate of milk synthesis was minimal when the breast was full and maximum when the breast was emptied.

The function of the mammary gland is unique in that it produces a substance that makes tremendous demands on the maternal system without producing any physiologic advantage to the maternal organism. Because lactation is anticipated, the body prepares the breast anatomically and physiologically.<sup>82</sup> When lactation begins, the mother's metabolism changes greatly. The blood supply is redistributed, and the demand for nutrients increases, which requires an increased metabolic rate to accommodate their production. The mammary gland may need to produce milk at the metabolic expense of other organs. The supply of materials to the lactating breast for milk production and energy metabolism requires extensive cardiovascular changes in the mother. There is increased mammary blood flow, increased blood flow into

the gastrointestinal tract and liver, and a high cardiac output. The mammary blood flow, cardiac output, and milk secretion are suckling dependent. Suckling induces the release of anterior pituitary hormones that act directly on breast tissue.<sup>44</sup>

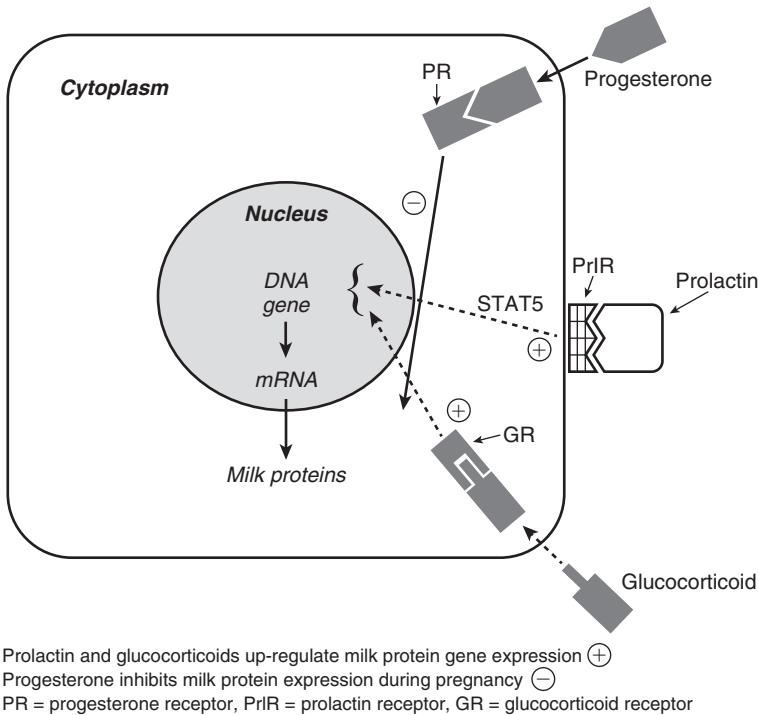

Milk is isosmotic with plasma in all species.<sup>44</sup> Human milk differs from many other milks in that the concentration of major monovalent ions is lower and that of lactose is higher; in other milks, the higher the ions, the lower the lactose, and vice versa. Many disparities in the intermediary metabolism among species of animals can be linked to evolutionary adaptations involving the digestive process.<sup>43</sup> Nonruminants rely on glucose, derived from carbohydrate in the diet. Ruminants, because of extensive fermentation in the rumen, absorb little glucose. The microbial fermentation products, which include acetate, propionate, and butyrate, play a significant part as energy and carbon sources for tissue metabolism. Amino acids are primary substitutes for glucose in ruminants.<sup>44</sup>

The biosynthesis of milk involves a cellular site where the metabolic processes occur. The epithelial cells of the gland contain stem cells and highly differentiated secretory alveolar cells at the terminal ducts. The stem cells are stimulated by hGH and insulin. Prolactin synergizes the insulin effect to stimulate the cells to secretory activity.

Prolactin binds to specific prolactin receptors on the surface of the lactocytes. There is a lactogenic signaling pathway which creates the switching on of the transcription of genes. These genes regulate the secretion of milk proteins, including casein and lactalbumin. The prolactin receptor is part of the cytokine receptor family. These are activated at the onset of pregnancy and lactogenesis. The binding of prolactin to the site triggers the kinase and the chain of reactions of phosphorylation and activation of transcription<sup>16</sup> (Figure 3-22).

The cells of the acini and smaller milk ducts are active in milk synthesis and milk secretion into the alveoli and smaller milk ducts. Most milk is synthesized during the process of suckling; its production is stimulated by prolactin. Cortisol plasma levels are increased during suckling as well. The secretory cells are cuboidal, changing to a cylindrical shape just before milk secretion, while cellular water uptake is increased. The cell's single nucleus is at the base in the dormant cell but migrates to the apex just before milk secretion.

The differentiated structure of the functional cell is acquired gradually during pregnancy, differing little from species to species. Very early in lactation, mammary cells show active synthesis and secretion of proteins and fat. The cells are polarized with abundant rough endoplasmic reticulum and Golgi dictyosomes above the nucleus, which is smooth and rounded with many mitochondria.

**Figure 3-22.** Intracellular hormonal signaling in the lactocyte during lactation. (Adapted from Mercier and Gaye: Chapter 7. In Mepham TB, editor: *Biochemistry of lactation*, New York, 1983, Elsevier.)

The apical surface has microvilli, and the basal surface is extensively convoluted for the active transport of materials from the bloodstream into the cell. Fat droplets are in the cytoplasm and bulging at the membrane. Proteins, lactose, calcium, phosphate, and citrate are packaged into secretory vesicles and pass into the lumen of the alveolus by exocytosis.

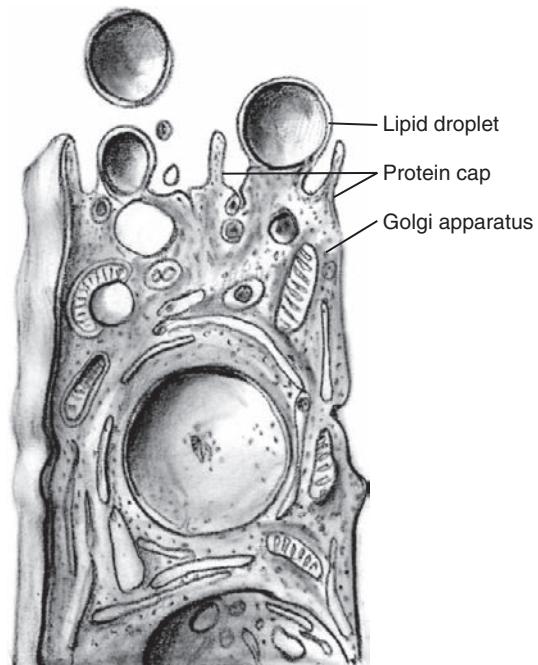

The cytoplasm is finely granular in the resting phase but striated as milk secretion begins. As secretion commences, the enlarged cell with its thickened apical membrane becomes clublike in shape. The tip pinches off, leaving the cell intact. The protein is thus free in the secreted solution, retaining a cap of membrane (Figure 3-23).

## Function of Cellular Components of the Lactating Breast

The schema of the mammary secretory cell is represented in Figures 3-24 and 3-25.

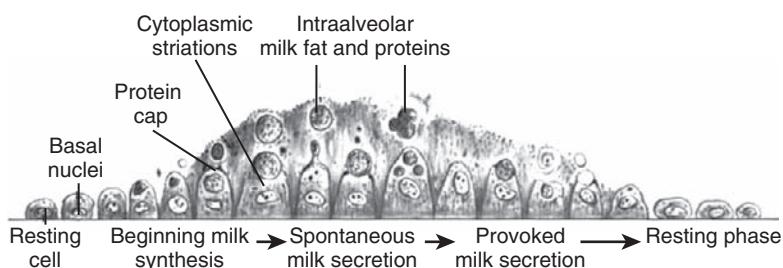

### NUCLEUS

The nucleus is essential to the duplication of genetic material and the transcription of the genetic code.<sup>97</sup> The nucleus is also considered a regulatory organelle

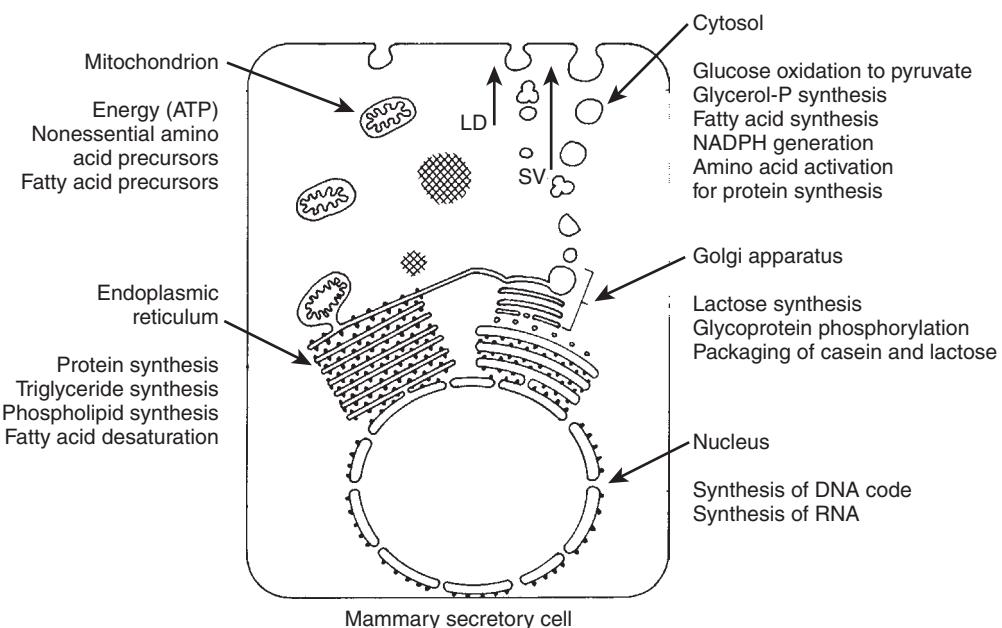

**Figure 3-23.** Apocrine secretory mechanism for lipids, proteins, and lactose in milk.

in cell metabolism, transmitting the design of the cell's enzymatic profile. The DNA and RNA content of the cellular nuclei increases during pregnancy and is highest during lactation.

**Figure 3-24.** Diagram of cycle of secretory cells from resting stage to secretion and return to resting stage. (Modified from Vorherr H: *The breast: morphology, physiology and lactation*, New York, 1974, Academic Press.)

**Figure 3-25.** Schema of cytologic and biochemical interrelationships of secretory cell of mammary gland. LD, Lipid droplet; SV, secretory vesicle.

## CYTOSOL

The cytosol, which consists of the cytoplasm minus the mitochondrial and microsomal fractions, is also called the particle-free supernatant. The cytosol contains enzymes that involve key intermediates and cofactors essential to the process of milk synthesis.

## MITOCHONDRIAL PROLIFERATION

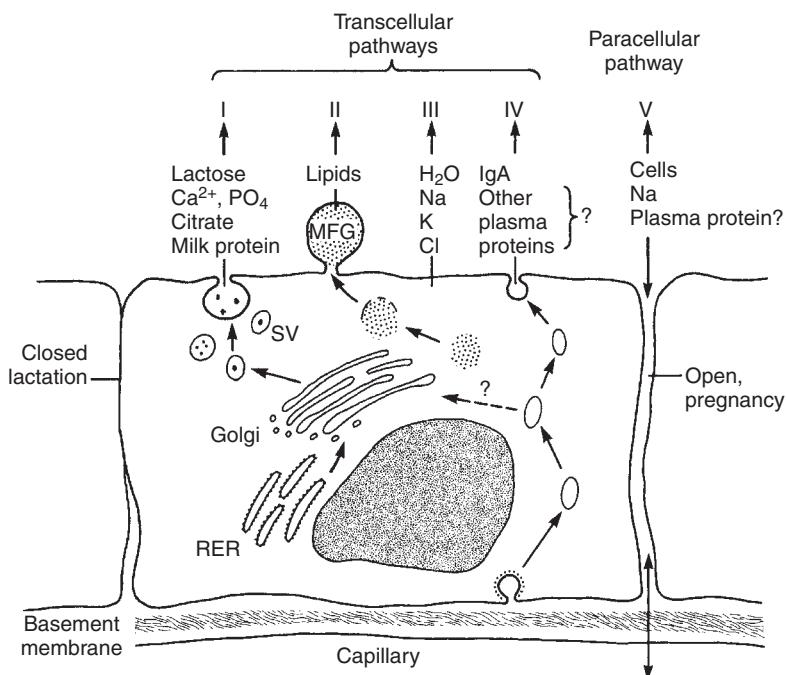

The alveolar cell population of the mammary gland must have a greatly expanded oxidative capacity during lactation. It is supplied by an increase in size and function of the cell's mitochondrial population. Mitochondria are increased in the epithelial cell at the onset of the lactation process. Mitochondrial proliferation has been observed in all cells with a high metabolic rate and high oxygen utilization.

During the presecretory differentiation phase in late pregnancy and early lactation, each mito-

chondrion undergoes a type of differentiation in which the inner membrane and matrix expand greatly. As with other cells, the mitochondria are key to the respiratory activity of the cell. Mitochondria control some cellular metabolism through differential permeability to certain anions. The citrate in the mitochondria is a major source of carbon for fatty acid biosynthesis. Mitochondria also supply the carbon for synthesis of nonessential amino acids.

## MICROSOMAL FRACTION

The microsomal fraction of the cell, which includes the Golgi apparatus, the endoplasmic reticulum, and the cell membranes, is involved in lipid synthesis. The role of the microsomal fraction is also to assemble the constituent parts (e.g., amino acids, glucose, fatty acids) into the final products of protein, carbohydrate, and fat for secretion.

**Figure 3-26.** Pathways for milk synthesis and secretion into mammary alveolus. **I**, Exocytosis of milk protein and lactose in Golgi-derived secretory vesicles. **II**, Milk fat secretion via milk fat globule. **III**, Secretion of ions and water across apical membrane. **IV**, Pinocytosis-exocytosis of immunoglobulins. **V**, Paracellular pathway for plasma components and leukocytes. MFG, Milk fat globule; RER, rough endoplasmic reticulum; SV, secretory vesicle. (Modified from Neville MC: The physiological basis of milk secretion. Part I. Basic physiology, *Ann NY Acad Sci* 586:1, 1990.)

## INTERMEDIARY METABOLISM OF MAMMARY GLAND

The pathways identified for milk synthesis and secretion in the mammary alveolus, as described by Neville et al.,<sup>50</sup> include four major transcellular pathways and one paracellular pathway (Figure 3-26):

1. Exocytosis of milk protein and lactose in Golgi-derived secretory vesicles
2. Milk fat secretion via the milk fat globule
3. Secretion of ions and water across the apical membrane
4. Pinocytosis-exocytosis of immunoglobulins
5. Paracellular pathway for plasma components and leukocytes

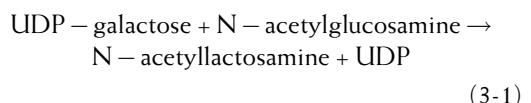

## CARBOHYDRATES

The major carbohydrate for most species is lactose, a disaccharide found only in milk. In addition to lactose, more than 50 oligosaccharides of different structures have been identified in human milk. One of the most important is glucose.

Glucose metabolism has a key function in milk production.<sup>4</sup> Glucose serves as the main source of energy for other reactions as well as a critical source of carbon. Glucose is critical to the volume of milk produced and is used in the production of lactose. The synthesis of

lactose combines glucose and galactose, the latter originating from glucose-6-phosphate.<sup>33</sup>

Lactose synthesis is carried out by the following equations

UDP is uridine diphosphogalactose. The catalyst in the first equation is a galactosyl transferase, N-acetyllactosamine synthetase. The reaction is activated by metal ions that bind to the galactosyltransferase.

Most of the intracellular glucose is derived from blood sugar. A specific whey protein,  $\alpha$ -lactalbumin, catalyzes the lactose synthesis. It is a rate-limiting enzyme, which is inhibited by progesterone during pregnancy. In the absence of  $\alpha$ -lactalbumin, little lactose is present. With the drop in progesterone and estrogen levels after the removal of the placenta at delivery, prolactin increases. The synthesis of  $\alpha$ -lactalbumin becomes greater, and large amounts of lactose are produced from glucose. Progesterone regulates the onset of lactose synthesis, causing the initiation of production just as the infant is in need of nutrition.

Because lactose is synthesized only from glucose, maternal glucose utilization is increased by 30% in full lactation.<sup>59</sup>

Various aspects of lactose synthesis continue to be vigorously investigated.<sup>33</sup> The molecular mechanism of lactose synthesis is activated by metal ions, manganese (Mn), and calcium (Ca). Lactose synthesis takes place within the Golgi apparatus (see Figure 3-26). The onset of copious milk secretion depends on rapid increase of lactose synthesis. Lactose synthetase performs the rate-limiting step in lactose synthesis, which is one of the few anabolic reactions involving glucose itself rather than a phosphorylated derivative.<sup>5</sup> Although progesterone, thyroxine, and lactogenic hormones are important in controlling synthesis, it is not known how they act in this system. The areas available for investigation about lactose synthesis remain vast.

## FAT

Fat synthesis takes place in the endoplasmic reticulum. The alveolar cells are able to synthesize short-chain fatty acids, which are derived predominantly from acetate. Long-chain fatty acids, derived chiefly from blood plasma, are used in milk fat. Triglycerides are utilized from the plasma, as well as synthesized from intracellular glucose oxidized via the pentose pathway. Synthesis of fat from carbohydrate plays a predominant role in fat production in human milk.<sup>36</sup>

Two enzymes, lipoprotein lipase and palmitoyl-coenzyme A (CoA) 1-glycerol-3-phosphate palmitoyl transferase, increase greatly after delivery. The lipase acts at the walls of the capillaries to catalyze the lipolysis and uptake of glycerol into the epithelial cells. The transferase catalyzes the process of synthesizing glycerides to triglycerides. It is believed that the marked increase of the lipase and transferase is stimulated by prolactin. Hormonal control of the glycerol precursors and the enzymatic release of fatty acids, leading to the formation of triglycerides, have been associated not only with prolactin but also with insulin, which stimulates the uptake of glucose into the mammary cells.

Esterification of fatty acids also takes place in the endoplasmic reticulum. The triglycerides subsequently accumulate into fat droplets in several cisternae. The small droplets sit on the base of the cell and coalesce to large droplets that move toward the apex of the cell. The fat droplets are engulfed in the apical membrane and project into the alveolar lumen. The discharge of fat droplets involves the bulging of the cell apex to envelop the fat globules, protein, and a small amount of cytoplasm; with the pinching off, the globule

becomes detached into the lumen. The membrane of the fat globule contains all the normal plasma enzymes. The fat droplets contain predominantly polar lipid and phosphatidyl choline.

Fatty acid synthesis involves a source of substrates and associated enzymes for their conversion to acetyl-CoA and reduced nicotinamide-adenine dinucleotide phosphate in the cytoplasm of the cell and the conversion of acetyl-CoA to malonyl-CoA. The newly synthesized fatty acid is then released from the fatty acid-synthetase complex.

The milk-fat-globule membrane in human milk serves several roles. A layer of amphophilic (bipolar) substances at the globule/skim milk interface is required for the maintenance of emulsion stability of the fat globules.<sup>36</sup> This physicochemical fact applies to all emulsions and to the fat globules in the milk of all species. The globules and the milk-fat-globule membrane are compartments within the emulsion component of milk. Once in place, the components of the milk-fat-globule membrane, which is the oil-water interfacial compartment, are more or less firmly held in place by a variety of chemical and electrical forces. The stabilizing membrane acts as a reactive barrier on the interface between the globule and milk serum.<sup>36</sup> It is rate controlling for the binding of enzymes and trace elements, the controlled release of the products of lipolysis, the transfer of polar materials into milk serum, the maintenance of emulsion stability by the prevention of globule fission, and the availability of fatty acids and cholesterol for micellar absorption in the small intestine. All these interactions are dynamic. The envelopment mechanism involves rapid turnover of the plasma membrane lipids and proteins during milk production.

Study of RNA sequencing of the human fat layer transcription resulted in distinct gene expression profiles in all stages of lactation, colostral, transitional, and mature milk production. The contribution of maternal physiology to problems with lactation is just being explored. It is known that human milk fat globules, by enveloping cell contents as they are secreted into milk, are great sources of mammary cell RNA. Strong modulation of key genes is involved in lactose synthesis and insulin signaling. Protein tyrosine phosphatase is thought to serve as a biomarker linking insulin resistance to insufficient milk supply. The methodology is just being developed to research the physiologic contributions of suboptimal lactation.<sup>42</sup>

## PROTEIN

Most proteins in milk are formed from free amino acids in the secretory cells of the mammary gland. The definitive data confirming the origin of milk

proteins have been accumulated since 1980. The vast majority of proteins present in normal milk are specific to mammary secretions and are not identified in any quantity elsewhere in nature.<sup>43</sup>

The formation of milk protein and mammary enzymes is induced by prolactin and further stimulated by insulin and cortisol. De novo synthesis of protein uses both essential and nonessential plasma amino acids. Nuclear RNA, induced by prolactin, stimulates synthesis of mRNA and transfer RNA (tRNA). The mRNA conveys the genetic information to the protein-synthesizing centers of the cells. The tRNA interprets the message to assemble the amino acids in the appropriate sequence of polypeptide chains of the specific milk proteins. The newly synthesized proteins are secreted into the milk during lactation. Casein,  $\alpha$ -lactalbumin, and  $\beta$ -lactoglobulin from plasma amino acids are synthesized on the ribosomes of the endoplasmic reticulum, where they are condensed and appear as visible secretory granules moving toward the cellular apex.

After some processing, the proteins pass to the Golgi complex, where they are further glycosylated and phosphorylated and then placed in secretory vesicles for export<sup>54</sup>;  $\alpha$ -lactalbumin, a protein necessary for lactose synthesis by the enzyme galactosyltransferase, is among the proteins synthesized in the mammary gland. Lactose is synthesized within the trans-Golgi complex and secreted together with the major milk proteins. The casein micelle is formed with calcium within the Golgi compartment, which presents a high concentration of calcium, phosphate, and protein via the milk. Most of the casein is bound in this manner. This pathway I (see Figure 3-26) begins in the rough endoplasmic reticulum, where the proteins are inserted through the membrane into the lumen by exocytosis.<sup>54</sup>

The Golgi membrane is impermeable to lactose; thus the sugar is osmotically active. Water is drawn into the Golgi apparatus.<sup>67</sup> Casein micelle formation begins in the terminal Golgi vesicles, adding calcium in the secretory vesicle. These secretory vesicles move to the plasma membrane and through exocytosis extrude their contents into the alveolar lumen.<sup>49</sup>

Human casein micelles are smaller in size (30 to 75 nm in diameter) than bovine casein (600 nm). Human milk contains only  $\beta$ -casein. Only 6% of calcium in human milk is bound to casein, compared with 65% in bovine milk. The gene for human  $\beta$ -casein has been cloned and sequenced.<sup>67</sup>

Some merocrine secretion also occurs, in which proteins and other cellular constituents are secreted, leaving the cell membrane intact. Protein caps, or signets, protruding into alveolar lumen, have been described on the outside of the apical

**TABLE 3-3** Alveolar Epithelial Membrane Permeability

Sulfate	Phosphate

membrane. Protein and lactose secreted into the lumen cannot be reabsorbed (Table 3-3).

The synthesis of proteins in the mammary gland follows the general pathway of all proteins under genetic control. Induction of synthesis is under hormonal control. This process involves synthesis from amino acids through the detailed system controlled by RNA and under genetic control of DNA. Glucocorticoid is required for the expression of the casein gene in the presence of prolactin. Cortisol is the limiting factor for casein gene expression.<sup>28</sup> Shennan<sup>88</sup> has reviewed the mechanisms of mammary gland ion transport.

## IONS AND WATER

Sodium, potassium, chloride, magnesium, calcium, phosphate, sulfate, and citrate pass through the membrane of the alveolar cell in both directions.<sup>58</sup> Water also passes in both directions, predominantly from the alveolar cells but also from the interstitial fluid. Plasma water passage depends on the amount of intracellular glucose available for lactose. The aqueous phase of milk is isosmotic to plasma. The major osmole of the aqueous phase of milk is lactose. The concentrations of sodium and chloride are less than those in plasma.

Human milk differs from that of many other species in that the monovalent ions are in low concentration and lactose is in high concentration.<sup>45</sup> The osmolarity is the same, that is, isosmotic with plasma; thus the higher the lactose, the lower the ions. It is presumed that the intracellular concentration of potassium is held high and that of sodium low by a pump on the basal membrane. The sodium and potassium ions are distributed according to the electrical potential gradient.<sup>58</sup> Milk is electrically positive compared with intracellular fluid. The sodium/potassium ratio is 1:3 in both milk and intracellular fluid. Vorherr<sup>98,99</sup> thinks that lactose secretion is responsible for the potential difference across the apical membrane, thus keeping sodium and potassium ion concentration low.

The variation among species in the concentration of lactose and ions is caused by the rate of lactose synthesis, the permeability of the membrane, and the number of fixed negative charges on the membrane. The potential difference is higher in the human mammary gland than in any other species evaluated to date.

The relationship between infrastructure and function in the mammary gland changes from pregnancy to lactation. The junction between alveolar cells has attracted much interest. Cell junctions do not merely hold cells together but enable epithelia to function as permeable barriers, allowing communication between cells and coordination of activities. The three functions of cell junctions are adhesion, occlusion, and communication, which are carried out by desmosomes, tight junctions, and gap junctions, respectively. Changes in tight junctions may provide the basis for a reduction in permeability between cells. For instance, at the initiation of lactation, a tight junction changing from "leaky" to very tight blocks the paracellular movement of lactose and ions. This requires transport across cells of these materials and the maintenance of control of high intracellular potassium and low intracellular sodium concentrations.<sup>20</sup>

Citrate is thought to be the harbinger of lactogenesis. Citrate plays a central role in the metabolism of all cells, but its significance and mode of secretion remain unknown.<sup>69</sup> In the final stages of lactogenesis in ruminants, the previously quiescent epithelial cells suddenly start to secrete large quantities of protein, fat, and carbohydrates. The exact lactogenic trigger is unknown, although significant hormonal changes occur. In women, the onset of copious milk secretion does not begin until 3 to 4 days postpartum. Significantly, citrate levels are low at delivery and rise quickly, reaching a peak on day 4.<sup>69</sup> In cows and goats, copious production occurs at delivery, and the citrate levels begin to rise, increasing 10 to 100 times the baseline values.

Citrate is the main buffer system of milk.<sup>58</sup> It is formed within the secretory cell, but how it is secreted into the milk is not clear. Citrate and lactose may be secreted by a similar route. After dilution of milk in the gland with isosmotic lactose, the equilibrium is restored across the apical membrane in experimental models by the entrance of sodium, potassium, and chloride into the milk. No citrate, calcium, or protein enters in excess of the normal secretion rate. Inorganic phosphate is the other major buffer system, but how it is secreted is also unknown.

Calcium, much of which is bound to casein, enters the Golgi apparatus, where it is essentially

trapped with casein in the micelle, and then enters the alveolar milk by unidirectional flow.

The mammary gland is unusual among exocrine glands because the rate of secretion slows and some secretion can be stored in its ducts.<sup>80</sup> Direct neural control of secretion is lacking. The parenchyma of the gland also consists of ductal tissue in addition to secretory tissue. The ductal cells, however, are impermeable to the major milk ions during lactation, so in contrast to the ductal cells of other exocrine glands (e.g., sweat, salivary) they cannot modify the secretion.

A comparison of the levels of various constituents of the milk with corresponding plasma levels demonstrates the mechanism partly responsible for that difference in levels (see Table 4-18).

## MILK ENZYMES

Some milk enzymes enter the alveolar milk from the mammary blood capillaries via the intercellular fluid. Others come from the breakdown of the mammary secretory cells. The milk enzymes, xanthine oxidase, aldolase, and alkaline phosphatase, are contained in the fat globule, membrane, and milk serum. The most significant enzyme, lipase, splits triglycerides.

Human milk contains both proteolytic enzymes and protease inhibitors.<sup>29</sup> Amylase facilitates digestion of polysaccharides by the infant. Sulfhydryl oxidase catalyzes oxidation of sulfhydryl groups. Glutathione peroxidase facilitates the delivery of selenium to the infant. Lysozyme and peroxidase are bactericidal.

## CELLULAR COMPONENTS

Human milk has been called a "live fluid" by many and "white blood" in many ancient rites. Breast milk contains up to 4000 cells/mL, which have been identified with leukocytes and enter the milk via the paracellular pathway, pathway V.<sup>97</sup> The cell number is particularly high in colostrum. The cells in greatest number are the macrophages, which secrete lysozyme and lactoferrin. Lymphocytes, neutrophils, and epithelial cells are also present. Lymphocytes produce IgA and interferon.

Macrophages constitute a major cellular component in milk compared with levels in blood and can survive under conditions simulating the infant's gastrointestinal tract.<sup>31</sup> Because they release secretory IgA in association with phagocytosis, it is thought they play a role in host defense. Macrophage colony-stimulating factor in human milk and mammary gland epithelial cells are thought to be responsible for expansion of the macrophages in milk.

## *Involution: Weaning and Apoptosis*

During weaning, significant increases in milk protein, chloride, and sodium concentrations and a decrease in lactose occur when milk volumes fall below 400 mL per day. Glucose and magnesium levels are unchanged.<sup>57</sup> This suggests that volume is regulated differently during weaning than during lactogenesis. No sentinel substance is a reliable predictor of volume in all stages, but normal ranges of milk components during full lactation are sodium, 3 to 18 mmol/L; chloride, 8 to 24 mmol/L; protein, 8 to 23 g/L; and lactose, 140 to 230 mmol/L. Values outside these ranges suggest mastitis or weaning. During gradual weaning, between 6 and 15 months postpartum, glucose, citrate, phosphate, and calcium levels decrease, whereas lipid, potassium, and magnesium increase.<sup>63</sup>

Postlactational involution of the mammary gland is characterized by two distinct physiologic processes.<sup>51</sup> First, secretory epithelial cells undergo apoptosis and programmed cell death. Second, the mammary gland's basement membrane undergoes proteolytic degradation. Apoptosis is almost absent during lactation but develops within 2 days of involution. In the initial phase of involution, apoptosis of fully differentiated mammary epithelial cells occurs without visible degradation of the extracellular matrix. The second phase consists of extracellular remodeling and altered mesenchymal-epithelial interactions followed by apoptosis of cells no longer differentiating.<sup>85</sup> During postlactational mammary gland involution, most mammary epithelium dies and is reabsorbed.

In experimental models, apoptosis has been studied at weaning by using animals, removing the pups from the breast and studying the biochemical and genetic markers. Regulation of apoptosis during mammary gland involution is multifunctional. Forced weaning is used as a tool to accelerate and synchronize the involution process, thus allowing biochemical analysis. Apoptosis phenotypes resulting from specific gene deletions have been identified when these animal mothers are unable to nurse their pups.

When suckling ceases after lactation, the alveolar component of the gland involutes through a process that involves both apoptosis and tissue remodeling, which reconstructs the gland to the prepregnancy state. In situations of forced weaning, two phases occur. An initial apoptotic phase begins within 12 hours and persists for about 72 hours. The second phase involves further apoptosis, matrix degradation, and gland remodeling.

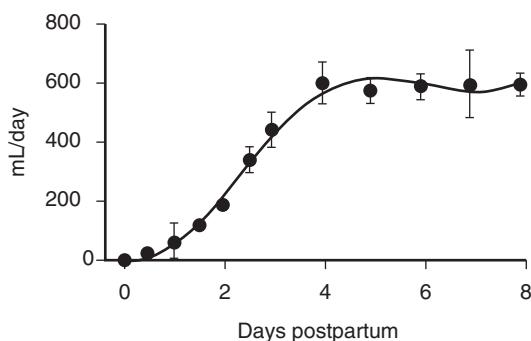

The first phase of involution before apoptosis is reversible and lactation can be reinstated within 2 days. During this time, milk accumulates within the alveolar lumen, and the level of lactogenic hormones drop. The initiation of apoptosis and the degradation of nuclear DNA into fragments is the best understood phase of the process. The second phase begins in which the gland remodeling takes place. The old connective tissue and the basement membrane are removed, then the ductal component is reformed. Apoptosis continues through this phase. High levels of tissue inhibitors of metalloproteinases are expressed, preventing excess matrix metalloproteinase activity.<sup>27</sup>

Significant advances have been made in the knowledge of signaling pathways that regulate epithelial cell apoptosis in the first phase. The precise nature of the triggers for apoptosis and the ultimate perpetrators of cell death are unknown. The available information suggests a complex network of signal transduction pathways that control apoptosis in the involuting mammary gland.<sup>87</sup>

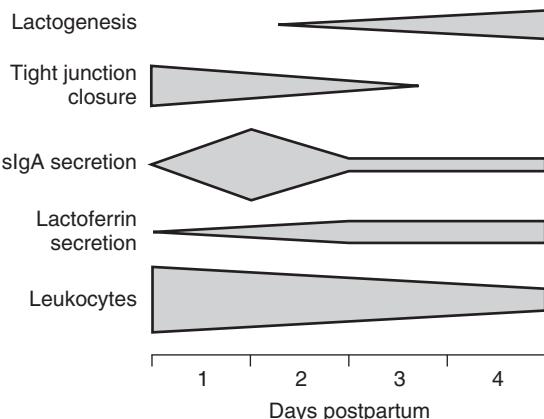

## *Summary*

In humans, lactogenesis occurs slowly over the first few days postpartum as progesterone levels drop. Women experience "milk coming in" as a feeling of fullness between 40 and 72 hours postpartum, usually corresponding to the degree of parity, with multiparas sensing this more quickly than primiparas. The physiologic explanation of the increase in milk volume, however, suggests that the sensation of "milk coming in" is not "normal" but a sign of overshooting the mark. Some women do not sense this special fullness but are excellent milk producers. Volume of milk increases over time for the first 2 weeks, starting at less than 100 mL per day and increasing to about 600 mL per day at 96 hours (Figure 3-27). This parallels the rise in citrate production, reflecting the metabolic activity of the mammary gland. Lactose, sodium chloride, and protein rise promptly, stabilizing at 24 hours and reflecting the closure of the pericellular pathway, which results in a decrease in direct flux into the milk. This suggests a two-step process of junctional closure followed by onset of secretory activity.

The changes in permeability of the tight junctions, rate of synthesis of lactose, lipids, and nutrient proteins; transport of glucose into the alveolar cells; transcytosis of secretory IgA; movement of immune cells into the alveolar lumen; and secretion of lactoferrin represent the distinct metabolic and cellular modifications. Neville<sup>56</sup> states, "The temporal sequence of these

**Figure 3-27.** Milk volumes during first week postpartum. Mean values from 12 multiparous white women who test-weighed their infants before and after every feeding for first 7 days postpartum. Redrawn from Neville MC: Determinants of milk volume and composition. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press.

**Figure 3-28.** Summary model for temporal sequence of changes in mammary gland function during lactogenesis in women. From Neville MC: Determinants of milk volume and composition. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press.

changes as they occur during lactogenesis suggests that they are either independently regulated or form part of an orderly cascade of temporally separate events." Figure 3-28 graphically illustrates these changes.

The use of new molecular techniques and the use of mutant animals with transgenic technology have advanced the understanding of human milk and the physiology of lactation. The regulation of mammary gland development has been demonstrated to depend not only on various hormones but their receptors, the signaling proteins such as protein kinases and transcription factors, as well as DNA binding proteins. The field is advancing rapidly. Signaling pathways are being identified and target genes of many regulatory pathways are being sought.

## CHAPTER 4

# *Biochemistry of Human Milk*

---

Human milk was considered a heavenly elixir, a living fluid. It was not until the end of the eighteenth century that chemical methods became available to decipher the content of milk. The biochemistry of human milk encompasses a mammoth supply of scientific data and information, most of which has been generated since 1970. Each report or study adds a tiny piece to the complex puzzle of the nutrients that make up human milk. The answers to some questions still elude us. A question as simple as the volume of milk consumed at a feeding remains a scientific challenge. The methodology must be accurate, reproducible, noninvasive, and suitable for home use night or day and must not interrupt breastfeeding. The precision analysis available for measuring the concentration of the most minuscule of elements, however, is remarkably accurate and reproducible in the laboratory. Milk has been demystified by laboratory chemistry.<sup>121</sup>

Advances in analytic methods bring greater sensitivity, resolving power, and speed to the analysis of milk composition. Previously unknown and unrecognized compounds have been detected. We now know milk provides both nutrients and non-nutritive signals to the neonate. With few exceptions, all milks contain the nutrients for physical growth and development. When the offspring develops rapidly, the milk is nutrient dense; when it develops slowly, the milk is more dilute. All milks contain fat, carbohydrates, and proteins, as well as minerals, vitamins, and other nutrients. The organization of milk composition includes lipids in emulsified globules coated with a membrane, colloidal dispersions of proteins as micelles, and the remainder as a true solution.<sup>113</sup> At no other time in life is a single food adequate as the sole source of nutrition.

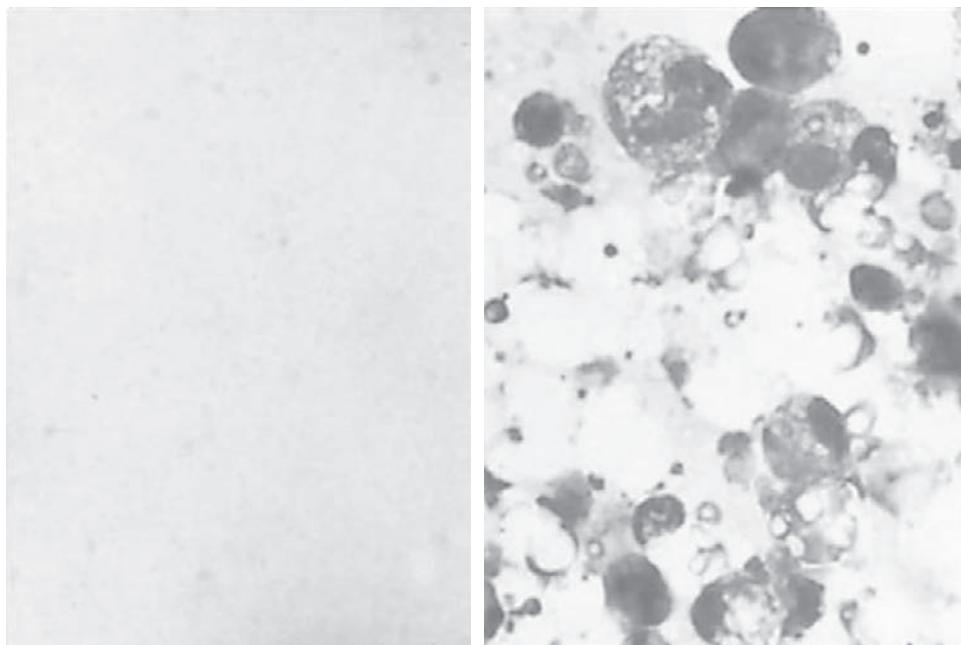

The discussion in this chapter is limited to information perceived as immediately useful to the clinician. Considerable detail and species variability are overlooked to help focus attention on details directly influencing management. Extensive and exhaustive reviews are referenced to provide the reader with easy access to greater detail and validation of the general conclusions reported here.

Human milk is not a uniform body fluid but a secretion of the mammary gland of changing composition (Figure 4-1). The first drops at the beginning of a feeding differ from the last drops. Colostrum differs from transitional and mature milks. Milk changes with the time of day and as time goes by. As concentrations of protein, fat, carbohydrates, minerals, and cells differ, physical properties such as osmolarity and pH change. The impact of changing composition on the physiology of the infant gut is beginning to be appreciated. Many constituents have dual roles, not only nutrition but infection protection, immunity, or a host of other effects.

The more than 200 constituents of milk include a tremendous array of molecules, descriptions of which continue to be refined as qualitative and quantitative laboratory techniques are perfected. Resolution of lipid chemicals has advanced dramatically in recent years, but new carbohydrates and proteins have been identified as well. Some of the compounds identified may well be intermediary products in the process that occurs within the mammary cells and may be only incidental in the final product.<sup>148</sup> Milk includes true solutions, colloids, membranes, membrane-bound globules, and living cells.

Human and bovine milks are known in the greatest detail; however, much information exists about the milk of rats and mice, as well as five other species: the water buffalo, goat, sheep, horse, and pig.

## Formula vs. human milk

**Figure 4-1.** A comparison of formula (left) and human milk (right). Human milk is a dynamic colloidal solution of perfect nutrients and growth factors for the infant. Formula is a totally homogenized solution of nutrient chemicals. (Courtesy of Nancy Wight MD, San Diego, Calif.)

**TABLE 4-1** Composition of Milks Obtained from Different Mammals and Growth Rate of Their Offspring

Species	Days Required to Double Birth Weight	Content of Milk (%)			
		Fat	Protein	Lactose	Ash
Human	180	3.8	0.9	7.0	0.2
Horse	60	1.9	2.5	6.2	0.5
Cow	47	3.7	3.4	4.8	0.7
Reindeer	30	16.9	11.5	2.8	—
Goat	19	4.5	2.9	4.1	0.8
Sheep	10	7.4	5.5	4.8	1.0
Rat	6	15.0	12.0	3.0	2.0

From Hambraeus L: Proprietary milk versus human breast milk in infant feeding: a critical appraisal from the nutritional point of view, *Pediatr Clin North Am* 24:17, 1977.

Several are listed in Table 4-1. Miscellaneous data are available on the milk of 150 more species, but almost no data are available for another 4000 species. Jenness and Sloan have compiled a summary of 140 species from which a sampling has been extracted (Table 4-2). The constituents of milk can be divided into the following groups, according to their specificity:

1. Constituents specific to both organ and species (e.g., most proteins and lipids)
2. Constituents specific to organ but not to species (e.g., lactose)
3. Constituents specific to species but not to organ (e.g., albumin, some immunoglobulins)

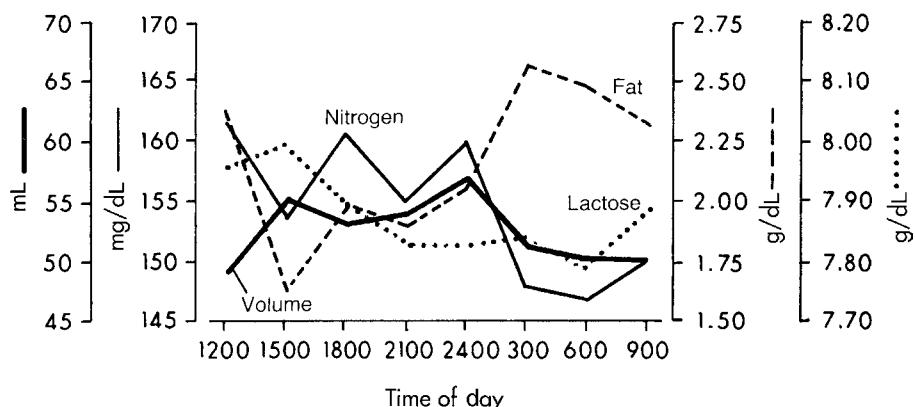

### Normal Variations in Human Milk

In defining the constituents of human milk, it is important to recognize that the composition varies with the stage of lactation, the time of day, the sampling time during a given feeding, maternal nutrition, and individual variation. Many early interpretations of the content of human milk were based on spot samples or even pooled samples from multiple donors at different times and stages of lactation. Samples obtained by pumping may vary from those obtained by the suckling infant because some variation exists in content among the various methods of pumping. Banked donor milk differs from freshly

**TABLE 4-2** Constituents of Milk (g/100 g) of Specific Mammals

Mammalian Species (in Taxonomic Position)	Total Solids	Fat	Casein	Whey Protein	Total Protein	Lactose	Ash
Human	12.4	3.8	0.4	0.6	—	7.0	0.2
Baboon	14.4	5.0	—	—	1.6	7.3	0.3
Orangutan	11.5	3.5	1.1	0.4	—	6.0	0.2
Black bear	44.5	24.5	8.8	5.7	—	0.4	1.8
California sea lion	52.7	36.5	—	—	13.8	0.0	0.6
Black rhinoceros	8.1	0.0	1.1	0.3	—	6.1	0.3
Spotted dolphin	31.0	18.0	—	—	9.4	0.6	—
Domestic dog	23.5	12.9	5.8	2.1	—	3.1	1.2
Norway rat	21.0	10.3	6.4	2.0	—	2.6	1.3
Whitetail jackrabbit	40.8	13.9	19.7	4.0	—	1.7	1.5

Modified from Jenness R, Sloan RE: Composition of milk. In Larson BL, Smith VR, editors: *Lactation, vol. 3, Nutrition and biochemistry of milk/maintenance*, New York, 1974, Academic Press.

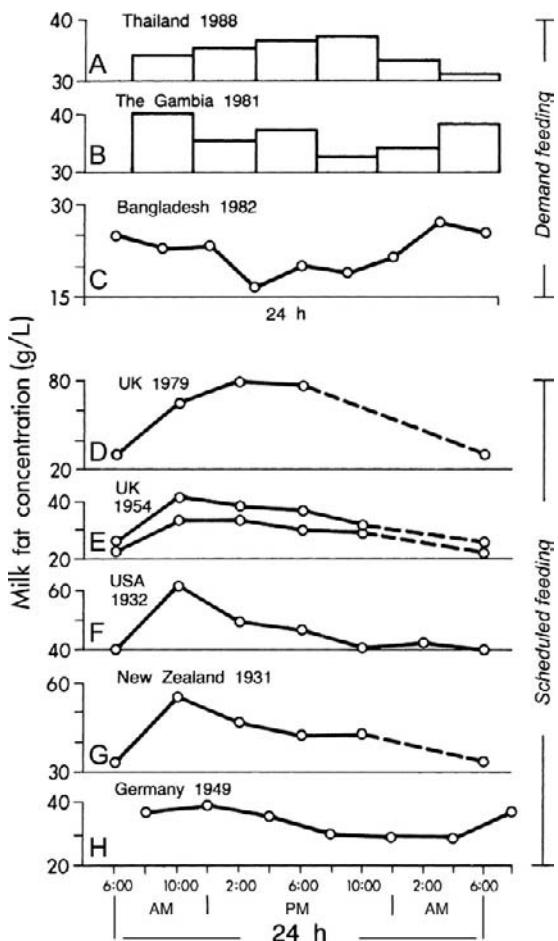

**Figure 4-2.** Mean concentrations of nitrogen, lactose, and fat in human milk by time of day. (Modified from Brown KH, Black RE, Robertson AD, et al: Clinical and field studies of human lactation: methodological considerations, *Am J Clin Nutr* 35:745, 1982.)

expressed, mature milk in nutrient content and energy value.<sup>151</sup>

Daytime consumption of milk in a given infant varies between 46% and 58% of the total 24-hour consumption, so that reliance on less than a 24-hour sampling may be misleading. Data from samples taken every 3 hours showed a variation in milk concentration of nitrogen, lactose, and fat, and in the volume of milk, by time of day (Figure 4-2). Furthermore, statistically significant diurnal changes occurred in the concentration of lactose and in the volume within individual subjects, but the times of those changes were not consistent for each individual. Some individuals varied as much as two-fold in volume production from day to day. A significant difference in the concentrations of both fat and lactose and the volume of milk produced by each breast was also found. At the extreme, the less productive breast yielded only 65% of the volume of the other breast.

The variation in the fat content has received some attention. Fat content changes during a given feeding, increasing as the feeding progresses. Fat

content rises from early morning to midday; as reported in early studies, when feedings were controlled the volume increased from two to five times. Multiple studies in different countries and different decades, summarized by Jackson et al., reveal that some of the variation is related to other factors. Demand feeding (mothers in 1988 in Thailand) has a different circadian variation than scheduled feeding (mothers in 1932 in the United States) (Figure 4-3). In the later part of the first year of lactation, fat content diminishes. Work done by Atkinson et al.<sup>11</sup> that was confirmed by other investigators showed that the nitrogen content of the milk of mothers who deliver prematurely is higher than that of those whose pregnancies reach full term. For a given volume of milk, the premature infant would receive 20% more nitrogen than the full-term infant if each were fed his or her own mother's milk. Other constituents of milk produced by mothers who deliver prematurely have also been studied. Some milk banks now provide donor milk from mothers who have delivered prematurely.

**Figure 4-3.** Circadian variation in fat concentration of breast milk from published studies. **A**, Thailand: Prefeed/postfeed expressed samples, 19 mothers studied for 24 hours each, infants aged 1 to 9 months. **B**, The Gambia: Demand feeding, pre/post expressed samples, 16 mothers studied for 24 hours each, infants aged 1 to 18 months. **C**, Bangladesh (Brown et al.): Samples collected at scheduled intervals by total breast extraction (breast pump), seven mothers studied for 24 hours each, infants aged 1 to 9 months. **D**, United Kingdom<sup>79</sup>: Prefeed/postfeed expressed samples, one mother studied for 72 hours. **E**, United Kingdom (Hytten): Samples collected by total breast extraction (breast pump). Lower curve, 29 mothers studied for 24 hours each, infants aged 3 to 8 days. Upper curve, 20 mothers studied for 24 hours each, infants aged 21 days to 4 months. **F**, United States (Nims et al.): Samples collected by total breast extraction (manual), three mothers studied, but values given only for one mother, for 24 hours on six occasions and 72 hours on one occasion, infant aged 6 to 60 weeks. **G**, New Zealand (Deem): Samples collected by total breast extraction (manual), 28 mothers studied for 24 hours each, infants aged 1 to 8 months. **H**, Germany (Gunther and Stainier): Collection of samples by total breast extraction (manual), two mothers studied for 24 hours each, six mothers studied for 52 hours each, infants aged 8 to 11 days. (Modified from Jackson DA, Imong SM, Silprasert A, et al: Circadian variation in fat concentration of breast milk in a rural northern Thai population, *Br J Nutr* 59:349, 1988; see article for complete bibliography.)

An additional consideration in reviewing information available on the levels of various constituents of milk is the technique used to derive the data. In 1975, Hamraeus reported less protein in human milk than originally calculated (see Table 4-1). The present techniques of immunoassay measure the absolute amounts; earlier figures were derived from calculations based on measurements of the nitrogen content. Of the nitrogen in human milk, 25% is nonprotein nitrogen (NPN). Cow milk has only 5% NPN.

A major concern about variation in content of human milk is related to the mother's diet. Maternal diet is of particular concern when the mother is malnourished or eats an unusually restrictive diet. Malnourished mothers have approximately the same proportions of protein, fat, and carbohydrate as well-nourished mothers, but they produce less milk. Levels of water-soluble vitamins, such as ascorbic acid, thiamin, and vitamin B<sub>12</sub>, are quickly affected by deficient diets. "From a nutritional perspective, infancy is a critical and vulnerable period. At no other stage in life is a single food adequate as a sole source of nutrition," writes Picciano.<sup>127</sup> This results from the immaturity of the tissues and organs involved in the metabolism of nutrients, which limits the ability to respond to nutrition excesses and deficiencies. The system is species-specific and depends on the presence of the self-contained enzymes and ligands to facilitate digestion at the proper stage while preserving function (such as secretory immunoglobulin A [sIgA]). The system continues to facilitate absorption and utilization.

Mother's milk is recommended for all infants under ordinary circumstances, even if the mother's diet is not perfect, according to the Committee on Nutrition During Pregnancy and Lactation of the Institute of Medicine.<sup>109</sup>

## The Cycles of Lactation

Two distinct phases occur during pregnancy, which have been identified as mammogenesis and lactogenesis I. Mammogenesis is the developmental differentiation that begins in early pregnancy. It includes the proliferation of the ductal tree, which results in the sprouting of multiple alveoli.

Mammogenesis results in the enlargement of the breast during pregnancy due to the proliferation of the ductoalveolar structure. Careful study of this development has been documented utilizing computerized breast measurement, first reported by Cox et al.<sup>30</sup> in 1999. Computerized breast measurement is an accurate noninvasive technology that is being used to determine changes in the size of human breasts (see Chapter 8, p. 261).

A longitudinal study using computerized breast measurement from before conception through pregnancy and lactation showed that growth began at week 10 of pregnancy. It was found that seven of eight women studied had an increase in breast size of about 170 mL with considerable individual variation on rate of change. Most women continued this growth immediately postpartum; at 1 month postpartum they had an average 211 mL of growth. The authors correlated this growth through pregnancy with an increase in placental lactogen.<sup>30</sup>

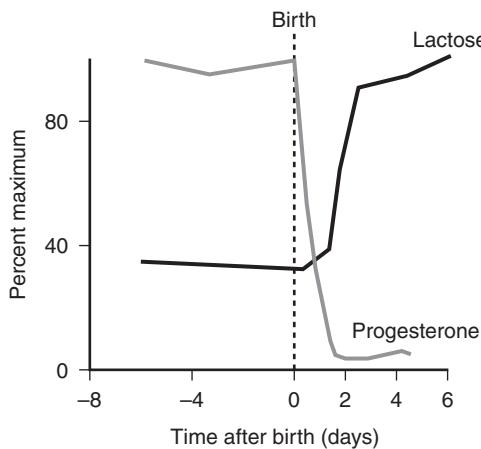

Stage I lactogenesis is the onset of milk secretion and begins with the early changes in the mammary gland during pregnancy and continues until full lactation has occurred after delivery. Stage I begins when small quantities of milk components such as casein and lactose are secreted. This amount is held in check by high levels of circulating progesterone. The first milk obtained by the newborn at birth is called colostrum, and the milk produced in the first 10 days is called transitional milk. Full volume is obtained in the next stage, lactogenesis II. The terms will be used in this text for clinical purposes (Figure 4-4). Neville et al.<sup>111</sup> state that the terms "colostrum" and "transitional milk" do not describe the mammary secretion product during the first 4 days or from days 4 to 10 postpartum. It has always been recognized that the content changes rapidly in the first 4 days and then more slowly in the next 6 days or so as a continuum. They suggest the abandonment of these terms. Colostrum and transitional milk are convenient clinical terms that are useful descriptive terms.

## Prepartum Milk

Prepartum milk is the first stage of lactogenesis and is especially conspicuous in other species, such as the goat.<sup>5</sup> It provides evidence that the junctions between alveolar cells are "leaky" during pregnancy, allowing fluid and solutes to flow between the milk space and the interstitial fluid of the mammary gland.<sup>112</sup> Figure 4-5 illustrates the composition of this milk in humans. The lactose concentration is directly correlated with that of potassium, but sodium and chloride are inversely related to lactose (Tables 4-3 through 4-7).

## Colostrum

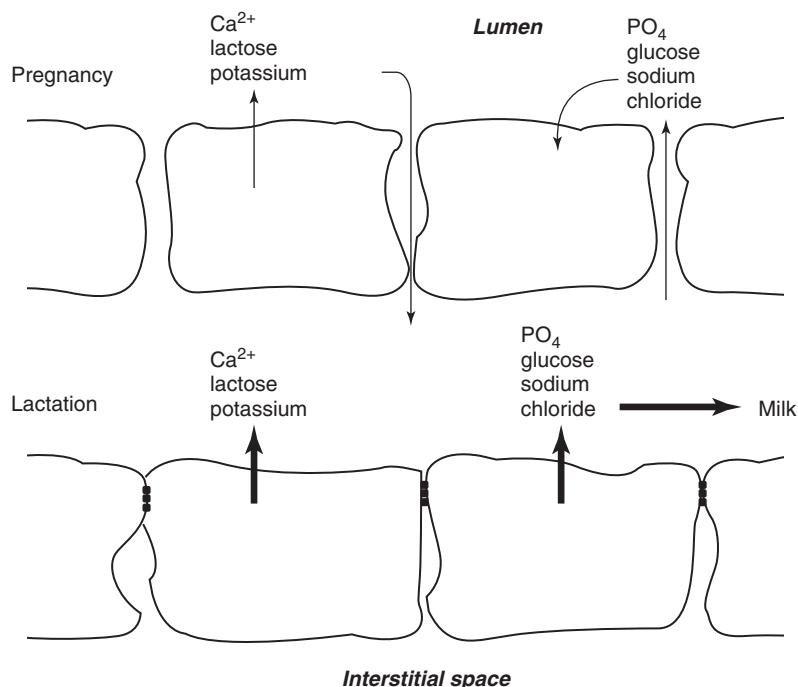

The stages in the continuum of human milk in traditional nomenclature are colostrum, transitional milk, and mature milk, and their relative contents are significant for newborns and their physiologic adaption to extrauterine life.

**Figure 4-4.** Progesterone withdrawal initiates lactogenesis II in women. The increase in lactose concentrations associated with increased synthesis of milk components coincides with a rapid decrease in progesterone concentration when the placenta is removed at parturition. (Modified from Kulski JK, Harman PE, Martin JD, et al: Effects of bromocriptine mesylate on the composition of the mammary secretion in non-breastfeeding women, *Obstet Gynecol* 52:38, 1978; Czank C, Henderson JJ, Kent JC, et al: Hormonal control of lactation cycle. In Hale TW, Hartmann PE, editors: *Textbook of lactation*, Amarillo, Texas, 2007, Hale Publishing.)

The mammary secretion during the first few days consists of a yellowish, thick fluid: colostrum. The residual mixture of materials present in the mammary glands and ducts at delivery and immediately after is progressively mixed with newly secreted milk, forming colostrum. Human colostrum is known to differ from mature milk in composition, both in the nature of its components and in the relative proportions of these components. The first changes are in sodium and chloride concentrations and an increase in lactose, probably as a result of the closure of the tight junctions. The specific gravity of colostrum is 1.040 to 1.060. The mean energy value is 67 kcal/dL compared with 75 kcal/dL of mature milk. The volume varies between 2 and 20 mL per feeding in the first 3 days. The total volume per day also depends on the number of feedings and is reported to average 100 mL in the first 24 hours (which is different from the first day, depending on the time of delivery) (see Table 4-4). Tables 4-5 and 4-6 list the yield and composition of colostrum (1 to 5 days) and mature milk (14 days and beyond). The increased production of citrate is paralleled by the increase in volume (Figures 4-6 and 4-7). The result is a decrease in sodium and chloride and an increase in lactose concentration due to water dilution.<sup>112,105</sup>

The antepartum milk glucose level is  $0.35 \pm 0.16$  mmol/L (see Table 4-3). Glucose levels vary among individuals. Glucose decreases during a feed as aqueous phase decreases and lipid increases.

**Figure 4-5.** Model for directions of major fluxes of several macronutrients during pregnancy and lactation in women. (From Neville MC: Determinants of milk volume and composition. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press.)

In early colostrum, glucose passes into the milk via the paracellular pathway and parallels lactose. When lactation is fully established, glucose levels are unrelated to lactose levels.<sup>108</sup> In mature milk, the level is  $1.5 \pm 0.4$  mmol/L.

Dewey et al.<sup>36</sup> clearly demonstrate that in a well-established milk supply, volume depends on infant demand, and the residual milk available at each feeding is comparable in both low-intake and average-intake dyads. Infant birth weight, weight at 3 months, and total time nursing were positively associated with intake. The volume also varies with

the mother's parity. Women who had other pregnancies, particularly those who previously nursed infants, have colostrum more readily available at delivery, and the volume increases more rapidly.

The yellow color of colostrum results from  $\beta$ -carotene. The ash content is high, and the concentrations of sodium, potassium, and chloride are greater than those of mature milk. Protein, fat-soluble vitamins, and minerals are present in greater percentages than in transitional or mature milk. IgA and lactoferrin increase in concentration. The complex sugars, oligosaccharides, also

increase, adding to the infection protection properties at this stage. It has been suggested that the mammary gland is actually evolved in part as an inflammatory response to tissue damage and infection and that the nutritional function then followed the protective function.

The higher protein, lower fat, and lactose solution is rich in immunoglobulins, especially IgA. The number of immunologically competent mononuclear cells is at its highest level. Fat, contained mainly in the core of the fat globules, increases from 2% in colostrum to 2.9% in transitional milk

and to 3.6% in mature milk. The concentration of fat in the prepartum secretion is only 1 g/dL, and the distribution among classes of lipids differs. Prepartum milk is 93% triglycerides, increasing to 97% in colostrum, with diglycerides, monoglycerides, and free fatty acids all increasing from prepartum to postpartum secretions. Phospholipid levels decline during the same period. Prepartum secretions contain higher amounts of membrane components such as phospholipids, cholesterol, and cholesterol esters, which decline from colostrum to mature milk.

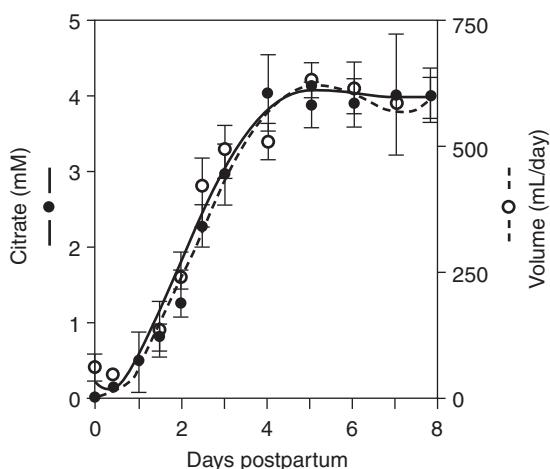

Cholesterol appears to be synthesized in the mammary gland. Beyond its use in brain tissue development, the myelinization of nerves, and as the base of many enzymes, the role of cholesterol in colostrum remains elusive. Little research has been done on cholesterol in colostrum.

Colostrum facilitates the establishment of *Lactobacillus bifidus* flora in the digestive tract. Colostrum also facilitates the passage of meconium. Meconium contains an essential growth factor for *L. bifidus* and is the first culture medium in the sterile intestinal lumen of the newborn infant. Human colostrum is rich in antibodies, which may provide protection against the bacteria and viruses that are present in the birth canal and associated with other human contact. Colostrum also contains antioxidants, which may function as traps for neutrophil-generated reactive oxygen metabolites.<sup>18</sup>

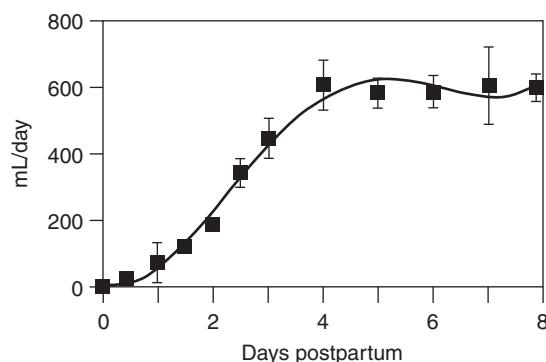

The progressive changes in mammary secretion in both breastfeeding and nonbreastfeeding women between 28 and 110 days before delivery and up to

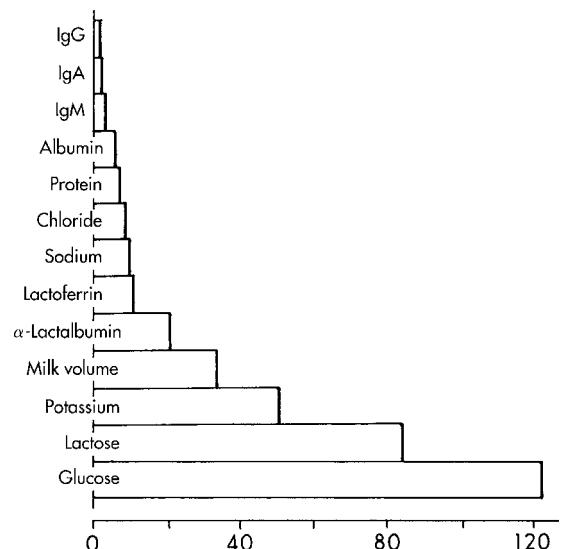

**Figure 4-6.** Changes in concentration of citrate in human milk in early postpartum period compared with increase in milk volume. (Data replotted from Neville et al., 1991.<sup>116</sup> Neville MC: Determinants of milk volume and composition. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press.)

**Figure 4-7.** Milk volumes during first week postpartum. Mean values from 12 multiparous white women who test-weighed their infants before and after every feeding for first 7 days postpartum. From Neville MC, Keller R, Seacat J, et al: Studies in human lactation: Milk volumes in lactating women during the onset of lactation and full lactation, *Am J Clin Nutr* 48:1375, 1988.

5 months after delivery were followed by Kulski and Hartmann to study the initiation of lactation. During late pregnancy the secretion contained higher concentrations of proteins and lower concentrations of lactose, glucose, and urea than those contained in milk secreted when lactation was well established. The concentrations of sodium, chloride, and magnesium were higher and those of potassium and calcium lower in colostrum than in milk. The osmolarity was relatively constant throughout the study. The authors described a two-phase development of lactation, with an initial phase of limited secretion in late pregnancy and a true induction of lactation in the second phase, 32 to 40 hours postpartum. Comparison with the

**Figure 4-8.** Relative increase in yield of milk components from day 1 to day 7 postpartum. Values presented are for day 7 expressed as percentage increase over day 1. (Modified from Kulski JK, Hartmann PE: Changes in human milk composition during the initiation of lactation, *Aust J Exp Biol Med Sci* 59:101, 1981.)

nonlactating women revealed similar secretion during the first 3 days postpartum. This, however, was abruptly reversed during the next 6 days as mammary involution progressed. Obtaining samples in these women, however, may have served to prolong the period of production. The authors point out that although breastfeeding was not necessary for the initiation of lactation in this study, it was essential for the continuation of lactation.

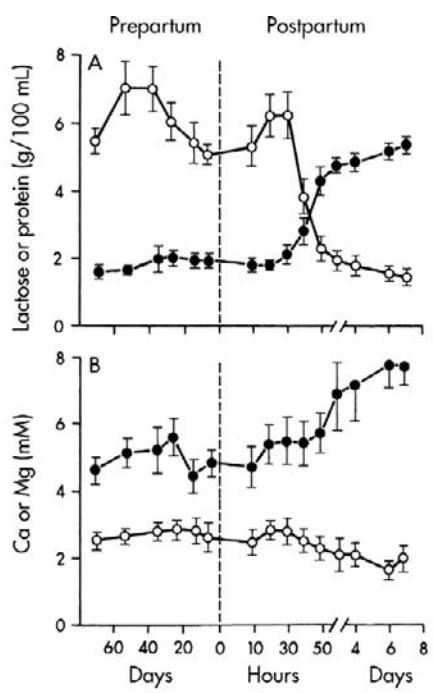

The yield of milk has been calculated from absolute values to demonstrate the increase in output of milk constituents during lactogenesis (Figure 4-8). Dramatic increases occurred in the production of all the milk constituents. The components synthesized by the mammary epithelium (lactose, lactalbumin, and lactoferrin) increased at a rate greater than those for IgA or proteins derived from the serum IgG and IgM. The greatest difference in yield between day 1 and day 7 postpartum was for glucose.<sup>115</sup>

A survey of the fatty acid components shows the lauric acid and myristic acid contents to be low in concentration the first few days. When the lauric and myristic acids increased, C<sub>18</sub> acids decreased. Palmitoleic acid increased at the same rate as the myristic acid. From this, it was concluded that the early fatty acids are derived from extramammary sources, but the breast quickly begins to synthesize fatty acids for the production of transitional and mature milk (see Table 4-7). The total fat content may have a predictive value. It was shown that 90% of the women whose milk contained 20 g or more of fat per feeding on the seventh day were successfully breastfeeding 3 months later. Women

who had only 5 to 10 g of fat on the seventh day had an 80% dropout rate by 3 months.

Colostrum's high protein and low fat are in keeping with the needs and reserves of the newborn at birth. Although the content of total nitrogen or any amino acid in breast milk in 24 hours is grossly related to the volume produced, the concentration in milligrams per deciliter (mg/dL) is not so related.<sup>77</sup> The relative distribution of the individual amino acids in each deciliter (100 mL) of milk differs in each mother. The colostrum may actually reflect a transitional maternal blood picture, which is associated with nitrogen metabolism of the postpartum period. The postpartum period is one of involution of body tissue and catabolism of protein in the mother (Figure 4-9).

Colostrum contains at least two separate antioxidants, an ascorbate-like substance and uric acid.<sup>18</sup> These antioxidants may function in the colostrum as traps for neutrophil-generated, reactive oxygen metabolites. The aqueous human colostrum interferes with the oxygen metabolic and enzymatic activities of the polymorphonuclear leukocytes that are important in the reaction

Key: calcium ○ magnesium ● lactose ● protein □

**Figure 4-9.** The levels of milk constituents prepartum and postpartum change to reflect the maturation from colostrum to fully mature milk. Volume is driven by lactose production. (Modified from Dumas BR: Modifications of early milk composition during early states of lactation in nutritional adaptations of the gastrointestinal tract of the newborn. In Kretchmer N, Minkowski A, editors: *Nutritional adaptation of gastrointestinal tract of the newborn*, vol. 3, New York, 1983, Nestlé Vevey/Raven.)

to acute inflammation.<sup>18</sup> This supports the belief that human milk is antiinflammatory.

The mineral and vitamin reserves of the newborn infant are related to the maternal diet. A fetal supply of vitamin C, iron, and amino acids is adequate because infant blood levels exceed those of the mother. Colostrum is rich in fat-soluble vitamin A, carotenoids, and vitamin E. The average vitamin A level on the third day can be three times that of mature milk. Similarly, carotenoids in colostrum may be 10 times the level in mature milk, and vitamin E may be two to three times greater than in mature milk.

Studies that looked at multiparas versus primiparas showed that the volume of milk was significantly greater on day 5 with earlier appearance of the casein band in multiparas (Figure 4-10).<sup>24</sup>

## SODIUM AS A PREDICTOR OF SUCCESSFUL LACTOGENESIS

Early in lactogenesis, the sodium levels are high but quickly drop from 60 to 20 mmol by day 3 in women who have been fully feeding their infant. Observations by Morton<sup>104</sup> have shown that high breast milk sodium concentrations on day 3 are suggestive of impending lactation failure. Even women who remove only a small amount of milk daily for research purposes have the physiologic drop in sodium.

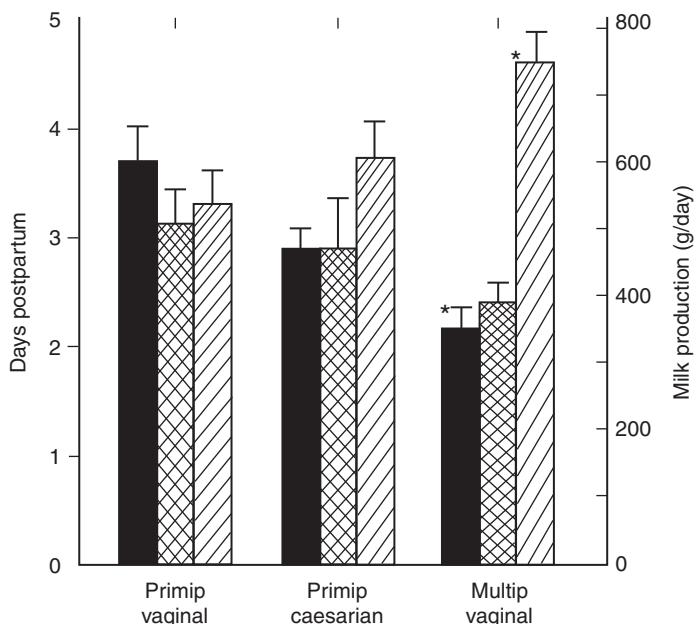

## Lactogenesis Stage II

Even though best practices recommend breastfeeding shortly after birth and frequently thereafter, Kulski et al. showed that milk removal is not needed for the programmed physiologic changes in mammary epithelium to trigger lactogenesis II. Studies by Woolridge confirmed this when no effect of breastfeeding in the first 24 hours was observed on later milk transfer to the infants. However, time of first breastfeeding and frequency of breastfeeding on day 2 are correlated with milk volume by day 5.<sup>24</sup> No relationship between concentration of prolactin in the plasma and the rate of milk synthesis in either the short or long term was found by Cox et al.<sup>31</sup>

## TRANSITIONAL MILK

The milk produced between the colostrum and mature milk stages is transitional milk; its content gradually changes. The transitional phase is approximately from 7 to 10 days postpartum to 2 weeks postpartum. The concentration of immunoglobulins and total protein decreases, whereas the lactose, fat, and total caloric content increases. The water-soluble vitamins increase, and the fat-soluble vitamins decrease to the levels of mature milk.

In a study of transitional milks, breast milk samples were obtained from healthy mothers of term

**Figure 4-10.** Effect of parity on measures of lactogenesis. Data show the mean time at which fullness of the breast was observed (solid bar), the day on which the casein band first appeared (crosshatched bar) in an electrophoretic analysis of daily milk samples, and the volume of milk produced on day 5 (hatched bar) by primiparous (primip) women delivered vaginally ( $n=19$ ), primiparous women delivered by cesarean section ( $n=5$ ), and multiparous (multip) women delivered vaginally ( $n=16$ ). \* Significant difference ( $p<0.05$ ) between multiparous and primiparous women delivered vaginally. The distance between the error bars represents two standard error of the mean (SEM). (Data from Chen DC, Nommsen-Rivers L, Dewey KG, et al: Stress during labor and delivery and early lactation performance, *Am J Clin Nutr* 68:335, 1998; Neville MC, Morton J, Umemura S: Breastfeeding 2001: the evidence for breastfeeding, *Pediatr Clin North Am* 48:35, 2001.)

infants on the 1st, 3rd, 5th, 8th, 15th, 22nd, 29th, and 36th days of lactation by Hibberd et al., who defined the first day of lactation to be the 3rd day postpartum. The researchers pooled 24-hour samples for analysis, and the remainder was fed to the baby. The authors found a high degree of variability, not only among mothers but also within samples from the same mother. The maximum value in almost every case was more than twice the minimum. They were able to show, however, that the changes in composition were rapid before day 8, and then progressively less change took place until the composition was relatively stable before day 36 (see Tables 4-5 and 4-6).

## MATURE MILK

### Water

In almost all mammalian milks, water is the constituent in the largest quantity, with the exception of the milk of some arctic and aquatic species, who produce milks with high-fat content (e.g., the northern fur seal produces milk with 54% fat and 65% total solids) (see Table 4-2). All other constituents are dissolved, dispersed, or suspended in water. Water contributes to the temperature-regulating mechanism of the newborn because 25% of heat loss is from evaporation of water from the lungs and skin. The lactating woman has a greatly increased

obligatory water intake. If water intake is restricted during lactation, other water losses through urine and insensible loss are decreased before water for lactation is diminished. Because lactose is the regulating factor in the amount of milk produced, the secretion of water into milk is partially regulated by lactose synthesis. Investigations by Almroth show that the water requirement of infants in a hot, humid climate can be provided entirely by the water in human milk.

Human milk is a complex fluid that scientists have studied by separating the several phases by physical forces.<sup>76</sup> These forces include settling, short-term, low-speed centrifugation, high-speed centrifugation, and precipitation by micelle-destroying treatments, such as using the enzyme rennin (chymosin) or reducing the pH. On settling, the cream floats to the top, forming a layer of fat (about 4% by volume in human milk) (Table 4-8).<sup>71</sup> Lipid-soluble components such as cholesterol and phospholipid remain with the fat. With a slow-speed spin, cellular components form a pellet. The high-speed spin brings the casein micelles into a separate phase or forms a pellet. On top of the protein pellet is a loose pellet referred to as the "fluff," composed of membranes.<sup>112,114</sup> Casein precipitation (0.2% by weight) is caused by acid destruction of the micelles. The aqueous phase is whey, which also contains milk sugar, milk proteins, IgA, and the monovalent ions.

Estimates of the Concentrations of Nutrients in Mature Human Milk

## Lipids

Intense interest in the lipids in human milk has been sparked by the reports from long-range studies of breastfed infants that show more advanced development at 1 year<sup>100</sup> 8 to 10 years,<sup>99</sup> and now 18 years of age<sup>70</sup> compared with formula-fed infants. This attention has resulted from the interest in supplementing formula with various missing factors, such as cholesterol and docosahexaenoic acid (DHA).<sup>125</sup> These compounds function in a milieu of arachidonic acid, lipases, and other enzymes, and no evidence indicates that they are effective in isolation or that more is better. The value of

supplementing the mother's diet in pregnancy and lactation is an equally important question, because dietary DHA levels have declined in the last half century as women have reduced eggs and animal organs in their diet (see Chapter 9).

Lipids are a chemically heterogeneous group of substances that are insoluble in water and soluble in nonpolar solvents. Lipids are separated into many classes and thousands of subclasses. The main constituents of human milk are triacylglycerols, phospholipids, and their component fatty acids, the sterols. Jensen, a renowned milk lipidologist, and

From Jensen RG: *The lipids of human milk*, Boca Raton, Fla., 1989, CRC.

his coauthors<sup>77</sup> remind readers, in a comprehensive review of the lipids in human milk, of the nomenclature, such as palmitic acid (16:0), oleic acid (18:1), and linoleic acid (18:2). The figure to the left of the colon is the number of carbons and to the right is the number of double bonds. Polyunsaturated fatty acids (PUFAs) have a designation for the location of the double bond; in human milk, the designation is *cis* (c), which identifies the geometric isomer. Because milk is an exceptionally complex fluid, Jensen<sup>79,80</sup> and other scientists have found it helpful to classify components according to their size and concentration, with solubility in milk, or lack thereof, as additional categories (Table 4-9). The lipids fulfill a host of essential functions in growth and development,<sup>15</sup> provide a well-tolerated energy source, serve as carriers of messages to the infant, and provide physiologic interactions, including the following:

1. Allow maximum intestinal absorption of fatty acids
2. Contribute about 50% of calories
3. Provide essential fatty acids (EFAs) and PUFAs
4. Provide cholesterol

By percentage of concentration, the second greatest constituent in milk is the lipid fraction. Milk lipids provide the major fraction of kilocalories in human milk.<sup>77</sup> Lipids average 3% to 5% of human milk and occur as globules emulsified in the aqueous phase. The core or nonpolar lipids, such as triacylglycerols and cholesterol esters, are

coated with bipolar materials, phospholipids, proteins, cholesterol, and enzymes. This loose layer is called the milk-lipid-globule membrane, which keeps the globules from coalescing and thus acts as an emulsion stabilizer.<sup>77</sup> Globules are 1 to 10 mm in diameter, with 1-mm globules predominating.<sup>78</sup>

Fats are also the most variable constituents in human milk, varying in concentration over a feeding, from breast to breast, over a day's time, overtime itself, and among individuals (Table 4-10). This information is significant when testing milk samples for energy intake, fat-soluble constituents, and physiologic variation and when clinically managing lactation problems.<sup>63</sup> Much of the early work was based on lactation in women who "nursed by the clock" rather than tuned into infant needs. When circadian variation in fat content was studied in a rural Thai population who had practiced demand feeding for centuries, Jackson et al. found fat concentrations in feeds in the afternoon and evening (1600 to 2000 hours) were higher than those during the night (400 to 800 hours). When Kent et al.<sup>84</sup> reexamined volume, frequency of breastfeedings, and the fat content of the milk throughout the day in 71 mother-infant dyads, they found similar trends. They found, however, that fat content was  $41.1 \pm 7.8$  g/L and ranged from 22.3 to 61.6 g/L. It was not related to time after birth or number of breastfeedings during the day. No effect on the average milk fat content was related to the sex of the infant, clustered breastfeedings, or whether the infant fed at night. Fat content was

**TABLE 4-10** Factors That Influence Human Milk Fat Content and Composition

Factor	Influence
Duration of gestation	Shortened gestation increases the long-chain polyunsaturated fatty acids secreted
Stage of lactation ( $\uparrow$ )	Phospholipid and cholesterol contents are highest in early lactation
Parity ( $\downarrow$ )	High parity is associated with reduced endogenous fatty acid synthesis
Volume ( $\downarrow$ )	High volume is associated with low milk fat content
Feeding ( $\uparrow$ )	Human milk fat content progressively increases during a single nursing
Maternal diet	A diet low in fat increases endogenous synthesis of medium-chain fatty acids (C6 to C10)
Maternal energy status ( $\uparrow$ )	A high weight gain in pregnancy is associated with increased milk fat

( $\uparrow$ ) Increase; ( $\downarrow$ ) decrease.

Modified from Picciano MF: Nutrient composition of human milk. Breastfeeding 2001, Part I: the evidence for breastfeeding, *Pediatr Clin North Am* 48:53, 2001.

higher during the day and evening compared with night and early morning. They recommended that infants be fed on demand day and night and not by schedule.

When milk of the mothers of preterm infants was measured ( $6.6\% \pm 2.8\%$ ), the fat content was significantly higher in the evening ( $7.9\% \pm 2.9\%$ ) than in the morning ( $D < 0.001$ ).<sup>97</sup>

It is speculated that the altered posture at night, horizontal and relatively inactive, may redistribute fat. The larger the milk consumption at a feed, the greater is the increase in fat from beginning to end of the feed. Less fat change occurs during "sleep" feeds than in the daytime. Unless 24-hour samples are collected by standardized sampling techniques, results will vary. During the course of a feeding, the fluid phase within the gland is mixed with fat droplets in increasing concentration. The fat droplets are released when the smooth muscle contracts in response to the let-down reflex.

The lipid fraction of the milk is extractable by suitable solvents and may require more than one technique to extract all the lipids.<sup>79,80</sup> Complete extraction in human milk is difficult because the lipids are bound to protein. From 30% to 55% of the kilocalories are derived from fats; this represents a concentration of 3.5 to 4.5 g/dL. Milk fat is dispersed in the form of droplets or globules maintained in solution by an absorbed layer or membrane. The protective membrane of the fat globules is made up of phospholipid complexes.<sup>71</sup> The rest of the phospholipids found in human milk are dispersed in the skim milk fraction. Vitamin A esters, vitamin D, vitamin K, alkyl glyceryl ethers, and glyceryl ether diesters are also in the lipid fraction but do not fall into the classes listed.

Renewed interest in defining the constituents of human milk lipid has developed as investigators look for the causes of obesity, atherosclerosis, and other degenerative diseases and their relationship to infant nutrition. A number of reports of historic value have technical problems of sampling. Because the fat content of a feeding varies with time, spot samples give spurious results. Ferris and

Jensen have reviewed the literature exhaustively and describe the fractionated lipid constituents in detail.

Most studies on fat content of milk have been based on a geographically limited population. Milk fat changes with diet and maternal adipose stores; Yuhas et al.<sup>153</sup> studied milk samples from nine countries (Australia, Canada, Chile, China, Japan, Mexico, Philippines, the United Kingdom, and the United States). Saturated fatty acids were constant across countries, and monounsaturated fatty acids varied minimally. Arachidonic acid (C20: 4n-6) was also similar. DHA (22: 6n-3), however, was variable everywhere, but was dramatically different with milk from Japan having the highest values and the United States and Canada having the lowest values. Of note is the fact that the timing of collections was comparable in all countries. All samples were collected by electric pump, except in Japan where they were hand expressed.<sup>153</sup>

The average fat content of pooled 24-hour samples has been reported from multiple sources to vary in mature milk from 2.10% to 5.0% (Table 4-11). Maternal diet affects the constituents of the lipids but not the total amount of fat. A minimal increase in total lipid content was observed when an extra 1000 kcal of corn oil was fed to lactating mothers. A diet rich in polyunsaturated fats will cause an increased percentage of polyunsaturated fats in the milk without altering the total fat content. When the mother is calorie deficient, depot fats are mobilized, and milk resembles depot fat. When excessive nonfat kilocalories are fed, levels of saturated fatty acids increase as lipids are synthesized from tissue stores.

When fish oil supplementation is given during pregnancy it significantly alters the early postpartum breast milk fatty acid composition (omega-3 PUFA). Levels of omega-3 fatty acids are increased as are IgA and many other immunomodulatory factors (CD14).<sup>40</sup>

A 2-week crossover study of three nursing women was done by Harzer et al., alternating high fat/low carbohydrate and the reverse. The first diet

was 50% fat, 15% protein, and 35% carbohydrate for a total of 2500 calories, which resulted in a reduction of triglycerides (4.1% to 2.6%) and an increase in lactose (5.2% to 6.4%) (Table 4-12).

The U.S. Department of Agriculture (USDA) has reported that the average American diet now includes 156 g of fat per day, up from 141 g in 1947. The significant change is from animal to vegetable fat, which is now 39% of total dietary fats, especially resulting from the switch from butter and lard. A change in fatty acid content to more long-chain fatty acids and a two-fold to three-fold increase in linoleic acid have occurred. Except for 18:2 content in mature milk, the fatty acid composition is remarkably uniform unless the maternal diet is unusually bizarre.

Polyunsaturated fats include C18:2 and C18:3, or linoleic and linolenic acid. The bovine ratio of polyunsaturated to saturated fats (P/S ratio) is 4. The P/S

ratio has shifted as a result of recent dietary changes to 1.3 from 1.35 in human milk. The P/S ratio is significant in facilitating calcium and fat absorption. Calcium absorption is depressed by a 4:5 P/S ratio. The breast can dehydrogenate saturated and monounsaturated fatty acids in milk synthesis.

At least 167 fatty acids have been identified in human milk; possibly others are present in trace amounts. Bovine milk has 437 identified fatty acids. Major dietary changes would greatly change fatty acid composition.

Milk from vegetarians (lacto-ovo) contained a lower proportion of fatty acids derived from animal fat and a higher proportion of PUFAs derived from dietary vegetable fat. Women who consumed 35 g or more of animal fat per day had higher C10:0, C12:0, and C18:3 but lower levels of C16:0 and C18:0. Finley et al.<sup>49</sup> suggest that a maximum amount of C16:0 and C18:0 can be taken up from

the blood and subsequently secreted into milk ([Table 4-13](#)).

The milk of strict vegetarians has extremely high levels of linoleic acid, four times that of cow milk (see [Table 4-13](#)). Some researchers include other long-chain fatty acids (e.g., C20:2, C20:3, C24:4, C22:3) as essential nutrients because they are structural lipids in the brain and nervous tissue. The effects of diet are also discussed in [Chapter 9](#).

One important outcome of linoleic and linolenic acids is the conversion of these compounds into longer-chain polyunsaturates. These metabolites have been shown to be important for fluidity of membrane lipids and prostaglandin synthesis. They are present in the brain and retinal cells. Long-chain polyunsaturates are needed for development of the infant brain and nervous system.<sup>49</sup> When Gibson and Kneebone studied fatty acid composition of colostrum and mature milk at 3 to 5 days

and later at 6 weeks postpartum, they reported that mature milk had a higher percentage of saturated fatty acids, including medium-chain acids, lower monounsaturated fatty acids, and higher linoleic and linolenic acids and their long-chain polyunsaturated derivatives.

Infant intake of fatty acids from human milk over the first year of lactation (solids were started at 4 to 6 months) was studied by Mitoulas et al.<sup>103</sup> among mothers and infants in Australia. They determined the volume, fat content, and fatty acid composition of milk from each breast at each feed over 24 hours at 1, 2, 4, 6, 9, and 12 months. Volume of production was greater in the right breast (414 to 449 versus 336 to 360). Fat content also varied between breasts. Amounts of fat per 24 hours did not differ in the first year and only arachidonic acid and DHA differed between mothers. Changes in proportions of individual fatty acids may not result in commensurate changes in 24-hour infant intakes. The authors<sup>84,103</sup> note their findings were similar to Jensen's work in 1995 in the United States.

When this same group of investigators in Australia (Kent et al.<sup>84</sup> and Mitoulas et al.<sup>103</sup>) measured volume of milk, frequency of feedings, and fat content at 1 to 6 months of age in a normal group of mothers using demand feeding, they concluded infants should be fed on demand, day and night. They observed no relationship between total number of feeds and total volume. Furthermore fat content was  $41.1 \pm 7.8$  g/L (range 22.3 to 61.6 g/L). Total fat was independent of frequency of feeding.

Prolonged lactation has long been suspected of providing reduced nutrition. It has been established that infection protection continues, but now there is evidence that high nutrition persists as well; 34 mother-baby dyads and 27 control dyads were studied by Mandel et al.<sup>102</sup> The mothers who were breastfeeding beyond 1 year (12 to 39 months) were older ( $34.4 \pm 5.1$  years), lighter ( $59.8 \div 8.7$  kg), and with lower BMI ( $22.1 \pm 3.0$ ) than controls (breastfeeding 2 to 6 months; age  $30.7 \pm 2.9$  years, weight  $66.3 \pm 11.8$  kg, and BMI  $24.5 \pm 3.9$ ). Feeding frequency per day was  $5.9 \pm 3.3$  versus  $7.36 \pm 2.65$  (controls). The milk of mothers who were breastfeeding beyond a year had significantly increased fat and increased energy content compared with controls.<sup>102</sup>

Factors affecting fatty acid composition include the stage of lactation, especially in specific fatty acids probably due to the recruiting of body fat stores. Milk from mothers of premature infants differs from that of mothers of full-term infants in fat content with higher levels of medium-chain fatty acids in premature milk. The significance of circadian rhythm on fatty acid composition is contradictory in the literature; therefore, studies of fat content should consider this in sample collection.<sup>33</sup>

Diet, on the other hand, has an extensive impact on fat content of milk with up to 85% derived from diet in the form of chylomicrons. This has led to dietary supplementation, especially utilizing the omega-3 fatty acids.<sup>139</sup>

**Brain Development.** To address the issue of nutrition during brain development, it is important to consider the different periods of brain development that have been described biochemically. First, cell division occurs, with the formation of neurons and glial cells, and second, myelination. In the rat brain, 50% of polyenoic acids of the gray matter lipids were laid down by the fifteenth day of life. The fatty acids characteristic of myelin lipids appeared later. Gray matter is largely composed of unmyelinated neurons, whereas white matter contains a very high proportion of myelinated conducting nerve fibers. Normal brain function depends on both. The synthesis and composition of myelin can be influenced by diet in the developing rat brain.

Myelin-specific messenger ribonucleic acid (mRNA) levels are developmentally regulated and influenced by dietary fat. The neonatal response to dietary fat is tissue specific at the mRNA level.<sup>37</sup>

The fatty acids characteristic of gray matter (C20:4 and C22:6) accumulate before the appearance of fatty acids characteristic of myelin (C20:1 and C24:1) in the developing brain. Arachidonic acid (C20:4) and DHA (C22:6) are synthesized from linoleic and linolenic acids, respectively, but the latter two must be obtained in the diet.

During the first year of life, the human brain more than doubles in size, increasing from 350 to 1100 g in weight. Of this growth, 85% is cerebrum; 50% to 60% of this solid matter is lipid. Cortical total phospholipid fatty acid composition in both term and preterm infants is greatly influenced by dietary fat intake. Phospholipids make up about one quarter of the solid matter and are integral to the vascular system on which the brain depends.<sup>47</sup> Brain growth is associated with an increase in the incorporation of long-chain PUFAs into the phospholipid in the cerebral cortex.<sup>76</sup> The transition from colostrum to mature milk leads to an increase in sphingomyelin and a decrease in phosphatidylcholine in the milk of mothers who deliver prematurely, along with a decrease in phospholipid content. Phospholipids are essential to brain growth, especially in a premature infant. Sphingomyelin and phosphatidylcholine are a source of choline, a major constituent of membranes in the brain and nervous tissue. Extreme dietary alterations in animal experiments have demonstrated an altered PUFA composition of the developing brain.

Such studies cannot be done in humans. Farquharson et al.<sup>47</sup> therefore examined the necropsy

specimens of cerebrocortical gray matter obtained from 20 term and 2 premature infants, all of whom died within 43 weeks of birth. All were victims of sudden death and were genetically normal. The infants had either received exclusively breast milk or exclusively formula. The latter group was divided by formula type into three groups: mixture of formulas, SMA, or CGOST (cow milk or Osterfeed). (SMA and CGOST are formulas or mixtures of formulas sold in the United Kingdom.) Breastfed infants had greater concentrations of DHA in their cerebrocortical phospholipids than formula-fed infants in all groups. A compensatory increase in *n*-6 series fatty acids (arachidonic, docosatetraenoic, and docosapentaenoic) occurred in the SMA group. No significant differences were seen between saturated and monounsaturated fatty acids. The two premature infants had the lowest levels of DHA.

Cerebrocortical neuronal membrane glycerophospholipids are composed predominantly (95%) of phosphatidylcholine, phosphatidylethanolamine, and phosphatidylserine.<sup>76</sup> After birth, neuronal membranes and retinal photoreceptor cells derive most of their phospholipid DHA from diet and liver synthesis and not from fat reserves. Neither the liver nor the retinal and neuronal cells can synthesize DHA without reserves or a dietary supply.  $\alpha$ -Linolenic acid, an EFA, is the precursor. If the enzymes are not activated or are inactivated by an excess of *n*-6 fatty acids, synthesis does not take place. Human milk provides the DHA and arachidonic acid.<sup>61</sup>

Dietary supplementation with fish oil in the latter part of pregnancy resulted in increased DHA status at birth when measured in the umbilical blood.<sup>101</sup> When postpartum women were supplemented with DHA by capsule in a blind study, breast milk levels of DHA ranged from 0.2% to 1.7% of total fatty acids, increasing with dose. Arachidonic acid levels and antioxidant status of plasma arachidonic acid and levels were unaffected.

Although DHA is essential to retinal development, levels peak in the retina at 36 to 38 weeks' gestation, suggesting that the most rapid rate of retinal accumulation occurs before term.<sup>65</sup> This further suggests that the premature infant is especially vulnerable to dietary deficiencies of DHA.

Dietary omega-3 ( $\omega$ -3) fatty acids may not be essential to life, reproduction, or growth, but they are important for normal biochemical and functional development.<sup>132</sup> Long-chain  $\omega$ -3 fatty acids, DHA in particular, form a major structural component of biologic membranes. When the ratio of omega-6 ( $\omega$ -6) is high compared to  $\omega$ -3, fatty acids aggravate the deficiency. Studies in monkeys have shown that DHA deficiency affects water intake and urine excretion, as well as  $\omega$ -3 fatty acid levels in red blood cells.<sup>132</sup> Much remains to be learned

about the effects of  $\omega$ -3 fatty acids and DHA deficiency on developing human infants.

The EFAs, linoleic and linolenic acids, may have greater significance in the quality of the myelin laid down. Dick, observing the geographic distribution of multiple sclerosis worldwide, noted that the disease is rare in countries where breastfeeding is common. He postulated that the development of myelin in infancy is critical to preventing degradation later. Dick investigated the difference between human milk and cow milk in relation to myelin production in multiple sclerosis.

Experimental allergic encephalitis is a demyelinating condition and can be produced by shocking animals that have been sensitized to central nervous system (CNS) antigens. Newborn rats deficient in EFAs are more susceptible to this disease, which has been described as resembling multiple sclerosis pathologically.

**Other Influences on Fat Content.** Infections will alter milk composition. Mastitis does not alter fat content but does lower volume and lactose and increase sodium and chloride.

Parity has been cited as a major influence on fat content, with primiparous women having more fat than multiparous women. Prentice et al. found a significant relationship between fat content and triceps skinfold thickness. The authors found seasonal changes in The Gambia, where volume and fat were lowest following the rainy season, when nutrient resources are scarce.

## Hyperlipoproteinemia

Milk from women with type I hyperlipoproteinemia has been investigated.<sup>78</sup> Because the primary deficiency is serum-stimulated lipoprotein lipase in the plasma, resulting in reduced transfer of dietary long-chain fatty acids from blood to milk, levels of fat as fatty acids were abnormally low (1.5%) and the amounts of 10:0 and 14:0 higher than normal (see Chapter 16).

## Cholesterol

Cholesterol is an essential component of all membranes and is required for growth, replication, and maintenance. Infants fed human milk have higher plasma cholesterol levels than formula-fed infants. Animal studies suggest that early postnatal ingestion of a diet high in cholesterol protects against high-cholesterol challenges later.

The cholesterol content of milk is remarkably stable at 240 mg/100 g of fat when calculated by volume of fat. The range, depending on sampling techniques, is 9 to 41 mg/dL. The amount of cholesterol changed slightly over time, decreasing 1.7-fold over the first 36 days, as reported by Harzer et al.,

and stabilizing at approximately day 15 postpartum at 20 mg/dL. This resulted in a change in the cholesterol/triglyceride ratio. The authors found no uniform pattern of circadian variations between mothers.

Neonatal plasma cholesterol levels range between 50 and 100 mg/dL at birth, with equal distribution of low-density lipoprotein (LDL) and high-density lipoprotein (HDL). Plasma cholesterol increases rapidly over the first few days of life, with LDL predominating regardless of mode of feeding.<sup>75</sup> In breastfed infants, however, plasma cholesterol progressively increases compared with that in infants fed low to no cholesterol and high-PUFA formulas. This may have a lasting effect on the individual's ability to metabolize cholesterol, a point yet to be confirmed.<sup>74</sup> Low-birth-weight (LBW) premature infants are at risk for stimulation of endogenous cholesterol biosynthesis, resulting in marked elevations in plasma cholesterol as a result of intravenous nutrition.

The effect of breastfeeding on plasma cholesterol, body weight, and body length was studied longitudinally in 512 infants by Jooste et al.<sup>81</sup> Breastfed infants had higher plasma cholesterol than the formula-fed infants, created by a direct mechanism that persisted for as long as the infants were breastfed. Body length was similar in breastfed and formula-fed infants, but formula-fed infants weighed more.

Cholesterol has been a factor of great concern because of the apparent association with risk factors for atherosclerosis and coronary heart disease. At present, commercial formulas have high P/S ratios and little or no cholesterol compared with those of human milk. Dietary manipulation does not change the cholesterol level in the breast milk. When the dietary cholesterol level is controlled, however, a fall in the infant's plasma cholesterol level is associated with an increase in the amount of linoleic acid present in the milk.

Kallio et al.<sup>83</sup> followed 193 infants from birth, measuring concentrations of cholesterol, very-low-density lipoprotein (VLDL), LDL, HDL2, and, on a limited group of 36 infants, HDL3 and apoprotein B. The largest differences between exclusively breastfed and weaned infants were at 2 months (0.8 mmol/L), 4 months (0.6 mmol/L), and 6 months (0.5 mmol/L). The LDL and apoprotein B concentrations were lower in weaned infants. VLDL and HDL3 were independent of diet. The authors concluded that the low intake of cholesterol and high intake of unsaturated fatty acids greatly modify the blood lipid pattern in the first year of life.<sup>83</sup>

In a retrospective epidemiologic study of 5718 men in England born in the 1920s, 474 died of ischemic heart disease.<sup>46</sup> The infant-feeding groups were divided into those breastfed but weaned before 1 year, breastfed more than a year, and

bottle fed. The first group had the lowest death rate from ischemic heart disease and had lower total cholesterol, LDL cholesterol, and apolipoprotein B than those who were weaned after a year and especially those who were bottle fed. In all feeding groups, serum apolipoprotein B concentrations were lower in men with higher birth weights and weights at 1 year.<sup>107</sup>

No long-range effect of serum cholesterol level has been identified, although Osborn described the pathologic changes in 1500 young people (newborns to age 20). He observed the spectrum of pathologic changes from mucopolysaccharide accumulations to fully developed atherosclerotic plaques. Lesions were more frequent and severe in children who had been bottle fed. Lesions were uncommon or mild in the breastfed children.

Animal investigations indicated that rats given high levels of cholesterol early in life were better able to cope with cholesterol in later life and maintained a lower cholesterol level.<sup>37</sup>

In a study of six breastfed and 12 formula-fed infants, ages 4 to 5 months, Wong et al. measured the fractional synthesis rate. The breastfed infants had higher cholesterol intakes ( $18.4 \pm 4.0$  mg/kg/day) than formula-fed infants (only  $3.4 \pm 1.8$  mg/kg/day). Plasma cholesterol levels were  $183 \pm 47$  versus  $112 \pm 22$  mg/dL; LDL cholesterol levels were  $83 \pm 26$  versus  $48 \pm 16$  mg/dL. An inverse relationship existed between the fractional synthesis rate of cholesterol and dietary intake of cholesterol. The authors concluded that the greater cholesterol intake of breastfed infants is associated with elevated plasma LDL cholesterol concentrations. In addition, cholesterol synthesis in human infants may be efficiently regulated by coenzyme A (CoA) reductase when infants are challenged with dietary cholesterol.

A carefully designed, well-controlled longitudinal study is needed to determine the long-range impact of cholesterol because it is a consistent constituent of human milk throughout lactation. The brain contains cholesterol especially in early development.

### *n*-3 Fatty Acids

The *n*-3 fatty acids are important components of animal and plant cell membranes and are selectively distributed among the lipid classes. The role of DHA (22: *n*-3) in infantile nerve and brain tissue and retinal development has been discussed. It is also found in high levels in testis and sperm. Human milk contains DHA, and studies to evaluate the effects of "fish oil" supplements to the diet suggest an elevation of the dose-dependent levels.

Eicosapentaenoic acid (20: 5*n*-3) is part of another group of *n*-3 fatty acids, the eicosanoids, which comprise two families: the prostanoids

(prostaglandins, prostacyclins, and thromboxanes) and the leukotrienes.<sup>78</sup> The prostanoids are mediators of inflammatory processes. Leukotrienes are key mediators of inflammation and delayed hypersensitivity. The eicosanoids are highly active lipid mediators in both physiologic and pathologic processes.<sup>136</sup> Eicosanoids provide cytoprotection and vasoactivity in the modulation of inflammatory and proliferative reactions. Their precursors, long-chain PUFAs, can affect the generation of eicosanoids. The role of eicosanoids in physiologic and pathophysiologic processes is beginning to be identified. It clearly goes beyond adding a little DHA to the brew. Sellmayer and Koletzko<sup>136</sup> reviewed this work.

In other species, restriction of *n*-3 fatty acids results in abnormal electroretinograms, impaired visual activity, and decreased learning ability. The influence of dietary *n*-3 fatty acids on visual activity development in very-low-birth-weight (VLBW) infants was evaluated by Birch et al.,<sup>14</sup> using visual-evoked response and forced-choice preferential-looking procedures at 36 and 57 weeks postconception. Feeding groups were randomized to one of three diets: corn oil (only linoleic), soy oil (linoleic and linolenic), and soy/marine oil (added *n*-3 fatty acids). The marine oil group matched the "gold standards" of VLBW infants fed human milk. Visual activity parameters in the other infants who did not receive *n*-3 oils were considerably lower.

The *n*-3 fatty acids appear to function in the membranes of photoreceptor cells and synapses. Jensen and Jensen<sup>80</sup> suggest a daily intake of 18:3*n*-3 (0.5% of calories) with the inclusion of *n*-3 long-chain PUFA, which is available in human milk. Many studies affirm the value of *n*-3 fatty acids in the diet and as protection against heart disease, chronic inflammatory disease, and possibly cancer.<sup>140</sup> When synthetic DHA and arachidonic acid are added to infant formula, the measurements of visual acuity do not match those of human milk. The tolerance for these formulas is still undocumented and long-range outcomes unreported.

## Carnitine

Carnitine is  $\gamma$ -trimethylamino- $\beta$ -hydroxybutyrate and is essential for the catabolism of long-chain fatty acids. Only two conditions in life have been described when carnitine is indispensable: total parenteral nutrition lasting more than 3 weeks and early postnatal life. In older individuals it is synthesized in the liver and kidney from the essential amino acids lysine and methionine. Carnitine serves as an essential carrier of acyl groups across the mitochondrial membrane to sites of oxidation and,

therefore, has a central role in the mitochondrial oxidation of fatty acids in humans.<sup>124</sup>

Newborns undergo major metabolic changes during transition from fetal to extrauterine life, including the rapid development of the capacity to oxidize fatty acids and ketone bodies as fuel alternatives to glucose. The fatty acids derived from high-fat milk and endogenous fat stores become the preferred fuel of the heart, brain, and tissues with high-energy demands. In addition, a dramatic increase occurs in serum fatty acids in the first hours of life. After the interruption of the fetoplacental circulation and in the absence of an exogenous supply of carnitine, neonatal plasma levels of free carnitines and acylcarnitines decrease very rapidly. Carnitine administration seems to act by increasing ketogenesis and lipolysis. When serum carnitine and ketone body concentrations were measured in breastfed and formula-fed newborn infants, lower carnitine levels were found in infants fed formulas than in those fed breast milk.

The levels of carnitine range from 70 to 95 nmol/mL in breast milk (up to 115 nmol/mL in colostrum) and from 40 to 80 nmol/mL in commercial formula (Enfamil). The bioavailability of carnitine in human milk may be a significant factor in the higher carnitine and ketone body concentrations in breastfed babies. In omnivorous mothers, carnitine levels do not vary considerably over time.<sup>15</sup> Levels in the milk of lacto-ovovegetarian mothers were always consistently lower than those of omnivores. The lower serum level of lysine in these women is a possible cause of lower carnitine.

The carnitine levels in human milk were followed for 50 days postpartum and the mean level was found to be 62.9 nmol/mL (56.0 to 69.8 nmol/mL range) during the first 21 days and  $35.2 \pm 1.26$  nmol/mL until days 40 to 50. Levels were not related to volume of milk secreted.

## PROTEINS

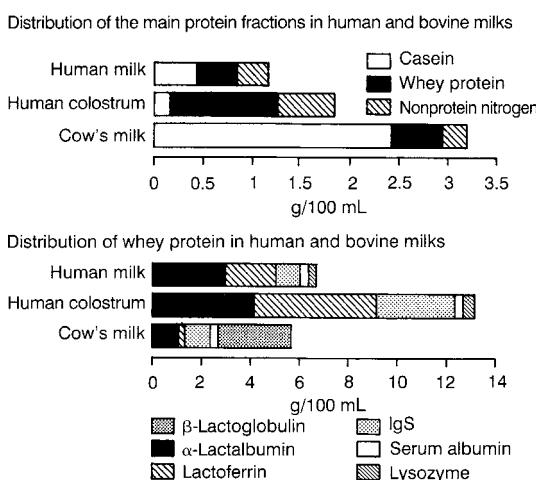

All varieties of milks have been evaluated for their protein contents, which vary from species to species. Proteins constitute 0.9% of the contents in human milk and range up to 20% in some rabbit species. Proteins of milk include casein, serum albumin,  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulins, immunoglobulins, and other glycoproteins. Eight of 20 amino acids present in milk are essential and are derived from plasma. The mammary alveolar epithelium synthesizes some nonessential amino acids. Human milk amino acids occur in proteins and peptides, as well as a small percentage in the form of free amino acids and glucosamine<sup>3</sup> (Table 4-14; Figure 4-11).

Tikanona et al. reported that postprandial changes in plasma amino acids in breastfed infants were proportional to dietary intake and were

**TABLE 4-14** Free Amino Acid Concentrations in Human Milk

Amino Acid	Colostral Milk ( $\mu\text{mol}/\text{dL}$ )	Transitional Milk ( $\mu\text{mol}/\text{dL}$ )	Mature Milk ( $\mu\text{mol}/\text{dL}$ )
Glutamic acid	36-68	88-127	101-180

From Carlson SE: Human milk nonprotein nitrogen: occurrence and possible function, *Adv Pediatr* 32:43, 1985.

**Figure 4-11.** Distribution of main protein fractions (top) and whey protein (bottom) in human and bovine milk. (Modified from Dumas BR: Modifications of early human milk composition during early states of lactation in nutritional adaptation of the gastrointestinal tract of the newborn. In Kretchmer N, Minkowski A, editors: *Nutritional adaptation of gastrointestinal tract of the newborn*, vol. 3, New York, 1983, Nestlé Vevey/Raven.)

highest for the branched-chain amino acids. This was also found to be true for most semiessential and nonessential amino acids. The blood urea levels also reflect dietary intake, with values in breastfed infants being substantially lower than levels in bottle-fed infants. The sum of plasma free amino acids rose and the glycine/valine ratio fell after a feed. When breastfed and formula-fed infants were compared by Järvenpää, concentrations of citrulline, threonine, phenylalanine, and tyrosine were higher in formula-fed than in breastfed infants. Concentrations of taurine were lower in the formula-fed infants. The peak time was different for formula-fed and breastfed infants, which points out the need to standardize sampling times.

The DARLING (Davis Area Research on Lactation, Infant Nutrition, and Growth) Study was the first longitudinal study to follow a large group of mother-infant dyads to 12 months.<sup>36</sup> The investigators report protein intake to be positively associated with milk lipid concentrations after 16 weeks. Milk protein concentration was negatively related to milk volume at 6 and 9 months and positively related to feeding frequency at

these times. Milk composition is more sensitive to maternal factors such as body composition, diet, and parity during later lactation than during the first few months.<sup>119</sup>

## Casein

Milk consists of casein, or curds, and whey proteins, or lactalbumins. The term *casein* includes a group of milk-specific proteins characterized by ester-bound phosphate, high-proline content, and low solubility at a pH of 4.0 to 5.0.<sup>79,93</sup> Caseins form complex particles or micelles, which are usually complexes of calcium caseinate and calcium phosphate. When milk clots or curdles as a result of heat, pH changes, or enzymes, the casein is transformed into an insoluble caseinate-calcium phosphate complex. Physiochemical differences exist between human and cow caseins.<sup>93</sup> Casein has a species-specific amino acid composition.

When Lönnnerdal and Forsum<sup>93</sup> originally measured the casein content of human milk by three different methods—isolectric precipitation, sedimentation by ultracentrifuge, and indirect analysis—they consistently had three separate results.

Utilizing two newer techniques, Kunz and Lönnnerdal<sup>92</sup> report confirming results revealing that casein synthesis is low or absent in early lactation, then increases rapidly, and then decreases. The concentration of whey proteins decreases from early lactation. The whey protein/casein ratios change accordingly from 90:10 in early milk to 60:40 in mature milk and 50:50 in late lactation. The authors suggest whey and casein are regulated by different mechanisms.<sup>92</sup>

## Methionine/Cysteine Ratio

The cysteine content is high in human milk, whereas it is very low in cow milk. Because the methionine content is high in bovine milk, the methionine/cysteine ratio is two to three times greater in cow milk than in the milk of most mammals and seven times that in human milk. Human milk is the only animal protein in which the methionine/cysteine ratio is close to 1. Otherwise, this ratio is seen only in plant proteins.

Two significant characteristics of amino acid composition of human milk are the ratio between the sulfur-containing amino acids methionine and cysteine and the low content of the aromatic amino acids phenylalanine and tyrosine. Newborns and especially premature infants are poorly prepared to handle phenylalanine and tyrosine because of their low levels of the specific enzymes required to metabolize them.

## Taurine

Taurine, 2-aminoethanesulfonic acid (so named because it was first isolated from the bile of the ox), is a third sulfur-containing amino acid that has been found in high concentrations in human milk and is virtually absent in cow milk. It is now being added to some prepared formulas. Free taurine and glutamic acid have been measured in breast milk in high concentrations. Taurine has been associated in the body at all ages with bile acid conjugation; in newborns, bile acids are almost exclusively conjugated with taurine.

Sturman et al. suggest that taurine may also be a neurotransmitter or neuromodulator in the brain and retina. Taurine in the nutrition of human infants was reviewed by Neville,<sup>116</sup> who reports that evidence is accumulating that taurine has a more general biologic role in development and membrane stability.

Taurine is found in very high concentrations in the milk of cats.<sup>131</sup> Kittens deprived of taurine by feeding with purified taurine-free casein diets after weaning develop retinal degeneration and blindness. The process can be reversed by feeding taurine, but not by feeding methionine, cysteine, or inorganic sulfate. The structural integrity of the retina of the cat has been shown to be taurine dependent. The taurine levels were more severely depleted in the brain tissue, but the significance of this finding has not yet been determined.<sup>147</sup> Both humans and cats are unable to synthesize taurine to any degree as newborns and young infants and are, therefore, wholly dependent on a dietary supply. The process requires cystathionase and cysteine-sulfinic acid decarboxylase, which are enzymes that convert methionine, cysteine, or cystine to taurine.

In studies of amino acid levels, only the concentrations of taurine in plasma and urine of breastfed term infants were higher than those of preterm infants fed formula. Levels in term infants were higher than those of preterm infants fed pooled human milk at a fixed volume. The effects of feeding taurine-deficient formula to human infants, which occurred before the addition of taurine to infant formula, are not as severe as seen in the kitten. The presence of taurine in human milk and predominance of taurine conjugates in the gut at birth suggest that bile acid conjugate status may be a controlling factor. When bile acid metabolism was measured in infants fed human milk, the infants consistently had higher intraluminal bile acid concentrations at all ages (1 to 5 weeks) than did formula-fed infants with and without additional taurine. Human milk also facilitated intestinal lipid absorption.<sup>149</sup>

Human infants conjugate bile acids predominantly with taurine at birth but quickly develop

the capacity to conjugate with glycine. Those infants fed human milk continue to conjugate with taurine, whereas those fed formulas soon conjugate with glycine predominantly. The cat, in contrast, uses only taurine throughout life.<sup>149</sup> In humans the various pools of taurine in the body cannot be predicted by measurement of plasma taurine alone.

Since 1968, when scientists' attention was drawn to taurine, more than a thousand reports, including reviews, have been published. The physiologic actions of taurine have been reviewed exhaustively by Huxtable.<sup>72</sup> Nonmetabolic actions such as osmoregulation, calcium modulation, and interactions with phospholipid protein and zinc are reported. Taurine is also observed to be a product of metabolic action and a precursor of many other metabolic actions. All these actions demonstrate the careful balance in nature of a number of interdependent constituents. Taurine does not function in isolation. Because of the growing evidence for the role of taurine during development, the requirement for taurine for the neonate remains under investigation.

## Whey Proteins

When clotted milk stands, the clot contracts, leaving a clear fluid called whey, which contains water,

electrolytes, and proteins. The ratio of whey proteins to casein is 1.5 for breast milk and 0.25 for cow milk; that is, 40% of human milk protein is casein and 60% lactalbumin, and cow milk is 80% casein and 20% lactalbumin.<sup>93</sup>

Human milk forms a flocculent suspension with zero curd tension. The curds are easily digested. The total amount of protein has been recently measured to be 0.9%, which is lower than the previously reported 1.2%. The discrepancy is caused by recalculation of the data, in which the total amount of protein was determined by measuring the nitrogen content and multiplying by 6.25. Of the nitrogen content, 25% is NPN, whereas in bovine milk, 5% of the nitrogen is from NPN. Hamraeus has reported the composition of the nonprotein fraction to be urea, creatine, creatinine, uric acid, small peptides, and free amino acids (Table 4-15).

Closer examination of the whey proteins shows  $\alpha$ -lactalbumin and lactoferrin to be the chief fractions, with no measurable  $\beta$ -lactoglobulin, which is the chief constituent of cow milk. The term *lactalbumin* includes a mixture of whey proteins found in bovine milk and should not be confused with  $\alpha$ -lactalbumin, which is a specific protein that is part of the enzyme lactose synthetase. The  $\alpha$ -lactalbumin content parallels lactose levels in

**TABLE 4-15** Composition of Protein Nitrogen and Nonprotein Nitrogen in Human Milk and Cow Milk\*

	Human Milk		Cow Milk	
Protein nitrogen	1.43	(8.9)	5.3	(31.4)
Casein nitrogen	0.40	(2.5)	4.37	(27.3)

Total nitrogen	1.93		5.31	

\*Values refer to grams of nitrogen per liter; values within parentheses refer to grams of protein per liter.

From Forsum E, Lönnerdal B: Protein evaluation of breast milk and breast milk substitutes with special reference to the nonprotein nitrogen: effect of protein intake on protein and nitrogen composition of breast milk, *Am J Clin Nutr* 33:1809, 1980.

different species. Human milk is high in both lactose and  $\alpha$ -lactalbumin. Many investigators, however, have continued to measure nitrogen compounds in human milk (see Table 4-15).

## Lactoferrin

Lactoferrin is an iron-binding protein that is part of the whey fraction of proteins in human milk. Structurally, lactoferrin is a 78 to 80 kDa single peptide consisting of two lobes, each of which binds a molecule of iron.<sup>143</sup> It appears in very low amounts in bovine milk. Lactoferrin has been observed to inhibit the growth of certain iron-dependent bacteria in the gastrointestinal (GI) tract. It has been suggested that lactoferrin protects against certain GI infections in breastfed infants. Giving iron to newborn infants appears to inactivate the lactoferrin by saturating it with iron and promoting the growth of *Escherichia coli* in particular. It has other functions including cell growth regulation, deoxyribonucleic acid (DNA) binding, transcriptional activation of specific DNA sequences, natural killer cell activation, and antitumor activity. Lactoferrin also has enzyme activity. Those identified are protease, deoxyribonuclease, ribonuclease, adenosine triphosphatase (ATPase), phosphatase, and oligosaccharide hydrolysis. The role of these enzymes in lactoferrin's antimicrobial functions is under study.<sup>33</sup>

When lactoferrin is digested in the stomach by pepsin, the polypeptides produced also have biological functions including antimicrobial, antiviral, antitumor, and immunological functions. These proteins are under continued study because of their active infection protection. Regarding the impact of storage on lactoferrin, it was noted that 5 days of refrigeration does not change levels but 3 or more months of freezing significantly lowers the lactoferrin levels.

## IMMUNOGLOBULINS

The immunoglobulins in breast milk are distinct from those of the serum, but are the key mechanism by which a mother passes immunity to the infant.<sup>48</sup> The main immunoglobulin in serum is IgG, which is present in the amount of 1210 mg/dL. IgA is found in the serum at 250 mg/dL, one fifth the level of IgG. The reverse is true of human colostrum and milk. Colostrum IgA is 1740 mg/dL, and milk IgA level is 100 mg/dL. Colostrum has 43 mg/dL of IgG, and milk has 4 mg/dL. The IgA and IgG in human milk are derived from serum and from synthesis in the mammary gland.

Lactation is associated with the appearance of catalytically active antibodies or abzymes (Abzs) with DNase, RNase, ATPase, amylolytic, protein

kinase, and lipid kinase activities in breast milk. Odintsova et al.<sup>122</sup> have demonstrated that the immune system of clinically healthy mothers can generate IgAs with  $\beta$ -casein-specific serine protease-like activity.

slgA is the principal immunoglobulin in colostrum and milk and all human secretions. slgA contains an antigenic determinant associated with a secretory component. It is synthesized in the gland from two molecules of serum IgA linked by disulfide bonds. slgA levels are very high in colostrum the first few days and then decline rapidly, disappearing almost completely by the fourteenth day. slgA is stable at low pH and resistant to proteolytic enzymes. It is present in the intestine of breastfed infants and provides a protective defense against infection by keeping viruses and bacteria from invading the mucosa. The protective qualities are further described in Chapter 5.

## Nonimmunoglobulins

Human milk contains numerous nonimmunoglobulins that are being identified and their actions isolated and quantified.<sup>152</sup> Mucins and sialic acid-containing glycoproteins have been isolated and demonstrated to inhibit rotavirus replication and prevent experimental gastroenteritis. The rotavirus has been observed to bind to the milk mucin complex, inhibiting its replication both *in vitro* and *in vivo*. (See later discussion of oligosaccharides and glycoconjugates.)

## Lysozyme

Lysozyme is a specific protein and basic polypeptide with lytic properties<sup>64</sup> found in high concentration in egg whites and human milk but in low concentration in bovine milk. It has been identified as a nonspecific antimicrobial factor. This enzyme is bacteriolytic against Enterobacteriaceae and gram-positive bacteria. It has been found in concentrations up to 0.2 mg/mL. Lysozyme is stable at 100°C (212°F) and at an acid pH. Lysozyme contributes to the development and maintenance of specific intestinal flora of the breastfed infant. (See later discussion of enzymes and Chapter 5 "Host Resistance Factors.")

## Polyamines

Polyamines are ubiquitous intracellular cationic amines recognized as participants in cell proliferation and differentiation in many tissues, especially those of intestinal tract development, absorption, and biologic activity, in both sucklings and adults of the species.<sup>129</sup> The synthesis of polyamines is

an active process in the mammary gland throughout lactation.<sup>12</sup>

Putrescine, spermidine, and spermine have been identified and quantitated in human milk by Pollack et al.<sup>129</sup> They reported mean values per liter of 0 to 615 nmol putrescine, 73 to 3512 nmol spermidine, and 722 to 4458 nmol spermine. In contrast, levels in formula are low and dependent on the protein source. Levels of spermine and spermidine increase greatly during the first few days of lactation, plateauing at levels 12 and 8 times, respectively, the levels immediately postpartum.<sup>11</sup> These findings have been confirmed by Romain et al.,<sup>133</sup> who noted that levels in human milk remained stable throughout lactation. They demonstrated the effects of spermine or spermidine on maturation and "gut closure" and suggest a protective effect of spermine against alimentary allergies.

## NONPROTEIN NITROGEN

NPN accounts for 18% to 30% of the total nitrogen in human milk, compared with only 3% to 5% in cow milk. The NPN fraction of human milk is traditionally identified as the acid-soluble nitrogen

remaining in the supernatant after protein precipitation or as the dialyzable nitrogen after dialysis of whole milk.<sup>12</sup> Because large-molecular-weight glycoproteins are also soluble in the acid, the fraction should be called acid-soluble nitrogen.<sup>106</sup>

Although there are large interindividual variations, acid-soluble nitrogen ranges from 350 to 530 mg/L. The total nitrogen ranges from 1700 to 3700 mg/L, depending on length of gestation, duration of lactation, and maternal diet. Some of the nitrogen contributes to the pool available for synthesis of nonessential amino acids in the neonate. Those compounds having more specialized roles are peptide hormone/growth factors, epidermal growth factor (EGF), amino sugars of oligosaccharides, free amino acids, amino alcohols of phospholipids, nucleic acids, nucleotides, and carnitine. Their importance is not based on percentage of concentration because they may serve roles as catalysts. Many protein factors in human milk serve roles other than growth, such as the host resistance factors (lactoferrin, sIgA, and lysozyme).

**Table 4-16** presents the significance of these compounds and their relative concentrations. The wide variety of nitrogenous compounds within

**TABLE 4-16** Levels and Significance of Nonprotein Nitrogen (NPN) Constituents of Human Milk

NPN	Concentration in Milk		Significance
	Less Than 30 Days	More Than 30 Days	
<b>Amino sugars</b>			
N-Acetylglucosamine	230 mg N/L	150 mg N/L	Low oral osmotic load; controls gut colonization; constituent of gangliosides for brain development
N-Acetylneuraminic acid	63 mg N/L	3-27 mg N/L	Substrate for gut epithelium
Peptides	—	60 mg N/L	
Epidermal growth factor	88 ng/mL	—	Regulates intestinal mucosal development
Somatomedin-C/insulin-like growth factor	18 ng/mL	6-8 ng/mL	Stimulates DNA synthesis and cell division in gut
Delta sleep-inducing peptide	30 ng/mL	5 ng/mL	Diurnal pattern highest at 2 PM and 8 PM; ? influences sleep/awake patterns
Insulin	21 ng/mL	2 ng/mL	? Regulates development of gut
<b>Free amino acids</b>			
Taurine	41-45 μmol/dL	27-67 μmol/dL	See under "Taurine" in paragraph below
Glutamic acid/glutamine	2-9 μmol/dL	13-58 μmol/dL	Improves zinc absorption; precursor to brain glutamate
Carnitine	1.0 mg N/L	0.7 mg N/L	Brain lipid synthesis
Choline and ethanolamine	7-20 mg N/L	10-20 mg N/L	Possible growth requirement
Nucleic acid	—	19 mg N/L	Pool of DNA and RNA
Nucleotides	3 mg N/L	3 mg N/L	Growth and immune advantage
Polyamines	0.1 mg N/L	0.2 mg N/L	Increase rate of transcription, translation, and amino acid activation

DNA, Deoxyribonucleic acid; N/L, nitrogen per liter; RNA, ribonucleic acid.

the fraction of human milk is only beginning to be investigated and understood. This information clearly widens the chemical gap between human milk and proprietary formulas. Increasing evidence suggests that the premature infant reaps even more benefit than the term infant from mother's milk, based on the investigations of NPN alone.

While glutamic acid and taurine are the most abundant free amino acids in colostrum, taurine remains constant throughout lactation, but glutamic acid and glutamine increased from 2.5 to 20 times in the first 3 months in studies in 16 healthy lactating women.<sup>3</sup> The total content of free amino acids remains stable during that period so that over 50% of the total is glutamine and glutamic acid at 3 months. These components have been associated with growth and development, protecting intestinal mucosa and potentiating immune responses.

Maternal milk production and the protein nitrogen (but not NPN) fraction of human milk are well preserved when lactating women are subjected to marginal dietary protein intakes in the short term.<sup>106</sup> In nitrogen balance studies on poor Mexican women who were lactating, equilibrium was attained at  $178.9 \pm 25.8$  mg nitrogen (1.1 g protein/kg body weight/day), which is close to current dietary standards.<sup>34</sup>

Interest in urea levels has been stimulated because women with various stages of renal failure were concerned about the effect of high serum levels of urea on their milk urea levels. Urea is 30% to 50% of the NPN in milk. Levels decrease from colostrum to mature milk (3.2 g/dL nitrogen in colostrum to 1.7 g/dL in milk). If the original milk urea was provided solely by passive diffusion from the maternal blood, a constant level of urea nitrogen would be anticipated at all stages of lactation instead of increasing from colostrum to mature milk.<sup>12</sup>

## NUCLEOTIDES

Increased attention has been paid to the presence and role of nucleotides in human milk, as their relative absence in bovine milk has led to experimental supplementation of some infant formulas. Nucleotides have been identified as playing key roles in biochemical processes within the cell, acting as metabolic regulators and altering enzyme activities. A dietary requirement has not been established because they can be synthesized de novo in the adult. Human milk provides 20% of NPN as nucleotides; furthermore, human milk provides a larger percentage (30%) of nitrogen as NPN, three times more than other species. The daily intake from human milk is 1.4 to 2.1 mg of nucleotide nitrogen.<sup>130</sup> Cytidine, adenine, and uridine compose the majority of soluble nucleotides.

Nucleotides are compounds derived from nucleic acid by hydrolysis and consist of phosphoric acid combined with a sugar and a purine or pyrimidine derivative. The level and components of acid-soluble nucleotides of several species, including humans, have been studied extensively. Work has shown a characteristic nucleotide composition in the milk that differs from that of the mammary gland. The large numbers of purine and pyrimidine nucleotides present in various tissues have a number of functions in the cell. They are part of nucleic acid synthesis and metabolism and are also part of milk synthesis. It is well known that ATP supplies usable energy for biosynthetic reactions.

Free nucleotides in human milk have been recorded at 6.1 to 9.0 mmol/dL.<sup>130</sup> The levels in colostrum and mature milk are similar. The conspicuous difference in quality and quantity of nucleotides between the mammary gland and its secretion would indicate that nucleotides are secreted from the epithelial cells of the gland into the milk. Distinct species differences exist in composition and content of nucleotides as well. Cytidine monophosphate and uracil are the nucleotides in the highest concentration in human milk, which also contains uridine diphosphate-N-acetyllactosamine and other oligosaccharides. Human milk contains only a trace of orotic acid and no guanosine diphosphate fucose. Orotic acid is the chief nucleotide of bovine milk. Nucleotide levels fall rapidly in bovine milk to minimal levels in mature bovine milk. Synthetic nucleotides produced for formula have a very different profile.

When the nitrogen fraction of human milk was further identified overtime at 2, 4, 8, and 12 weeks, a variance was noted in the pattern of nucleotides (Table 4-17).<sup>130</sup> Levels of cytidine-5'-monophosphate and adenosine-5'-monophosphate

**TABLE 4-17** Nucleotide Content of Human Milk

Nucleotide	Mean* (mg/dL)
Cytidine monophosphate	461 (17.9)
Uridine monophosphate	179 (19.8)
Adenosine monophosphate	175 (12.8)
Inosine monophosphate	228 (14.5)
Guanosine monophosphate	138 (8.5)
Uridine diphosphate	174 (12.8)
Cytidine diphosphate	474 (41.5)
Adenosine diphosphate	69 (17.9)
Guanosine diphosphate	96 (8.9)

\*Mean nucleotide content of human milk at weeks 2, 4, 8, and 12 of lactation.

From Hendricks K: Nucleotide content human milk, *Semin Pediatr Gastroenterol Nutr* 2:14, 1991; Modified from Janas LM, Picciano MF: The nucleotide profile of human milk, *Pediatr Res* 16:659, 1982.

declined from 594 to 321 mg/dL and from 244 to 143 mg/dL, respectively, whereas levels of inosine-5'-monophosphate increased from 158 to 290 mg/dL. The total nucleotide nitrogen remained constant, accounting for 0.10% to 0.15% of the total NPN. The average intake per day of a normal breastfed infant would be 1.4 to 2.1 mg of nucleotide nitrogen. Measurement of adenosine-5'-monophosphate and cyclic guanosine monophosphate showed variation in concentration within 15 minutes, which fluctuated throughout 24 hours.<sup>130</sup> Milk concentration differed widely from maternal plasma levels collected at the same time.

The biologic effects of dietary nucleotides involve the immune system, the intestinal microenvironment, and the absorption and metabolism of certain other nutrients (see Table 4-17) so they are considered "semiessential" for newborns.<sup>56</sup> Whether inosine-5'-monophosphate contributes to the superior iron absorption is still unanswered.

Metabolic disturbances in nucleotide metabolism can result in abnormal accumulation of specific intermediates in cells and tissues, causing a variety of diseases. An example is Lesch-Nyhan syndrome, a genetic disease characterized by mental retardation, self-mutilation, and gout, which is caused by the absence of the purine salvage enzyme. On the other hand, disturbances from lack of nucleotides in the diet have not been identified.

Nucleotides are formed by de novo synthesis by capturing or scavenging partially degraded nucleotides or are obtained completely from the diet. Dietary nucleotides are absorbed by action of the microvillus membrane as nucleosides. The developing neonate has a reduced capacity to synthesize or salvage nucleotides. Exogenous nucleotides are potential stimuli, modulating not only the gene control of their own metabolism but also that of a number of functions in the cardiovascular, neurologic, and immune systems.<sup>25</sup> Nucleotides are important as coenzymes for the processes involved in the metabolism of lipids, carbohydrates, and proteins. Nucleotides are recognized as an integral part of the immune system, acting as the host defense against bacteria, viruses, and parasites, as well as various malignancies. Nucleotides are important in the process of protein synthesis, which is enhanced in the newborn infant by a dietary supply of nucleotides. A high protein diet (20%) does produce significant growth increase when nucleotides are added. This result may explain the satisfactory growth pattern of breastfed infants on relatively low protein intake and the more efficient protein utilization of breastfed infants.

Study of the exact role of nucleotides continues *in vivo*, although some effort to supplement formula with synthetic nucleotides has already begun.

## Carbohydrates

---

The predominant carbohydrate of milk is lactose, or milk sugar. It is present in high concentration (6.8 g/dL in human milk and 4.9 g/dL in bovine milk). Lactose is a disaccharide compound of two monosaccharides, galactose and glucose. Lactose is synthesized by the mammary gland, described as a dynamic process.

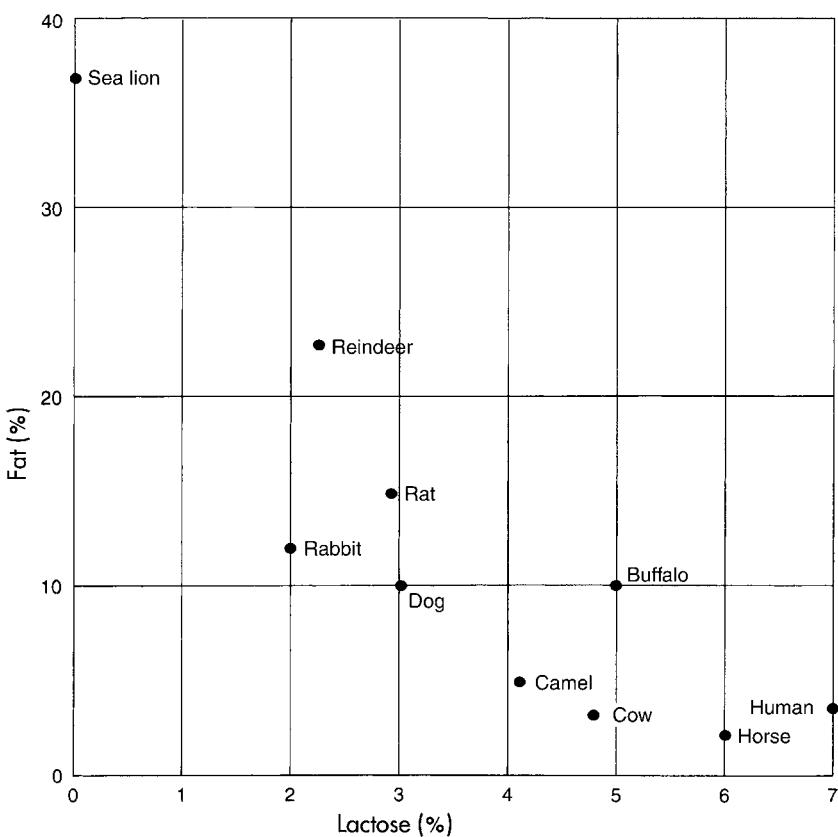

A number of other carbohydrates are present in milk. They are classified as monosaccharides, neutral and acid oligosaccharides, and peptide-bound and protein-bound carbohydrates. Small amounts of glucose (1.4 g/dL) and galactose (1.2 g/dL) also are present in breast milk. Other complex carbohydrates are present in free form or bound to amino acids or protein, such as *N*-acetylglucosamine. The concentration of oligosaccharides in human milk is about 10 times greater than in cow milk. These carbohydrates and glycoproteins possess bifidus factor activity. Fucose, which is not present in bovine milk, may be important to the early establishment of *L. bifidus* as gut flora. The nitrogen-containing carbohydrates are 0.7% of milk solids.

In a study of carbohydrate content over the first 4 months of lactation, Coppa et al.<sup>26</sup> observed that lactose concentrations increased from  $56 \pm 6$  g/L on day 4 to  $68.9 \pm 8$  g/L on day 120.

Lactose is hydrolyzed selectively by a brush border enzyme called lactase located predominantly in the tip of the intestinal villi. Digestion of lactose is the rate-limiting step in its absorption. Although lactase activity develops later in fetal life than that of other disaccharidases, it is present by 24 weeks of fetal life. Lactase concentration is greatest in the proximal jejunum. Levels continue to increase throughout the last trimester, reaching concentrations at term of two to four times those levels at 2 to 11 months of age. Premature infants rapidly increase their lactase levels given a lactose challenge. A well-fed breastfed infant ingesting 150 mL of milk/kg/day receives 10 g of lactose/kg/day, which ensures the normal unstressed infant at least 4 mg/kg/min of glucose, which is considered the optimal rate.

Lactose does appear to be specific, however, for newborn growth. It has been shown to enhance calcium absorption and has been suggested as being critical to the prevention of rickets, in view of the relatively low calcium levels in human milk. Lactose is a readily available source of galactose, which is essential to the production of the galactolipids, including cerebroside. These galactolipids are essential to CNS development.

Interesting correlations have been made between the amount of lactose in the milk of a species and the relative size of the brain (Figure 4-12).<sup>90</sup> Because lactose is found only in milk and not in other animal and

**Figure 4-12.** Concentration of lactose varies with source of milk. In general, less lactose, more fat, which can also be used by newborn animals as an energy source. (From Kretchmer N: Lactose and lactase, *Sci Am* 227:73, 1972. Copyright © 1972 by Scientific American, Inc. All rights reserved.)

plant sources, its high level in human milk is even more significant. Lactose levels are relatively constant throughout the day in a given mother's milk. Even in poorly nourished mothers, the levels of lactose do not vary. Because lactose is influential in controlling volume, the total output for the day may be diminished, but the concentration of lactose in human milk will be 6.2 to 7.2 g/dL.<sup>115</sup> An adequate source of carbohydrate is important for optimal lactation, which suggests that excessive amounts of sugar substitutes may have an effect on volume.<sup>87</sup>

## OLIGOSACCHARIDES AND GLYCOCOCONJUGATES

Oligosaccharides have become an area of intense investigation and study in human milk science. Oligosaccharides are the third largest solid component in milk after lactose and triglyceride. They reach up to 20 g/L in early milk.<sup>67</sup> Most of the milk oligosaccharides contain lactose at the reducing end of the structure and may also contain fucose or sialic acid at the nonreducing end. More than 200 neutral and acidic oligosaccharides have been identified.<sup>117</sup> One liter of milk contains 5 to 10 g

of unbound oligosaccharides. The high amount and structural diversity are unique to humans.<sup>16</sup> The structural complexity of milk oligosaccharides hampers the assignment of specific functions to single carbohydrates. The interactions of milk oligosaccharides with intestinal microbiota and the mucosal immune system provide proof that breast milk provides much more than just nutrition.<sup>67</sup> The human milk metabolome reveals diverse oligosaccharide profiles. The variability in certain milk metabolites suggests possible roles in infant gut microbial development. Biochemically, oligosaccharides result from the sequential addition of monosaccharides to the lactose molecule in the mammary gland by glycosyl transferases. The presence and quantity of different types of oligosaccharides in human milk are genetically determined.<sup>27</sup> Of the 21 oligosaccharides studied in depth, the highest amount is present by day 4 with gradual decreasing by 20% by day 30. The physiologic role of human milk and oligosaccharides had been limited to the enhancement of the growth of *L. bifidus* flora and indirectly to the protection against GI infections. It is now known they act as soluble decoys preventing the adhesion of viruses, bacteria,

and their toxins to their carbohydrate mucosal receptors.<sup>67</sup> Real efficacy has been demonstrated in core oligosaccharides against *Streptococcus pneumoniae*, *Helicobacter pylori*, *E. coli*, and influenza viruses.

The association between maternal milk levels of two-linked fucosylated oligosaccharide and the prevention of diarrhea as a result of campylobacter, caliciviruses, and all causes in breastfed infants was studied by Morrow et al.<sup>143</sup> Evidence was found that human milk oligosaccharides may offer clinically relevant protection against diarrhea.

Glycoproteins, glycosylated major milk proteins, include lactoferrin, immunoglobulins, and mucins. Their protective characteristics have been described as acting as receptor homologs, inhibiting the binding of enteropathogens to their host receptors. Research continues to link specific carbohydrate structures with protection against specific pathogens. These nonimmunoglobulin agents are also active against whole classes of pathogens.<sup>113</sup> The protective glyconjugates and oligosaccharides are unique to human milk and to date have not been replicated synthetically. They are synthesized exclusively in the mammary gland and only during lactation. Human oligosaccharides are distinct from other species with respect to quantity, quality, and diversity.<sup>16</sup> Human milk oligosaccharides, a major family of complex glycans are relevant to clinical illness in neonates and term infants. The newly emerging technologies for the biologic testing of these molecules open new opportunities to identify prophylactic and therapeutic agents that inhibit a variety of pathogens.

## Minerals

Minerals represent a special category of constituents. Their pathways into milk vary from simple diffusion to both positive and negative pump mechanisms.<sup>2</sup> Table 4-18 records the measurements of the constituents in human milk compared with maternal serum. By examining this relationship, it can be estimated how the particular constituent reaches the milk, that is, by passive diffusion or positive or negative pump.

The total ash content of milk is species-specific and parallels the growth rate and body structure of the offspring. A number of metallic elements and organic and inorganic acids are present in milk as ions, unionized salts, and weakly ionized salts. Some are bound to other constituents. Sodium, potassium, calcium, and magnesium are the major cations. Phosphate, chloride, and citrate are the major anions.<sup>28</sup>

The monovalent ions are sodium, potassium, and chloride. The divalent ions are calcium, magnesium, citrate, phosphate, and sulfate.<sup>11</sup> The monovalent

ions are among the most prevalent and contribute 30 mosmol, or one tenth of the total osmolarity of human milk.<sup>8</sup> The sum of the concentrations of the monovalent ions is inversely proportional to the lactose content across species. Monovalent ion concentration is regulated chiefly by the secretion mechanism in the alveolar cell, with humans having the highest lactose and lowest ion content.<sup>153</sup> This maintains osmolality close to that of serum.

Daily intakes of calcium, phosphorus, zinc, potassium, sodium, iron, and copper from breast milk were found to decrease significantly over the first 4 months of life, with only magnesium increasing. Despite seemingly low mineral intakes, growth during this time was found to be satisfactory by Casey et al.<sup>22</sup> High mineral content is associated with a rapid growth rate of specific species.

## POTASSIUM AND SODIUM

Potassium levels are much higher than those of sodium, which are similar to the proportions in intracellular fluids (Table 4-19). Although sodium, potassium, and chloride are present as free ions, the other constituents appear as complexes and compounds. Ions can pass through the secretory cell membrane in both directions and in and out of the lumen. Intracellular sodium, chloride, and potassium are in equilibrium with the ions of the plasma and alveolar milk. An apical pumping mechanism has been calculated for chloride release, whereas sodium, potassium, and intracellular chloride pass into milk because of their electrochemical gradients. The cellular pumping mechanism maintains the ionic concentrations in the extracellular fluid and alveolar milk.

The Committee on Nutrition of the American Academy of Pediatrics<sup>7</sup> has stated that the daily requirement of sodium for growth is 0.5 mEq/kg/day between birth and 3 months of age, decreasing to 0.1 mEq/kg/day after 6 months of age (Table 4-20). To cover dermal losses, an additional 0.4 to 0.7 mEq/kg/day is needed, with a little for urine and stool losses. Infants fed human milk receive enough sodium to meet their needs for growth, dermal losses, and urinary losses. Studies by Keenan et al. have demonstrated an apparent regulation in the levels of milk sodium and potassium concentrations by adrenocorticosteroids as well as a circadian rhythm.

Sodium levels in cow milk are 3.6 times those in human milk (human: 7 mEq/L or 16 mg/dL; bovine: 22 mEq/L or 50 mg/dL). Hypernatremic dehydration has been associated with cow milk feedings. Experiments with newborn rats on high salt intakes have shown that hypertension can develop.

The diurnal variation in milk electrolytes was found to vary between 22% and 80%. These

Age	Sodium (mg)	Potassium (mg)	Chloride (mg)
To 6 mo	115-350 (11.5 mg/kg)	350-925	275-700
6 mo-1 yr	250-750 (23 mg/kg)	425-1500	400-1200

From Food and Nutrition Board, National Research Council, National Academy of Sciences: *Recommended dietary allowances*, ed 10, Washington, D.C., 1989, U.S. Government Printing Office.

changes varied as the lactation period progressed but were independent of mother's diet. Sodium restriction did not influence milk levels. In a longitudinal study, sodium levels fell from 20 to 15 mEq/L in the first week. On day 8, levels were 8 mEq/L, and by the fifth week they were stabilized at 6 mEq/L.<sup>107</sup> Time-dependent changes in milk composition are also reported by Alaejos et al.<sup>4</sup> as a 25% or greater decrease in sodium, potassium, and citrate from 1 to 6 months. Calcium and glucose increase by 10% or more over this time. The authors suggest milk composition is always in transition.<sup>5</sup>

At a constant sodium intake, decreasing the sodium/potassium (Na/K) ratio in the diet by increasing potassium lowers blood pressure. The dietary Na/K ratio has an important role in determining the severity, if not the development, of salt-induced hypertension. The mechanism of potassium's antihypertensive effect is unclear, but the higher potassium and lower sodium levels of breast milk appear to be physiologically beneficial.

## CHLORIDE

Little attention has been paid to the adequacy of chloride in the diet, and it has always been assumed to be sufficient until recent events focused attention on this cation.

Chloride deficiency in infants has become associated with a syndrome of failure to thrive with hypochloremia and hypokalemic metabolic alkalosis. This was first described in infants fed formula that was deficient in chloride but has also been described in a breastfed infant whose mother's milk contained less than 2 mEq/L chloride (normal is greater than 8 mEq/L).<sup>9</sup> This is a rare phenomenon caused by unexplained maternal production. This mother had previously successfully nourished five other infants.

## TOTAL ASH

Cow milk has three times the total salt content of human milk (Table 4-21). All the minerals that appear in cow milk also appear in human milk. The phosphorus level is six times greater in cow milk; the calcium level is four times higher (Table 4-21).

The renal solute load of cow milk is considerably higher than that of breast milk. This is magnified by the metabolic breakdown products of the high protein content, which are in increased amounts as well. This is shown in the high urea levels in formula-fed infants (Table 4-23). Although the mean urea levels in breast milk are 37 mg/dL and only 15 mg/dL in cow milk, the blood urea levels

in breastfed infants are about 22 mg/dL, whereas those of infants fed formula are 47 mg/dL and those of infants fed formula plus solids are 52 mg/dL (see Table 4-23). The plasma osmolarity of infants fed breast milk is lower and approximates the physiologic level of plasma.

## CALCIUM/PHOSPHORUS RATIO

The calcium/phosphorus (Ca/P) ratio is considerably lower in cow milk (1:4) than in human milk (2:2). Many investigators have studied calcium and phosphorus values in human milk and found some variation from mother to mother and from

study to study. The Ca/P ratio varied from 1.8 to 2.4, with the absolute values for calcium varying from 20 to 34 mg/dL and those for phosphorus varying from 14 to 18 mg/dL. Fetal and newborn plasma concentrations for calcium decline sharply from 10.4 mg/dL at birth to 8.5 mg/dL by day 4. Unlike calcium, phosphorus concentrations rise in the postnatal period. The drop in serum calcium levels in the bottle-fed infants was more marked than in the breastfed infants. Infant serum phosphorus concentrations rise during the postnatal period. When gestation is prolonged or the mother has preeclampsia, the concentrations are even higher at birth.

Longitudinal studies by Greer et al., measuring calcium and phosphorus in human milk and maternal and infant sera, have shown progressive increases in infant serum calcium in association with decreasing phosphorus content of breast milk and infant serum. Maternal serum calcium also increased, although the mother's dietary intake was below recommended levels for lactating women. Calcium uptake in the maternal duodenum is enhanced during lactation.

Although the Ca/P ratio has been stressed in the past, recent investigations have not found a statistical correlation between the calcium and phosphorus contents of plasma and corresponding breast milk Ca/P ratio. This finding suggests that Ca/P ratio is not critical in the low mineral loads present in breast milk. Calcium and phosphorus decrease over time during lactation.<sup>7</sup>

Lactating women contribute 210 mg of calcium per day in breast milk. A study of intestinal calcium absorption of women during lactation and after weaning revealed that serum calcium and phosphorus concentrations were greater in lactating compared with nonlactating postpartum women, but levels were the same after weaning.<sup>82</sup> Calcitriol, however, was greater in women after weaning compared with postpartum control subjects. Lactating women lost significantly more bone throughout the body and in the lumbar spine than nonlactating postpartum women in the first 6 months. After weaning, the lactating women regained significantly more bone in the lumbar spine than nonlactating women. Early resumption of menses was associated with a smaller loss and greater increase after weaning.<sup>32</sup> Parathyroid hormone concentrations are reported to be higher only after weaning.

Calcium supplementation does not prevent bone loss during lactation and only slightly enhances the gain in bone density after weaning.<sup>82</sup> Supplementation did not affect levels in the milk. Krebs et al.<sup>89</sup> reported that excesses of protein have a negative effect on calcium absorption in lactating women. The calcium/protein ratio appears to be critical to efficient utilization. Estradiol stimulated the osteoblastic proliferation and enhanced the collagen gene expression. Calcium was shown to be well absorbed in 5- to 7-month-old breastfed infants who had begun to receive beikost (solids and semisolids).

## MAGNESIUM AND OTHER SALTS

Magnesium is present as a free ion and in complexes with casein and phosphate in caseinate micelles or citrate complexes. Cow milk has three times as much magnesium as human milk (12 mg/dL compared with 4 mg/dL) (see Table 4-21). Magnesium was measured

in human milk by Fransson and Lönnnerdal,<sup>54</sup> who found  $41.4 \pm 15.4$  mg/mL in whole milk samples, with most of the magnesium in the skim milk fraction but significant amounts in the fat fraction and less than 4% in the casein. The bound fraction was associated with low-molecular-weight proteins, thus enhancing bioavailability.

Longitudinal magnesium concentrations were measured by Greer et al. in milk and maternal sera and in the infants over a 6-month period. Progressive increases in serum magnesium level were seen in the breastfed infants in association with decreasing phosphorus content of the milk. Citrate is found in the milks of many species and is three to four times higher in cow milk than in human milk (see Table 4-21). The distribution of ions and salts differs among various milks and depends on the relative concentrations of casein and citrate.

Citrate is made in the mitochondria from pyruvate and transported into the cytoplasm, where it is available for lipid synthesis and for transport into the Golgi complex.<sup>10</sup> Citrate levels are not often measured in human milk, although citrate may be a marker of milk production potential (see Figure 4-5). Levels are high the first few days and rise as calcium levels rise.

Most of the sulfur in milk is in the sulfur-containing amino acids, with only about 10% present as sulfate ion. Some organic acids are present, and they appear as anions in milk.

## Trace Elements

Tables 4-21 and 4-22 list the recommended daily intake of trace elements for infants.<sup>50</sup>

### IRON

Because of the great emphasis on iron in the modern diet, and especially in the diet of the infant in the first year of life, the iron in human milk has been closely scrutinized. It has been determined that normal infants need 1500 mg of exogenous elemental iron in the first year of life, which can be translated into 8 to 10 mg/day (see Table 4-22). Prepared infant formulas currently supply 10 to 12 mg/day. Human milk has 100 mg/dL, which does not meet the requirements just given. Historically, however, breastfed infants have not been anemic (see Table 4-19).

In 350 samples of breast milk, there was a variation between less than 0.1 and 1.6 mg of iron/mL. Age, parity, and lactation history influenced the levels in some studies. The distribution of iron in various fractions of human milk of Swedish women was determined using multiple methods

by Fransson and Lönnérda<sup>53</sup> who also found low levels: 0.26 and 0.73 ng/mL. The lipid fraction bound 15% to 46% of the iron; 18% to 56% of the iron was in the low-molecular-weight protein fraction, with only a small amount bound to lactoferrin. Feeley et al. studied 102 American women by stage of lactation; 96% of the women took prenatal iron supplements. A diurnal variation was observed, and a significant decrease occurred from 4 to 45 days postpartum. The authors estimated that fully breastfed infants would receive 0.10 mg/kg/day of iron.

Iron absorption from human milk is more efficient and has been noted to be 49% of iron available, whereas only 10% of cow milk iron and 4% of iron in iron-fortified formulas are absorbed. Hematologic values of bottle-fed infants were abnormal, whereas those of breastfed infants were not. The breastfed infants had high ferritin levels, indicating a long-term adequacy of iron assimilation.

The infant who is exclusively breastfed for the first 6 months of life is not at risk for iron deficiency anemia or the depletion of iron stores during that time, according to the iron depletion studies of Finley et al.<sup>49</sup> Studies in adults given tagged iron in human milk and in cow milk show better absorption from human milk solution.<sup>125</sup>

Other factors that influence iron absorption include higher amounts of vitamin C. Lactose, which promotes iron absorption, is in higher concentration in breast milk, especially compared with prepared formulas, which may not contain lactose. Calcium and phosphorus may interfere with iron absorption, as may high protein levels. Considerable doubt still exists as to whether it is physiologically sound to increase the hemoglobin of an infant with exogenous iron. All species of mammals have low iron content in their milks. All mammals investigated so far have a drop in their hemoglobin levels after birth and a gradual rise to adult levels for the species.

A study of 40 normal, full-term infants followed in an Argentinian clinic found that the exclusively breastfed infants had a 27% incidence of anemia compared with a 7% rate in those who received iron-supplemented formula.<sup>19</sup> No storage iron was found in the breastfed infants with anemia. The average incidence of anemia in children in Argentina is 46%. The mothers had been instructed to start beef, liver, and orange juice at 6 months. Most of the iron was present in hemoglobin, the body storage iron being a small fraction of total body iron (2.05% for breastfed and 2.79% for formula-fed infants).<sup>19</sup>

Pisacane et al.<sup>128</sup> studied the iron status of 30 infants breastfed until their first birthday who

never received cow milk, supplemental iron, or iron-enriched formula. Examination of their iron stores and hematocrits revealed that those exclusively breastfed for 6.5 months versus 5.5 months were less likely to have anemia.<sup>128</sup> None of the infants exclusively breastfed for 7 months had anemia and all of these infants continued to have good iron status at 12 and 24 months. In a study in Peru, young exclusively breastfed infants up regulated iron absorption when iron stores were depleted.<sup>48</sup>

Absorption of iron from breast milk by 5- to 7-month-old infants receiving solid foods was studied using stable isotope Fe.<sup>1</sup> Iron was well absorbed from human milk in older infants after the introduction of solid foods to the diet.<sup>1</sup>

After extensive studies in Sweden and in Honduras, it was concluded that iron stores in human milk provide sufficient iron for full term, normal birth-weight infants with good prenatal iron stores. Infants who are at risk for iron deficiency at 6 months are LBW or preterm or with inadequate prenatal iron stores. At 9 months, infants with iron deficiency absorb more iron than infants with normal iron stores. No effect on weight gain was observed in infants with normal hemoglobins who received iron supplements from 4 to 9 months. Slower gain in linear growth and in head circumference, however, was seen in the infants supplemented with iron. When the hemoglobin was normal, the incidence of diarrheal disease was also greater in the supplemented group.<sup>35,39</sup>

## ZINC

Zinc has been identified as essential to humans. Its chief roles described to date are as part of the enzyme structure and as an enzyme activator. Zinc has been identified as a first limiting nutrient in breast milk when anthropometric indicators of growth are correlated with zinc levels in healthy breastfed infants.<sup>38</sup> Zinc deficiency has been described as well, most dramatically in newborns and premature infants on hyperalimentation regimens. The chief clinical symptoms are failure to thrive and typical skin lesions. Human milk has been identified as a food with bioavailable zinc.

Zinc absorption from human milk, cow milk, and infant formula was tested in healthy adults with labeled zinc chloride, using  $^{65}\text{Z}$ . The absorption was 41% from human milk, 28% from cow milk, 31% from standard infant formula, and 14% from soy formula. The dietary zinc intake of both lactating and nonlactating postpartum women was found by Moser and Reynolds<sup>105</sup> to be 42% of recommended allowances. No correlation was found

between zinc concentrations in breast milk and maternal dietary zinc and maternal plasma and erythrocyte zinc.

Changes in hair zinc concentrations of breastfed and bottle-fed infants during the first 6 months of life were measured by MacDonald et al. Only the bottle-fed boys had a significant decline in hair zinc concentration. No decline of zinc was found in any breastfed infant, which supports the concept of the superior bioavailability of zinc in breast milk.

Picciano and Guthrie studied milk from 50 mothers in 350 samples. They found zinc levels to average 3.95 mg/mL and to be consistent regardless of time of day, duration of lactation, or other variables. They estimated that breastfed infants receive 0.35 mg of zinc/kg/day. They found zinc levels to decline slightly from the first to the third month postpartum (33.8 to 29.5 mmol/L). At 6 months, zinc levels are 1.1 and 0.5 mg/L at 1 year. Longitudinal changes in dietary zinc requirements for infants acquiring new lean body mass through growth were studied by Krebs and Hambidge.<sup>88</sup> As growth velocity declines, zinc requirements decline in the male infant from a high of 780 mg/day at 1 month to 480 mg/day in the fifth through twelfth months. Meanwhile, the percentage of absorption increased overtime.

Human milk was fractionated and analyzed by Fransson and Lönnnerdal<sup>54</sup> for the distribution of zinc. Most of the zinc was found in the skim milk fraction, but significant amounts were found in the fat associated with the fat globule membrane; less than 4% was found in the casein.

Khoshoo et al.<sup>85</sup> reported zinc deficiency in a full-term, breastfed infant (previously reported in a breastfed premature infant). This case was diagnosed at 7 months of age by the characteristic perineal and perioral rash in an otherwise healthy, well-grown infant. The presumed cause was defective zinc uptake by the mammary gland, because the milk level was only 0.13 mg/L. The infant responded promptly to oral zinc supplements.

In a 9-week-old infant with intractable diaper rash, the mother's milk was noted to have low zinc levels after the rash responded to zinc therapy.<sup>8</sup>

She had nursed two other children without difficulty. Maternal diet does not influence zinc concentrations in the milk. Breast milk has been therapeutic in the treatment of acrodermatitis enteropathica, an inherited zinc metabolism disorder, whereas cow milk formulas are ineffective.

Copper, selenium, chromium, manganese, molybdenum, and nickel are trace elements that constitute less than 0.01% of body weight; however, their atoms are present in large numbers and play a critical role in growth and development. The technical ability to measure these elements is expanding. The effects of trace element deficiencies in fetal and neonatal development are yet to be understood.

Picciano and Guthrie studied copper levels in human milk and noted that the content varied considerably among women and within each woman. The range was 0.09 to 0.63 mg/mL. Copper levels were higher in the morning. Dietary supplements did not alter results. Age, parity, and lactation history showed that older mothers and multiparas had higher levels. A fully breastfed infant would receive 0.05 mg of copper/kg/day ([Table 4-24](#)).

Fractionated analysis by Fransson and Lönnnerdal<sup>54</sup> revealed whole milk concentration of copper to be  $0.27 \pm 0.13$  mg/mL, with most of the copper in the skim milk fraction, significant amounts in the fat, and little in the casein. The predominant binding was with low-molecular-weight proteins, which would enhance bioavailability.<sup>54</sup>

MacDonald et al. studied changes in hair copper concentrations among breastfed and bottle-fed infants. Hair copper levels rose in the first 3 months in all infants and then declined, regardless of feeding or sex of infant. The authors associated this with the redistribution of copper in early infancy (see [Table 4-19](#)). Copper is a component of a number of metalloenzymes.

The bioavailability of selenium depends on the sources and chemical form, and the quantitative significance is under investigation. Except for Keshan disease, a potentially fatal cardiomyopathy seen in infants in China, no convincingly associated clinical deficiency syndrome has been reported. Dietary recommendations have been based on those for adults. Dietary intakes less than the lower

**TABLE 4-24** Recommended Dietary Intake of Trace Elements for Infants\*

Age	Copper (mg)	Manganese (mg)	Fluorine (mg)	Chromium (mg)	Selenium (mg)	Molybdenum (mg)
To 6 mo	0.4-0.6	0.3-0.6	0.1-0.5	0.01-0.04	0.01-0.04	0.015-0.03
6 mo-1 yr	0.6-0.7	0.6-1.0	0.2-1.0	0.02-0.06	0.015-0.06	0.02-0.04

\*Because the toxic levels for many trace elements may be only several times the usual intakes, the upper levels for the trace elements given in this table should not be habitually exceeded.

From Food and Nutrition Board, National Research Council, National Academy of Sciences: *Recommended dietary allowances*, ed 10, Washington, D.C., 1989, U.S. Government Printing Office.

limits, however, should not be considered deficient, especially in breastfed infants.

Selenium concentrations in human milk are consistent in samples collected from many parts of the world, according to work by Hadjimarkos and Shearer. The mean value was 0.020 ppm, which was similar to the value from many parts of the United States, where the range was 0.007 to 0.033 ppm.

Increased selenium requirements have been observed in pregnant and lactating women. Supplementation with different compounds, such as selenium-enriched yeast and selenomethionine, significantly influenced selected indices of selenium status, including milk concentrations.<sup>4</sup>

Selenium is considered an essential nutrient in humans. It is an integral component of glutathione peroxidase, an enzyme known to metabolize lipid peroxides, and deficiency states have been described. Questions have been raised about the detrimental effects of high selenium intake on dentition. Smith et al. assessed selenium status in infants exclusively fed human milk or infant formula for 3 months. Foremilk samples had a mean concentration of 15.7 ng/mL, hindmilk mean concentration was 16.3 ng/mL, and mean formula concentration was 8.6 ng/mL. Breastfed infants have greater intakes and higher serum levels of selenium than formula-fed infants in the first 3 months (see Table 4-24).

The concentration of chromium is highest in the organs of the newborn and declines rapidly during the first years of life. A longitudinal study of chromium in human milk was undertaken by Kumpulainen and Vuori.<sup>91</sup> Mothers collected samples at 8 to 18 days, 47 to 54 days, and 128 to 159 days postpartum, representing every feed during a 24-hour period with equal portions of foremilk and hindmilk. The mean concentration was 0.39 (SD=0.15) ng/mL and the intake 0.27 mg/day (SD=0.11). The values did not change overtime. These values are the same as those in human serum and urine. The mothers' dietary intake averaged about 30 mg/day, which is lower than the 50 to 200 mg recommended daily allowance.

When chromium metabolism was studied in 17 lactating postpartum subjects, breast milk chromium content was independent of dietary chromium intake and serum and urinary values.<sup>7</sup> Chromium intake did not correlate with serum or urinary chromium.

HDL cholesterol levels can be increased with chromium supplementation. Chromium also is reported to have a favorable effect on serum lipid profiles. Deficiency of chromium in infancy may be an issue with LBW infants or those with inadequate fetal stores. Chromium is present

in all tissues of the body and is in high levels in nucleic acids.

Inordinately high levels of manganese have been found in infant formula, but little is known about its role in infant nutrition. Manganese is a component of comparatively few metalloenzymes, including pyruvate carboxylase and mitochondrial superoxide dismutase. It does, however, activate others. Deficiencies cause impaired growth and skeletal abnormalities in all species studied. In human milk, the major fraction of manganese is the 71% found in the whey, with 11% in the casein and 18% in the lipid. Levels in human milk in the first month of lactation decreased from a mean of  $5.4 \pm 1.6 \mu\text{g/dL}$  on day 1 to  $2.7 \pm 1.6 \text{ ng/mL}$  from day 5 through day 28. The average intake of the breastfed infant in the first month was 2.0  $\mu\text{g/day}$ . Elevated manganese levels have been associated with ADHD, hyperactive behaviors, and low verbal and visual memory.<sup>146</sup>

The main biochemical role of molybdenum in mammals is as a cofactor for several enzymes.<sup>20</sup> Deficiencies are rare, usually occurring in those receiving total parenteral nutrition. Molybdenum levels in human milk were measured from day 1 through day 38. Levels began at  $15.0 \pm 6.1 \mu\text{g/dL}$  and leveled off at 1 to 2  $\mu\text{g/dL}$  at 1 month.<sup>22</sup>

Nickel is generally accepted as an essential trace element for animals, but its role in humans is undefined. Levels in human milk are stable over time at 1.2  $\mu\text{g/dL}$ . The average daily intake of nickel at 1 month was 0.8  $\mu\text{g}$ .

## FLUORINE

Fluorine has been widely accepted as a significant dietary factor in decreasing dental caries (see Table 4-24). The effect has been associated with the conversion of the enamel hydroxyapatite to fluorapatite with a reduction in acid solubility. The presence of fluorine during the formation of hydroxyapatite may create less soluble, more resistant crystals.

Conflicting reports of the fluorine levels in human milk have led to the belief that breastfed infants needed supplementation.<sup>94</sup> More accurate studies in communities where fluoride has been in the public drinking water supply show 7 mg of fluorine per liter (range 4 to 14 mg/L).<sup>44</sup> The American Academy of Pediatrics no longer recommends routinely supplementing breastfed infants with fluorine<sup>7</sup> (see Chapter 9).

The significant development of deciduous and permanent teeth occurs after birth and depends on fetal stores of fluorine as well as on fluorine available in the diet. Studies comparing breastfed

and bottle-fed infants show a distinct difference, with fewer dental caries and better dental health in breastfed infants. The role of fluorine and other factors, such as selenium, that predispose the breastfed infant to healthier teeth has yet to be defined completely. Nursing-bottle caries add to the total dental caries of the bottle-fed infant.

## IODIDE

Many individuals are iodide deficient, especially women of reproductive age. Cause is unknown but the lack of use of iodized salt, the use of processed foods, and geographic location are considerations. This is of serious concern because iodine deficiency during pregnancy and lactation is associated with brain development in the offspring. The risk is greater with the increase in environmental pollutants such as nitrate, thiocyanate, and perchlorate. Pregnant and lactating women should take a supplement containing adequate iodide. Not all supplements contain enough. The American Thyroid Association and the National Academy of Sciences recommend that lactating women have a total intake of 290 µg of iodide per day, which usually requires a supplement with 150 µg of iodide. An intake of 150 µg of potassium iodide is equivalent to only 120 µg or less of iodide.<sup>29</sup> Environmental chemicals such as thiocyanate, nitrate, and perchlorate compete for transport by the sodium-iodide symporter (NIS). The NIS is an integral plasma membrane glycoprotein found in the thyroid gland and the breast, which mediates the iodide transport into thyroid cells, the first step in thyroid hormone synthesis. In the mammary gland, NIS mediates the transport of iodide into milk. Thiocyanate is found in cruciferous vegetables and tobacco smoke. Nitrate is found in some drinking water and root vegetables. Perchlorate is used in industry as an oxidizer and is found naturally in arid regions such as the southwestern United States. It has been detected in many foods, drinking water, and cow milk. The EPA developed regulations for perchlorate in drinking water in 2011. Worldwide agencies have taken similar steps.

Mothers should take at least 150 µg of iodide daily and use iodized table salt, according to the Council on Environmental Health of the AAP.<sup>29</sup> They should also avoid nitrates, especially from well water, which should be checked annually. Tobacco smoke and second hand smoke contain thiocyanates, which should also be avoided. The World Health Organization has also adopted similar guidelines for adults and children.

Spot urine tests of iodine in mcg/L

Mean UI Concentration (g/L)	Corresponding Intake (µg/dL)	Iodine Status
<20	<30	Severe deficiency
20-49	30-74	Moderate deficiency
50-99	75-149	Mild deficiency
100-199	150-299	Optimal
200-299	300-449	More than adequate
>299	>449	Possible excess

Assessment of iodine intake is most commonly done by random urinary spot iodine assessments. The World Health Organization has adopted these guidelines for adults and children.

## PH AND OSMOLARITY

The pH range in human milk is 6.7 to 7.4, with a mean of 7.1. The mean pH of cow milk is 6.8. The caloric content of both human and cow milk is 65 kcal/dL or 20 kcal/oz. The specific gravities are 1.031 and 1.032, respectively.

The osmolarity of human milk approximates that of human serum, or 286 mosmol/kg of water, whereas that for cow milk is higher at 350 mosmol. The renal solute load of human milk is considerably lower than that of cow milk. Renal solute load is roughly calculated by totaling the solutes that must be excreted by the kidney. It consists primarily of nonmetabolizable dietary components, especially electrolytes, ingested in excess of body needs, and metabolic end products, mainly from the metabolism of protein. Renal solute load can be estimated by adding the dietary intake of nitrogen and three minerals—sodium, potassium, and chloride. Each gram of protein is considered to yield 4 mosmols (as urea), and each milliequivalent of sodium, potassium, and chloride is 1 millesmoll. The renal solute load of cow milk is 221 milleosmol, compared with 79 milleosmols for human milk.

Dearlove and Dearlove investigated osmoregulation in human lactation in an effort to determine whether fluid loading was a valid clinical maneuver. It is known that an oral hypotonic fluid load results in suppression of prolactin in adults. After an intravenous hypotonic saline infusion, a significant correlation was seen between serum osmolarity and prolactin. No changes in serum prolactin, milk yield, serum, or breast milk osmolarity were noted, however, when normal lactating women were given a hypotonic fluid load in a controlled study.

## CAROTENOIDS: LUTEIN

Lutein is the dominant carotenoid in the infant brain and the major carotenoid found in the retina of the eye. Its levels vary in breast milk reflecting the mother's dietary intake. Supplementation was studied in 89 lactating women<sup>137</sup> who were 4 to 6 weeks postpartum. They were randomly given a placebo of 0 mg/day of lutein, or 6 mg/day (low dose), or 12 mg/day (high dose). The dose was taken for 6 weeks along with their normal diet. Breast milk levels of plasma carotenoids were measured weekly by high performance liquid chromatography (HPLC) and at the end of the study. Infant plasma levels were measured at the end of the study and maternal plasma levels were assessed both at the beginning and the end of the study. No significant differences were found between dietary lutein plus zeaxanthin intake, and levels found of carotenoid in the milk, the infant plasma, or body mass index were higher by 170% and 250% in the treated groups compared to the placebo group. Other carotenoids were not affected.

## VITAMINS

### Vitamin A

Vitamin A content is 75 mg/dL or 280 international units (IUs) in mature human milk and only 41 mg/dL or 180 IU in cow milk (Table 4-25). Thus the supply of vitamin A and its precursors, carotenoids (e.g., β-carotene), is considered adequate to meet the estimated daily requirement, which varies from 500 to 1500 IU/day if the infant consumes at least 200 mL

of breast milk per day (Table 4-26). Twice as much vitamin A is present in colostrum as in mature milk. During the first 6 months, the retinol equivalent (RE) content of term milk in developing countries is only 330 mg RE/L compared to 660 mg in developed countries.<sup>118</sup> Retinol content of milk of mothers who deliver prematurely is even higher. A single 60-mg supplement of β-carotene sustained elevated β-carotene concentrations in serum and milk longer than 1 week in normal mothers but did not affect concentrations of other major carotenoids, retinol, or tocopherol.<sup>18</sup> Vitamin A intake and serum vitamin A concentrations during pregnancy influence the composition of breast milk. Human milk is a vital source of vitamin A in developing countries, even beyond the first year of life.<sup>123,126</sup>

Vitamin A supplementation has been a major project of WHO. Technology used to test samples of milk for vitamin A before and after treatment have been studied.<sup>45</sup> HPLC gave higher values than iCheck. When checks are being done to measure change with treatment, the same method must be used throughout.

### Vitamin D

Vitamin D has always been included in the fat-soluble vitamin group because that is the form in which it had been identified in nature. The levels in human milk were 0.05 mg/dL, previously reported in the fat fraction. Human milk was shown to have vitamin D in both the fat and the aqueous fractions. Investigators measured the water-soluble

**TABLE 4-25** Vitamins and Other Constituents of Human Milk and Cow Milk (per Deciliter)

Milk Elements	Colostrum	Transitional	Mature	Cow Milk
Vitamin A (μg)	151.0	88.0	75.0	41.0
Vitamin B <sub>1</sub> (μg)	1.9	5.9	14.0	43.0

sulfate conjugate of vitamin D and evaluated the biologic activity of the water-soluble metabolites. The water-soluble fraction is considered to be inactive metabolites. When activity is calculated by an assay that measures stimulation of intestinal calcium transport, human milk is found to contain 40 to 50 IU/L of vitamin D activity. The metabolite 25-hydroxyvitamin D<sub>3</sub> accounts for 75% of the activity; vitamins D<sub>2</sub> and D<sub>3</sub> account for 15%. Vitamin D sulfate, or any other as yet unidentified water-soluble metabolite of vitamin D, has not been proven to have significant biologic activity.

The impact of the maternal diet content of vitamin D was measured in a double-blind study of white mothers in a temperate climate in the winter. A direct relationship was seen between maternal and infant levels of 25-OH-vitamin D<sub>3</sub> and maternal diet.<sup>150</sup> An additional group of infants, whose mothers' diets were unsupplemented, received 400 IU of vitamin D per day and had even higher serum concentrations of 25-OH-vitamin D<sub>3</sub>. When mothers have been given large doses of vitamin D, the content of vitamin D and D<sub>3</sub> in their milk increases as it does with exposure to sunshine. The level of 25-OH-vitamin D does not change. The majority of the activity in human milk is in the form of 25-OH-vitamin D. This may be an advantage for the breastfed infant, who utilizes this form most readily. Clearly, the levels vary and may be inadequate in human milk in some situations, especially in cold climates in the winter with little sunshine and for dark-skinned individuals.

In a review of vitamin D in adults, especially pregnant women, Hollis<sup>69</sup> clearly demonstrated that traditional levels of vitamin D of 400 IU/day or less are grossly inadequate today when few women get adequate sun exposure and many wear sunscreen or clothing that obstructs the exposure. Most recommendations were done before it was possible to measure circulating 25-(OH)-vitamin D, the true indicator of nutritional vitamin D status. The dose of 10 mg or 400 IU daily had little effect on adult 25-(OH)-vitamin D levels. When

submariners were given 600 IU/day for several months, they failed to maintain adequate 25-(OH)-vitamin D levels.<sup>68</sup> The dose that is adequate during pregnancy is a minimum of 1000 IU daily. Doses of 10,000 IU daily in adults did not elevate circulating 25-(OH)-vitamin D above the normal range, and doses of 1000 IU may not maintain normal levels. The resurgence of rickets in infants may well begin with inadequate levels in pregnancy.<sup>150</sup>

Cases of vitamin D-deficiency hypocalcemia and rickets in nonwhite infants have been reported in increasing numbers in exclusively breastfed infants.<sup>23</sup> The epidemic is aggravated by the use of sunscreen, ethnic traditions of covering the body, and lack of sunshine.<sup>145</sup> Serum 1,25-dihydroxyvitamin D concentrations are significantly higher in lactating compared with nonlactating women and among vegetarian compared with nonvegetarian women, report Specker et al.<sup>142</sup> All lactating women in a study by Chang had elevated serum parathyroid hormone levels (see Table 4-26). Levels of vitamin D are higher in colostrum than in mature milk.<sup>95</sup> Studies by Waggoner et al. provided high levels of vitamin D (4000 IU/day) to mothers to increase their milk levels.<sup>149</sup> A study of exclusively breastfed infants was conducted placing the infants at 1 month of age in one of four doses of vitamin D categories (200, 400, 600, 800 IU/day). At 1 month most of the infants had levels below normal. Seventy-two percent had levels below 88.2 + 23.0 nmol/L 25(OH) D concentrations. During the study, low levels were noted occasionally in all categories. Ziegler et al.<sup>154</sup> concluded that 400 IU/day should be standard for infants and that supplementation should start at birth.

It has been recommended by the AAP that all breastfed infants receive 400 IU of vitamin D beginning at birth. Until pregnant and lactating women who are at risk for inadequate intake receive adequate supplements, it will be necessary to supplement normal breastfeeding infants.<sup>126,57</sup>

The concern for toxicity of excessive vitamin D was based on the reported relationship with cardiac disease and supravalvular aortic stenosis syndrome

and William syndrome, which has been proved to be genetic. Hypervitaminosis from high levels of vitamin D has resulted from therapeutic misadventures resulting in hypercalcium when the circulating 25-(OH)-vitamin D concentrations were over 100 ng/mL (normal levels of 25-(OH)-vitamin D are over 15 ng/mL serum). No case of hypervitaminosis D has been reported from sun exposure even though a half hour in the summer sun between 10 AM and 2 PM in a bathing suit (approximately 3 minimal erythema dose exposures) will release about 50,000 IU or 1.25 mg/day of vitamin D within 24 hours in most white persons.<sup>69</sup>

## Vitamin E

Vitamin E has been a subject of much interest. Levels in colostrum are 1.5 mg/dL, whereas transitional milk has 0.9 mg/dL and mature milk has 0.25 mg/dL. The difference at different stages has been found to be caused by  $\alpha$ -tocopherol, because the contents of  $\beta$ - and  $\gamma$ -tocopherol are similar. Total tocopherol in mature milk correlates with total lipid and linoleic acid contents. Significantly higher tocopherol/linoleic acid ratios are found in both colostrum and transitional milk than in mature milk.

Cow milk has 0.07 mg/dL of vitamin E (see Table 4-25). Correspondingly, serum levels in breastfed infants rise quickly at birth and maintain a normal level, whereas cow milk-fed infants have depressed levels. Vitamin E includes a group of fat-soluble compounds ( $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocopherol) and their unsaturated derivatives ( $\alpha$ -,  $\beta$ -,  $\gamma$ -, and  $\delta$ -tocotrienol). An IU of vitamin E is equal to 1 mg of synthetic  $\alpha$ -tocopherol or 0.74 mg of natural  $\alpha$ -tocopherol acetate.

Vitamin E is required for muscle integrity, resistance of erythrocytes to hemolysis, and other biochemical and physiologic functions. The requirement for vitamin E is related to the PUFA content of the cellular structures and of the diet (see Table 4-26). Satisfactory plasma levels are 1 mg/dL, and these levels can be maintained by feedings with a vitamin E/PUFA ratio of 0.4 mg/g. The requirement for infants to age 6 months is 3 mg/day and after 6 months 4 mg/day. The requirement during lactation is 14 mg during the first 6 months and 17 mg/day after 6 months postpartum.

An estimate of the tocopherol/linoleic acid ratio in mature milk is 0.79 mg  $\alpha$ -tocopherol equivalents per gram, which is comparable to a daily requirement of 0.5 mg for term infants but may be low for premature infants, especially those receiving iron supplements. Ordinarily, this would be supplied by 4 IU of vitamin E per day. Because human milk contains 1.8 mg/L or 40 mg of vitamin E per gram of lipid, it supplies more than adequate levels of vitamin E.<sup>88</sup>

## Vitamin K

Vitamin K is essential for the synthesis of blood-clotting factors, which are normal in the serum at birth. The previous levels of vitamin K reported in human milk (15 mg/dL) have been replaced with those calculated by more accurate techniques and are lower: 2.1 mg/L for mature milk and 2.3 mg/L for colostrum,<sup>21</sup> which are less than the recommended daily intake of 12 mg/day (Table 4-27).

The measurements of the homologs of vitamin K have been equivocal. When mothers are given a single dose of 20 mg of phylloquinone (K<sub>1</sub>), the milk level increases from 1 to 140 mg/L in 12 hours, dropping to 5 mg/L in 48 hours.

When infants are given 1 mg vitamin K<sub>1</sub> at birth, as is the practice in many countries, the concentration of K<sub>1</sub> in both breastfed and formula-fed infants in the first week of life remains elevated. When no neonatal prophylaxis is given, Büller et al.<sup>17</sup> reported no difference in coagulating factors among a sample of 113 breastfed, formula-fed, or combination-fed infants. They reported a case of low vitamin K levels in the milk of a mother whose infant died at 6 weeks from intracranial bleeding without neonatal prophylaxis.

Vitamin K is produced by the intestinal flora but takes several days in the previously sterile neonatal gut to be effective. Vitamin K-dependent clotting factors in normal breastfed infants were normal. The prothrombin time and partial thromboplastin time were similar in breastfed and bottle-fed infants. The Normotest and Thrombotest coagulation tests were significantly prolonged in the breastfed group. The authors concluded that 5% of breastfed children have possible vitamin K deficiency. In several case reports, 179 infants exclusively breastfed with no vitamin K given at birth developed late-onset hemorrhagic disease that responded to vitamin K administration. O'Connor et al.<sup>120</sup> note the association of vitamin K

**TABLE 4-27** Recommended Daily Dietary Allowances of Vitamins for Infants\*

Diets should be based on a variety of common foods in order to provide other nutrients for which human requirements have been less well defined.

From Food and Nutrition Board, National Research Council, National Academy of Sciences: *Recommended dietary allowances*, ed 10, Washington, D.C., 1989, U.S. Government Printing Office.

deficiency with home birth and suggest that the physician give vitamin K immediately as recommended by the American Academy of Pediatrics if it has been omitted.<sup>7</sup>

At 3 months of age, 165 breastfed infants who had received 1 mg vitamin K<sub>1</sub> at birth had reduced serum levels of vitamin K<sub>1</sub>. Their clotting factors were unchanged. For complete protection, Cornelissen et al.<sup>28</sup> recommend a second oral dose of vitamin K<sub>1</sub> at 3 months. In a similar study, Greer et al. found that despite low plasma phylloquinone concentrations in the breastfed infant (less than 0.25 ng/mL) for the first 6 months, continued vitamin K<sub>1</sub> supplementation was not recommended. Canfield et al.<sup>21</sup> confirm the low levels of vitamin K<sub>1</sub> in breastfed infants compared with those in infants fed formula containing many times the recommended daily dose (0.5 ng/day). No requirements have been set for breastfed infants. No data are available regarding the potential toxicity of excessive vitamin K.

It is recommended that all infants receive vitamin K at birth, regardless of feeding plans, to prevent hemorrhagic disease of the newborn caused by vitamin K deficiency in the first few days of life.<sup>7</sup>

The vitamin content of common foods has been recalculated downward so that diets of average women are probably deficient in vitamin K. Furthermore, vitamin K levels in the serum of lactating women are not good markers of deficiency. Carboxylated prothrombin (des-γ-carboxyprothrombin) is produced in the absence of vitamin K and is a marker of vitamin K deficiency. Greer et al.<sup>58</sup> followed breastfed infants and found normal des-γ-carboxyprothrombin levels at birth and 4 weeks but elevations by 8 weeks. The authors recommend maternal supplementation during lactation.

## Vitamin C

Vitamin C is part of several enzyme and hormone systems, as well as of intracellular chemical

reactions. It is essential to collagen synthesis (Tables 4-28 and 4-29).

Human milk is an outstanding source of water-soluble vitamins and reflects maternal dietary intake (see Table 4-26). Increased vitamin C has been measured in the milk within 30 minutes of a bolus of vitamin C being given to the mother. Human milk contains 43 mg/dL (fresh cow milk contains up to 21 mg). Levels obtained in normal lactating women 6 months postpartum were 35 mg/L in those on normal diets and 38 mg/L in those supplemented with multivitamins containing 90 mg vitamin C.<sup>138</sup> Levels obtained in 16 lactating women of low-socioeconomic level were 53 mg/L for unsupplemented and 65 mg/L for supplemented mothers at 1 week postpartum and 61 and 72 mg/L, respectively, at 6 weeks postpartum. Several subjects in the unsupplemented low-socioeconomic group had levels too low to provide 35 mg vitamin C per day to their infants.

When lactating women were given 250, 500, or 1000 mg/day vitamin C for 2 days, milk levels remained within the range of 44 to 158 mg/L and did not differ significantly between dosages, even at 10 times the recommended dietary allowance (RDA). Total intake of the infant through the milk ranged from 49 to 86 mg/day. These findings suggest a regulatory mechanism for vitamin C levels in milk. When women received high doses of vitamin C, levels of the vitamin excreted in the urine also increased proportionately.<sup>127</sup>

## VITAMIN B COMPLEX

### Vitamin B<sub>1</sub>

Vitamin B<sub>1</sub>, or thiamin, levels increase with the duration of lactation but are lower in human milk (160 mg/dL) than in cow milk (440 mg/dL) (see Tables 4-28 and 4-29). In a study by Nail et al., levels obtained by normal lactating women showed significant increases between 1 and 6 weeks postpartum, but no difference in levels between supplemented (1.7 mg daily) and unsupplemented women

**TABLE 4-28** Recommended Daily Dietary Allowances of Water-Soluble Vitamins for Infants\*

Age	Vitamin C (mg)	Thiamin (mg)	Riboflavin (mg)	Niacin (mg NE) <sup>†</sup>	Vitamin B <sub>6</sub> (mg)	Folacin <sup>‡</sup> (μg)	Vitamin B <sub>12</sub> (μg)
To 6 mo	30	0.3	0.4	5	0.3	25	0.3
6 mo-1 yr	35	0.4	0.5	6	0.6	35	0.5

\*The allowances are intended to provide for individual variations among most normal persons as they live in the United States under usual environmental stresses. Diets should be based on a variety of common foods in order to provide other nutrients for which human requirements have been less well defined.

<sup>†</sup>1 NE (niacin equivalent) is equal to 1 mg of niacin or 60 mg of dietary tryptophan.

<sup>‡</sup>The folacin allowances refer to dietary sources as determined by *Lactobacillus casei* assay after treatment with enzymes (conjugases) to make polyglutamyl forms of the vitamin.

From Food and Nutrition Board, National Research Council, National Academy of Sciences: *Recommended dietary allowances*, ed 10, Washington, D.C., 1989, U.S. Government Printing Office.

**TABLE 4-29** Estimated Secretion of Nutrients in Mature Human Milk Compared with Increments in Recommended Dietary Allowances (RDA) for Lactating Women

**A. Energy, protein, and fat-soluble vitamins**

Measure	Energy (kcal)	Protein (g)	Vitamin A ( $\mu$ g RE)	Vitamin D ( $\mu$ g)	Vitamin E (mg of $\alpha$ -TE)	Vitamin K ( $\mu$ g)
Estimated secretion in milk*	420-700	6.3-10.5	400-670	0.3-0.6	1.4-2.3	1.3-2.1

**Increment in RDAs<sup>†,‡</sup> for following lactation periods**

0-6 mo	500	15	500	5	4	0
6-12 mo	500	12	400	5	3	0
Comments	Estimated 80% efficiency in conversion to milk energy	Estimated 70% efficiency in conversion to milk protein	None	Increment advised in part to maintain calcium balance	Estimated 75% absorption	No increment listed because intakes usually exceed RDA

**B. Water-soluble vitamins**

Measure	Vitamin C (mg)	Thiamin (mg)	Riboflavin (mg)	Niacin (mg of NE)	Vitamin B <sub>6</sub> (mg)	Folate ( $\mu$ g)	Vitamin B <sub>12</sub> ( $\mu$ g)
Estimated secretion in milk*	24-40	0.13-0.21	0.21-0.35	0.9-1.5	0.06-0.09	50-83	0.6-1.0

**Increment in RDAs<sup>†,‡</sup> for following lactation periods**

0-6 mo	35	0.5	0.5	5	0.5	100	0.6
6-12 mo	30	0.5	0.4	5	0.5	80	0.6
Comments	Estimated 85% absorption	Increment higher than secretion because of increased energy needs	Estimated 70% utilization for milk production	Increment higher than secretion because of increased energy needs	Milk concentration used is for unsupplemented women	Estimated 50% absorption; RDA based on 50 rather than 83 $\mu$ g/L	RDA based on 0.6 rather than 1.0 $\mu$ g/L

**C. Minerals**

Measure	Calcium (mg)	Phosphorus (mg)	Magnesium (mg)	Iron (mg)	Zinc (mg)	Iodine ( $\mu$ g)	Selenium ( $\mu$ g)
Estimated secretion in milk*	168-280	84-140	21-35	0.18-0.30	0.9-1.5 <sup>§</sup> 0.3-0.5 <sup>¶</sup>	66-110	12-20
<b>Increment in RDAs<sup>†‡</sup> for following lactation periods</b>							
0-6 mo	400	400	75	0	7	50	20
6-12 mo	400	400	60	0	4	50	20
Comments	None	Based on desired 1:1 ratio for calcium/phosphorus intake	Estimated 50% absorption	Secretion during lactation is less than menstrual loss	Estimated 20% absorption	Based on need of infant, not maternal loss in milk	Estimated 80% absorption

$\alpha$ -TE,  $\alpha$ -tocopherol equivalents; NE, niacin equivalents; RE, retinol equivalents.

\*At volumes of 600-1000 mL/day, based on milk composition shown in [Table 4-13](#).

<sup>‡</sup>Women aged 25 to 50.

<sup>§</sup>0 to 6 months.

<sup>¶</sup>6 to 12 months.

From Report of Nutrition During Lactation Subcommittee, Institute of Medicine: *Nutrition during lactation*, Washington, D.C., 1991, National Academy Press.

was seen. Cases of beriberi in infants have been associated with a deficiency in the mother.

Because urinary excretion of thiamin is significantly higher in supplemented than in un-supplemented women, the amount of vitamin transferred into milk appears to be limited.<sup>127</sup> Mal-nourished women, however, do show significant increases in their milk when supplemented.<sup>94</sup> Thiamin is essential for the use of carbohydrates in the pyruvate metabolism (cofactor in pyruvic acid decarboxylation) and for fat synthesis. Insufficient thiamin produces insufficient carbohydrate oxidation with accumulation of intermediary metabo-lites such as lactic acid.

## Vitamin B<sub>2</sub>

Vitamin B<sub>2</sub>, or riboflavin, is significant for the new-born in whom intestinal tract bacterial synthesis is minimal (see Tables 4-28 and 4-29). Riboflavin is involved in oxidative intracellular systems and is essential for protoplasmic growth. Levels are 36 mg/dL in human milk and 175 mg/dL in cow milk.

Levels obtained in normal lactating women showed significantly lower levels of riboflavin in the milk of the unsupplemented women (36.7 mg/dL) at 1 week compared with the milk of the supple-mented women, who received 2 mg/day in a multi-vitamin (80.0 mg/dL). No significant difference was seen between 1 and 6 weeks in either group.

## Niacin

Niacin (nicotinamide) is an essential part of the pyridine nucleotide coenzymes and is part of the intracellular respiratory mechanisms. Human milk has 147 mg/dL and cow milk has 94 mg/dL (see Tables 4-28 and 4-29). Levels respond to dietary supplementation.

## Vitamin B<sub>6</sub>

Vitamin B<sub>6</sub> (pyridoxine) forms the enzyme group of certain decarboxylases and transaminases involved in metabolism of nerve tissue. The supply of vitamin B<sub>6</sub> is vital to DNA synthesis, which is needed to form the cerebrosides in the myelination of the CNS. Human milk has 12 to 15 mg/dL of vitamin B<sub>6</sub> and cow milk has 64 mg/dL (see Tables 4-28 and 4-29). The principal form of vitamin B<sub>6</sub> in human milk is pyridoxal, but pyridoxine is the principal form of vitamin B<sub>6</sub> fortification in infant formulas. Levels of vitamin B<sub>6</sub> in the milk of mothers consuming more than 2.5 mg of the vitamin daily (RDA for lactating women is

2.5 mg/day) were significantly higher in the first week than were levels in the unsupplemented mothers' milk. Average maternal diets in several studies were consistently below the recommended levels of vitamin B<sub>6</sub>.

The accumulated stores of vitamin B<sub>6</sub> during pregnancy are significant for the maintenance of adequate vitamin B<sub>6</sub> status of infants during the early months of breastfeeding. For some infants, human milk alone without supplementary foods may be insufficient to meet vitamin B<sub>6</sub> needs after 6 months of age.<sup>66</sup> The recommended daily intake for infants under 6 months of age is 0.30 mg. Vita-min B<sub>6</sub> deficiency has been associated with CNS disorders in three breastfed infants.

Long-term use of oral contraceptives has been shown to result in low levels of vitamin B<sub>6</sub> in mater-nal serum in pregnancy and at delivery and low levels in the milk of these mothers.<sup>144</sup> The relation-ship of vitamin B<sub>6</sub> supplements to suppression of prolactin and the treatment of galactorrhea is dis-cussed under lactation failure (see Chapter 16). The doses used to suppress lactation (600 mg/ day) far exceed the levels in multiple vitamins (1 to 10 mg) (see Table 4-29).

## Pantothenic Acid

Pantothenic acid is part of CoA, a catalyst of acetyl-lation reactions. The reaction of CoA with acetic acid to form acetyl-CoA is prime to intermediary metabolism. The levels of pantothenic acid in human milk were restudied by Johnston et al. because of the range of values in the literature. They found the mean to be 670 mg/dL in foremilk and hindmilk samples. No change occurred in concentrations from 1 to 6 months postpartum. They did find a positive correlation with dietary intake.

## Folacin

Folacin (folic acid) is part of the conversion of glycine to serine. It is also involved in the meth-ylation of nicotinamide and homocysteine to methionine. It is essential for erythropoiesis (see Table 4-28).

The folate (anionic form of folic acid) content of human milk produced by well-nourished women averages 80 to 130 mg/L (see Table 4-29).<sup>120</sup> These values are substantially greater than those reported in the literature previously because of difficulty in the analysis. Folate in human milk is quantitatively bound to folate-binding proteins and presents in multiple labile forms. Folate values typically increase as lactation progresses and are even main-tained as maternal stores begin to be depleted.

Supplementation with folic acid in deficient mothers caused prompt increase in levels in the milk. When mothers and their infants were evaluated, folate levels were two to three times higher in the breastfed infants than in their mothers, and a correlation was seen between levels in the milk and in the infants' plasma. Folic acid has also been identified as a critical element in deficiency states during pregnancy, being associated with abruptio placentae, toxemia, and intrauterine growth failure as well as megaloblastic anemia.

## Vitamin B<sub>12</sub>

Early studies reported that vitamin B<sub>12</sub> is found in human milk in a low concentration of 0.3 mg/L, whereas cow milk has 4.0 mg/mL. Well-nourished mothers on balanced diets appear to have adequate amounts for their infants.<sup>144</sup> Microbiologic assay has demonstrated that high concentrations of vitamin B<sub>12</sub> appear in early colostrum but level off in a few days to those of serum. Samples of colostrum reported by Samson and McClelland have a mean binding capacity of 72 ng/mL; in mature milk the capacity is one third of this value. Vitamin B<sub>12</sub> levels were compared by Sandberg et al.<sup>134</sup> in supplemented and unsupplemented mothers and were not significantly different. Levels were 33 to 320 ng/dL, with a mean of 97 ng/dL. When nutritionally deficient, low-socioeconomic lactating women were studied by Sneed et al., supplementation with a multivitamin did result in elevated vitamin B<sub>12</sub> levels. This was true for folate as well.

Although cow milk has five to 10 times more vitamin B<sub>12</sub> than mature human milk, cow milk has little vitamin B<sub>12</sub>-binding capacity, which is substantial in human milk. Vitamin B<sub>12</sub> functions in transmethylations such as synthesis of choline from methionine, serine from glycine, and methionine from homocysteine. It is involved in pyrimidine and purine metabolism. Vitamin B<sub>12</sub> also affects the metabolism of folic acid. Megaloblastic anemia is a common symptom of vitamin B<sub>12</sub> deficiency. Vitamin B<sub>12</sub> occurs exclusively in animal tissue, is bound to protein, and is minimal or absent in vegetable protein.<sup>126</sup>

The recommendation for the minimum daily requirement of B<sub>12</sub> for infants is 0.3 mg/day in the first year of life, when growth is rapid (see Table 4-28). Based on their data on omnivorous and vegetarian women, Specker et al.<sup>141</sup> conclude that the current RDA for infants provides little margin for safety (see Table 4-29).

## ENZYMES

Considerable data have been collected on the enzymatic activities of many milks. Jenness and

Sloan report 44 enzymes detected in bovine, human, and other milks. Xanthine oxidase, lactoperoxidase, uridine diphosphogalactose, galactosyl transferase, ribonuclease, lipase, alkaline phosphatase, acid phosphatase, and lysozyme have been isolated in crystalline form.

The role and significance of enzymes in human milk were reviewed by Hamosh,<sup>62</sup> who confirmed that more than 20 active human milk enzymes exist (Table 4-30). They can be categorized into three general groups by their activity: mammary gland function, which reflects physiologic changes occurring in the mammary gland itself during lactation; compensatory digestive enzymes in human milk, which have digestive functions in the neonate; and milk enzymes, important in stimulating neonatal development.<sup>62</sup> Some enzyme levels are significantly higher in colostrum than in mature milk. Most are whey proteins and contribute minimally to milk proteins. Some enzymes, like other proteins in milk, are probably produced elsewhere and transported to the breast via the bloodstream. The evidence to support the concept of local synthesis includes the demonstration of secretory tissue in the mammary gland. Amylase levels are twice as high in milk as in serum.<sup>96</sup> Casein proteins have been synthesized in vitro in cell-free mammary-derived mRNA-enriched systems. Mammary explants from mice, monkeys, and humans have accumulated lactose synthetase B. The enzymes of possible importance in infant digestion are those with pancreatic analogs: amylase, lipases, protease(s), and ribonuclease.

## Amylase

Amylase, the chief polysaccharide-digesting enzyme, is not developed at birth even in full-term infants, who have only 0.2% to 0.5% of adult values. Mammary amylase is present, however, throughout lactation, with levels higher in colostrum than in mature milk. Human milk levels are 0.5 to 1.0 g/dL oligosaccharides of varying chain length. Milk levels of preterm mothers are comparable to term milk levels.

Milk levels are twice those of serum in the first 90 days and remain higher than serum over 6 months. When exposed to a pH of 5.3, this salivary-type amylase remains active; at a pH of 3.5, one half the original activity is present at 2 hours and one third at 6 hours. Amylase is stable at -20°C to -70°C (-4°F to -94°F) for storage and at least for 24 hours at 15°C to 38°C (59°F to 100°F). Much milk amylase activity remains in the duodenum after a meal of human milk. This is significant for the digestion of starch because pancreatic amylase is still low in infants. Mammary

amylase may be an alternate pathway of digestion of glucose polymers and of starch (Table 4-31).

Milk amylase is part of the isozyme group as salivary amylase and is thought to inhibit the growth of certain microorganisms.

## Lipases

Milk fat is almost completely digestible. The emulsion of fat in breast milk is greater than in cow milk, resulting in smaller globules. Milk lipases play an active role in creating the emulsion, which yields

a finer curd and facilitates the digestion of triacylglycerols. The newborn easily digests and completely uses the well-emulsified small fat globules of human milk. Free fatty acids are important sources of energy for the infant.

Lipase in human milk was first described in 1901. At least two different lipases (glycerol ester hydrolases) were described then. The lipases in human milk make the free fatty acids available in a large proportion even before the digestive phase of the intestine. The lipolytic milk-enzyme activity is similar to the activity of pancreatic lipase,

**TABLE 4-30** Component Functions in Human Milk

Function	Component	Process
Biosynthesis of milk components in mammary gland	Phosphoglucomutase	Synthesis of lactose
	Lactose synthetase	Synthesis of lactose
	Fatty acid synthetase	Synthesis of medium-chain fatty acids
	Thioesterase	Uptake of circulating triglyceride fatty acids
	Lipoprotein lipase	Uptake of circulating triglyceride fatty acids
Digestive function in infant	Amylase	Hydrolysis of polysaccharides
	Lipase (bile salt-dependent)	Hydrolysis of triglycerides
	Proteases	Proteolysis (not verified)
	Xanthine oxidase	Carrier of iron, molybdenum
	Glutathione peroxidase	Carrier of selenium
	Alkaline phosphatase	Carrier of zinc, magnesium
Preservation of milk components	Antiprotease	Protection of bioactive proteins (i.e., enzymes and immunoglobulins)
	Sulfhydryl oxidase	Maintenance of structure and function of proteins containing disulfide bonds
Antiinfective agents	Lysozyme	Bactericidal
	Peroxidase	Bactericidal
	Lipases (lipoprotein lipase, bile salt-dependent lipase)	Release of free fatty acids that have antibacterial, antiviral, and antiprotozoan actions
Antiinflammatory agents	Vitamins A, C, and E	Scavenge oxygen radicals
	Catalase	Degradates hydrogen peroxide
	Glutathione peroxidase	Prevents lipid peroxidation
	Platelet-activating factor acetylhydrolase	Degradates platelet-activating factor
	α1-Antitrypsin	Inhibits inflammatory proteases
	α1-Antichymotrypsin	Inhibits inflammatory proteases
	Prostaglandin 1	Cytoprotective
	Prostaglandin 2	Cytoprotective
	Epidermal growth factor	Promotes gut growth and function
	Transforming growth factor-α	Promotes epithelial cell growth
	Transforming growth factor-β	Suppresses lymphocyte function
	Interleukin 10	Suppresses function of macrophages and natural killer and T cells
	Transforming growth factor-α receptors I and II	Binds to and inhibits transforming growth factor-α

From Hamosh M: Enzymes in human milk: their role in nutrient digestion, gastrointestinal function and nutrient delivery to the newborn infant. In Lebenthal E, editor: *Textbook of gastroenterology and nutrition in infancy*, ed 2, New York, 1989, Raven; Hamosh M: Bioactive factors in human milk. Breastfeeding 2001, Part I: the evidence for breastfeeding, *Pediatr Clin North Am* 48:69, 2001.

Characteristics of Milk Enzymes Active in Infant Digestion		
Characteristic	Amylase	BSSL
High parity ( $\geq 10$ )	Low activity	?
Malnutrition	?	Decrease in activity
Diurnal and within feed activity	Constant	Constant
Prepartum	?	Present
Presence in preterm (PT) and term (T) milk	Equal activity PT and T	Equal activity PT and T
Pattern through lactation	Colostrum greater than milk	Colostrum lower than milk
Weaning	?	Activity constant independent of milk volume
Distribution in milk	Skim milk	Skim milk
Effect of milk storage $-20^{\circ}\text{C}$ to $-70^{\circ}\text{C}$ , $15^{\circ}\text{C}$ to $38^{\circ}\text{C}$	Stable years Stable ( $\leq 24$ h)	Stable years Stable ( $\leq 24$ h)
Stability to low pH (passage through stomach)	pH > 3.0	pH > 3.0
Optimum pH	6.5-7.5	7.4-8.5
Enzyme characteristics	Salivary amylase isozyme	Identical with pancreatic carboxyl ester hydrolase
Evidence of activity in infant's intestine	Yes	Yes
Presence in milk of other species	?	Primates, carnivores, and rodents

BSSL, Bile salt-stimulated lipase.

From Hamosh M: Enzymes in human milk. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press; Hamosh M: Bioactive factors in human milk. Breastfeeding 2001, Part I: the evidence for breastfeeding. *Pediatr Clin North Am* 48:69, 2001.

breaking down triglycerides to free fatty acids and glycerol. One enzyme is present in the fat fraction and is inhibited by bile salts.<sup>62</sup>

Milk from undernourished mothers may lose some of its ability to hydrolyze milk-lipid esters over the course of lactation; this ability remains constant in well-nourished mothers.<sup>41</sup> This would have an effect on the utilization of the esters of lipid-soluble vitamins A, D, and E.

It appears that the function of this enzyme, inhibited by bile salts, is to facilitate the uptake by the mammary gland of fatty acids from circulating triglycerides for incorporation with milk lipids, because lipase *in vivo* depends on added serum for

activity. Its presence in milk probably represents "leakage" from the mammary gland, and it is unlikely to play a major physiologic role in the lipolysis of milk triglycerides.

Additional lipases in the skim milk fraction are stimulated by bile salts. Bile salt-stimulated lipase (BSSL) has greater activity and splits all three ester bonds of the triglyceride. This lipase is also stable in the duodenum and contributes to the hydrolysis of the triacylglycerols in the presence of the bile salts. BSSL is identical to carboxyl ester hydrolase (carboxylesterase), a pancreatic enzyme. BSSL activity is lower in colostrum than in mature milk. No correlation appears to exist between the volume of milk at various stages and the volume of enzyme secreted.<sup>51</sup> BSSL is present in early prepartum secretions less than 2 months before delivery and in the milk expressed during weaning. For a given well-nourished woman, levels remain stable even after prolonged lactation. BSSL activity is protective against infection by virtue of the production of free fatty acids and monoglycerides, products of fat digestion that have antiinfective properties (see Table 4-31).<sup>51</sup>

The enzyme activity of BSSL is remarkably stable during prolonged storage up to 2 years at either  $-20^{\circ}\text{C}$  or  $-70^{\circ}\text{C}$  ( $-4^{\circ}\text{F}$  or  $-94^{\circ}\text{F}$ ). It has also been noted to be stable at  $15^{\circ}$ ,  $25^{\circ}$ , and  $38^{\circ}\text{C}$  ( $59^{\circ}$ ,  $77^{\circ}$ , and  $100^{\circ}\text{F}$ ).<sup>63</sup>

Contrary to earlier suggestions, no association exists between jaundice and increased levels of free fatty acids produced as a result of high activity of milk lipase.<sup>51</sup>

Investigators have continued to study the action of these lipases in the presence of bile salts. The BSSL remains active during passage through the stomach because it is stable with a pH greater than 3.5 and only slowly inactivated by pepsin. The optimal bile salt concentration for activity is about 2 mmol/L, which is within the physiologic range in the newborn. Bile salts protect the enzyme from trypsin activity.

## Glucose-6-Phosphate Dehydrogenase

Glucose-6-phosphate dehydrogenase is rich in the milk of mothers with normal red blood cell dehydrogenase and absent in mothers with glucose-6-phosphate dehydrogenase deficiency. Its levels depend on the increased rate of carbohydrate metabolism in the mammary gland.

## Lactic and Malic Acid Dehydrogenases

Lactic and malic acid dehydrogenase levels are high in colostrum, are lower in mature milk, and are increased at the end of a feeding. The levels are higher in species with small body size; thus mice

and humans have more than cows. Because no correlation exists with serum levels, these enzymes are thought to be synthesized in the mammary gland. A change occurs in these enzymes during lactation.

### Lactose Synthetase

Lactose synthetase catalyzes the synthesis of lactose from UDP-galactose and glucose. This enzyme has two components: A-protein, a glycoprotein, and B-protein, an  $\alpha$ -lactalbumin. The control mechanism for lactose biosynthesis by the A-protein and  $\alpha$ -lactalbumin ensures that lactose is synthesized in the mammary gland only in response to specific hormones.<sup>90</sup>

### Lysozyme

Lysozyme is a thermostable, nonspecific antimicrobial factor that catalyzes the hydrolysis of  $\beta$ -linkage between N-acetylglucosamine and N-acetylmuramic acid in the bacterial cell wall. It is bacteriolytic toward Enterobacteriaceae and gram-positive bacteria and is considered to play a role in the antibacterial activity of milk as well as a significant role in the development of intestinal flora. It also hydrolyzes mucopolysaccharides. Human lysozyme is antigenically and serologically different from the bovine enzyme. The content in human milk is 3000 times that in bovine milk and the activity 100 times that of bovine milk. Lysozyme is considered to be a spillover product from breast epithelial cells.

### Phosphatases

Acid phosphatase is similar in human and bovine milk, but alkaline phosphatase is much less active in human milk by a factor of 40. Its level increases with the increase in fat concentration and increases as the feeding progresses. In 199 samples from 20 donors, no relationship to age, nationality, or other characteristics of the donor was found. Alkaline phosphatase concentrations appeared to be related to the fat concentration in human milk. Levels increased as lactation progressed.<sup>2</sup> Alkaline phosphatase is a metal-carrying enzyme with four zinc molecules and two magnesium atoms. It differs from the placental alkaline phosphatase.

Serum alkaline phosphatase is increased in pregnancy. The placenta produces alkaline phosphatase, which may contribute to this increase. The liver does not enlarge. The histologic appearance is normal. The spider angioma and palmar erythema that are observed are attributed to the increase in estrogen.<sup>55</sup>

### Proteases and Antiproteases

Several enzymes have caseinolytic activity and elastase-like activity. Beta casein and V-casein and galactothermin are probably the by-products of endogenous human milk proteolytic activity.<sup>60</sup> Also small peptides of only three to eight amino acids are derived from a casein group called  $\beta$ -casomorphins with specific physiologic activity. These peptides may be associated with the sleeping patterns of neonates and even have relevance to postpartum psychosis.

Proteases catalyze the hydrolysis of proteins. High levels of protease are found in human milk, suggesting that enzymes may provide the breastfed infant with significant digestive assistance immediately after birth.

Antiproteases' physiologic role is not entirely clear. The main protease inhibitors in human milk are  $\alpha_1$ -antichymotrypsin and  $\alpha_1$ -antitrypsin.<sup>62</sup> Trace amounts of others have been identified. One function may be to protect the mammary gland from local proteolytic activity by leukocytic and lysosomal proteases during different stages of lactogenesis. They may prevent the breakdown of proteins in stored milk.<sup>60</sup> The protection of immunoglobulins that are transferred intact to the neonate and the protection of growth hormones are probably other roles of the antiproteases. The presence of such inhibitors may restrain the invading bacterial enzymes in the host tissue (breast) or secretion (milk). Thus the presence of these inhibitors may protect the mammary gland and the recipient infant from infection.

### Xanthine Oxidase

Xanthine oxidase catalyzes the oxidation of purines, pyrimidines, and aldehydes. Although bovine milk contains high levels, it was only after much effort that investigators were able to identify it in human milk. The activity in human milk peaks on the third day after birth and decreases with the progression of lactation. It differs from that in bovine milk in that it is not of bacterial origin and its activity is correlated with protein concentration.

Many enzymes are being studied in humans and other species. See Table 4-30 for a summary of the most significant enzymes. For an extensive discussion, see Hamosh.<sup>62</sup>

### Hormones

Protein hormones, especially prolactin, and steroid hormones, such as gestagens, estrogens, corticoids, androgens, and opiate-like peptides, can be detected in human milk and in the milk of other mammals.<sup>135</sup>

Animal studies have shown that at least some of these hormones retain physiologic activity when ingested but not when pasteurized. Although their presence was recognized in the 1930s, advances in hormone assay techniques have brought more information to light.<sup>86</sup> Hormones with simple structures, such as steroids and thyroxine ( $T_4$ ), can pass easily by diffusion into the milk from circulating blood. Peptide hormones such as hypothalamic-releasing hormones, because of their small size, also would be expected to appear in milk. Of the larger-molecular-weight pituitary hormones, only prolactin has been found so far. The hormones identified in human milk include gonadotropin-releasing hormone, thyroid-releasing hormone, thyroid-stimulating hormone (TSH; thyrotropin), prolactin, gonadotropins, ovarian hormones, corticosteroids, erythropoietin (EPO), cyclic adenosine monophosphate, and cyclic guanosine monophosphate (Tables 4-32 and 4-33).

The concentration of hormones changes during lactation, with prolactin decreasing over time and triiodothyronine ( $T_3$ ) and  $T_4$  increasing. Evidence indicates that the GI tract of suckling mammals possesses the ability to absorb various proteins with substantial preservation of their immunologic properties. The absorption of large-molecular-weight hormones has been demonstrated in suckling rats and mice, with measurable amounts appearing in serum and other tissues.

The thyroid hormones have received considerable attention because of the apparent protection of hypothyroid infants who are breastfed. TSH content was investigated by both direct I-TSH radioimmunoassay and indirect radioimmunoassay.

TABLE 4-32 Nonpeptide Hormones in Human Milk		
Hormone	Concentration (ng/mL)	
<b>Thyroid</b>		
Thyroxine ( $T_4$ )	1-40.3-2.012.01.16-2.40.8-2.3	
Triiodothyronine ( $T_3$ )	0.02-0.400.05-0.10	
Reverse $T_3$	0.008-0.15	
Adrenal gland: Cortisol	0.2-32.0 (5:10)*3.7	
<b>Sexual</b>		
Progesterone	10-40	
Pregnanediol	0-450	
Estrogens	15-840 (15:60)*	
Contraceptives	Biologically significant quantities	

\*Ratio of values in colostrum/values in mature milk.

Modified from Koldovsky O, Strbak V: Hormones and growth factors in human milk. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press.

TSH was present in human milk in low concentrations comparable to those normally found in the serum of euthyroid adults. Experimentally, thyroidectomy of the lactating rat led to the disappearance of measurable  $T_4$  and an increase in the level of TSH in the milk. In contrast, administration of  $T_3$  decreased the TSH in the rat model.

Prolactin has been identified as a normal constituent of human milk. Levels are high in the first few days postpartum but subsequently decline rapidly. "Prolactin-like" biologic activity is measurable in human colostrum, with the highest levels on day 1. Concentrations in the milk tend to parallel concentrations in the blood plasma among different species. Three stages of neuroendocrine development are theorized: placental, milk, and autonomous, in which the milk phase is the adaptation to extrauterine life.<sup>62</sup>

The exact mechanism by which prolactin enters the milk is unclear. Prolactin-binding sites have been identified within the alveolar cells. The functional significance of prolactin also remains unclear. In rodents, milk prolactin influences fluid

**TABLE 4-33** Hormonally Active Peptides in Human Milk

Peptide	Concentration	Ratio (Colostrum/ Mature Milk)
Erythropoietin	Bioassay	?
<b>Growth factors</b>		
Epidermal growth factor	3-107 ng/mL	2:10
Insulin	0-80 $\mu$ U/mL	3:10
Insulin-like growth factor 1	1.3-7 ng/mL	2:3
Nerve growth factor	Present	
Transforming growth factor alpha (TGF- $\alpha$ )	0-8.4 ng/mL	1
Other growth factors	Present	?
<b>Gastrointestinal regulatory peptides</b>		
Gastrin	10-30 pg/mL	2:3
Gastric inhibitory peptide	33-59 ng/mL	1
Gastric regulatory peptide	31-55 pg/mL; 60-430 pg/mL	2:3
Neurotensin	7-15 pg/mL	2:3
Peptide histidine methionine	3-32 pg/mL	5:10
Peptide YY	15-30 pg/mL	2:3

Modified from Koldovsky O, Strbak V: Hormones and growth factors in human milk. In Jensen RG, editor: *Handbook of milk composition*, San Diego, 1995, Academic Press.

and ion absorption from the jejunum. It also may influence gonadal and adrenal function, as demonstrated in other species.

Endocrine responses in the neonate differ between breastfed and formula-fed infants. In a study of 34 healthy, 6-day-old full-term infants who were formula fed, plasma concentrations of insulin, motilin, enteroglucagon, neuropeptide Y, and pancreatic polypeptide changed significantly after a feeding. Similar levels were measured in 43 normal breastfed infants, and little or no change was noted. Further, the basal levels of gastric inhibitory polypeptide, motilin, neuropeptide Y, and vasoactive intestinal peptide were also higher in the bottle-fed than in the breastfed infants. Whether pancreatic and gut hormone-release changes affect postnatal development is yet to be determined.

EPO is synthesized in the maternal kidney and targets bone marrow where it stimulates erythropoiesis. The bioavailability of erythropoietin enterally is thought to be insufficient; however, when present in human milk, it may be different for newborns. In the rat model it has been shown to stimulate erythropoiesis in the suckling rat. It may have a physiologic effect on human breastfed newborns.<sup>13</sup>

## PROSTAGLANDINS

In the investigation of the factors in human milk that may modify or supplement physiologic functions in the neonate, the role of prostaglandins comes under review. Prostaglandins include any of a class of physiologically active substances present in many tissues and originally described in genital fluid and accessory glands. Among the many effects are those of vasodepression, stimulation of intestinal smooth muscle, uterine stimulation, aggregation of blood platelets, and antagonism to hormones influencing lipid metabolism. Prostaglandins are a group of prostanoic acids often abbreviated PGE, PGF, PGA, and PGB with numeric subscripts according to structure.

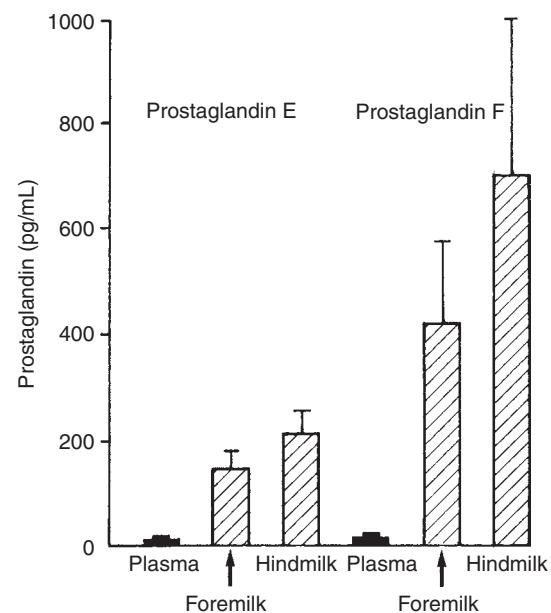

The synthesis of prostaglandins occurs when dietary linoleic acid is converted in the body by a series of steps involving chain lengthening and dehydration to arachidonic acid, the principal (but not the only) precursor of prostaglandins. Although the prostaglandins are similar in structure, the biologic effects of various prostaglandins produced from a single unsaturated fatty acid can be profoundly different and, in some cases, antagonistic.

Because of the possible beneficial effects of prostaglandins on the GI tract of infants, several investigators<sup>6,98</sup> have measured levels in human milk. The measurements were made in colostrum, transitional milk, and mature milk with collections of both foremilk and hindmilk. PGE and PGF have

been shown to be present in breast milk in more than 100 times the concentration in adult plasma (Figure 4-13). The ratio of the principal metabolite of PGFM to PGF itself suggests a relatively long half-life. Although prostaglandins occur in cow milk, none was measurable in cow milk-based formulas. Two inactive metabolites were found in milk in levels similar to those in the control adult plasma.

It is thought that prostaglandins play a role in GI motility, possibly assisting peristalsis physiologically. Infantile diarrhea may occasionally be caused by excessive prostaglandin secretion into the mother's milk during menstruation, when maternal plasma levels of PGF may be raised. The difference in stool patterns between infants who are breastfed versus formula fed may be partially attributable to the presence of prostaglandins in human milk and not in formulas. The role of prostaglandins in the pathogenesis of food intolerance is also under study, because prostaglandins have a cytoprotective effect on the upper bowel and reportedly are increased in patients with abnormal peristalsis and irritable bowel syndrome.

Prostaglandins E<sub>1</sub>, E<sub>2</sub>, and F<sub>2α</sub> (PGE<sub>1</sub>, PGE<sub>2</sub>, PGF<sub>2α</sub>) were determined in milk and plasma from mothers of term and preterm infants by Shimizu et al.<sup>138</sup> They found the concentration of PGE<sub>1</sub> in milk to be similar to that in plasma and the concentrations of PGE<sub>2</sub> and PGF<sub>2α</sub> to be about 1.2 to 2 times higher in milk than in plasma. Foremilk and hindmilk levels, however, were similar, as were

**Figure 4-13.** Prostaglandins E and F (PGE, PGF) (pg/mL ± SEM) in human milk and adult plasma. (From Lucas A, Mitchell MD: Prostaglandins in human milk, *Arch Dis Child* 55:950, 1980.)

term and preterm levels. Levels appeared to be constant throughout lactation. PGE<sub>1</sub> is credited with a variety of physiologic effects on the GI tract, including cytoprotection and a diarrhea-producing action. Other actions are expected and yet to be identified because of prostaglandins' stability throughout lactation and lack of degradation in milk and in the lumen of the gut.

In addition, human infants may require PGE<sub>2</sub> for maintenance of gastric mucosal integrity, as do adults. Therefore, it is not surprising that the use of prostaglandin synthesis inhibitors, such as indomethacin for closure of a patent ductus, is associated with necrotizing enterocolitis. PGE<sub>2</sub> in human milk may also promote the accumulation of phospholipids in the neonatal stomach, enhancing the gastric mucosal barrier.

## Relaxin

Relaxin is a hormone with a polypeptide structure similar to that of insulin. It is produced by the corpus luteum during pregnancy as well as by the decidua and the placenta. Relaxin induces cervical softening, loosens the pelvic girdle, and decreases myometrial activity during pregnancy in many species.<sup>43</sup> Its role in humans remains under study.

It has been postulated that human mammary tissue is a target and a source of relaxin synthesis. Relaxin was measured by specific human relaxin radioimmunoassay in milk and sera of women delivering at term, prematurely at 3 days, and at 6 weeks postpartum.<sup>43</sup> Sera and milk levels were similar in term and preterm mothers; however, at 6 weeks, relaxin concentrations in milk were higher in the preterm group. The presence in milk at 6 weeks suggests a nonluteal site of synthesis. The authors suggest that before lactation, relaxin may aid the growth and differentiation of mammary tissue, and then in the neonate, it may act directly on the GI tract.

## BILE SALTS

Another limiting factor in digestion in the newborn is the decreased bile salt pool and the low concentration of bile salts in the duodenum. The presence of some biologically active substances in human milk contributes to digestion in the newborn. For this reason, the role of bile salts was investigated, and cholate and chenodeoxycholate were found in all samples of milk obtained from 28 lactating women in the first postpartum week.<sup>52</sup> In both colostrum and milk, cholate predominated. Samples were randomly collected, and the range of concentration was wide. The ratio of maternal serum to milk levels was 1:1 for cholate and 4:1 for chenodeoxycholate. The significance of these findings is under study.

## EPIDERMAL GROWTH FACTOR

EGF is a small polypeptide mitogen that has been identified in many species and isolated and characterized in human milk. Of the growth factors that have been purified to date, EGF is one of the most biologically potent and best characterized as to its physical, chemical, and biologic properties. EGF has been associated with neonatal maturation, mechanisms of milk collection, and various protective effects. It is well established that EGF stimulates the proliferation of epidermal and epithelial tissues and has significant biologic effects in the intact mammal, particularly in the fetus and the newborn. Effects verified in humans also include increased growth and maturation of the fetal pulmonary epithelium, stimulation of ornithine decarboxylase activity and DNA synthesis in the digestive tract, and acceleration of the healing of wounds of the corneal epithelium. Unrelated is the observation that EGF inhibits histamine- or pentagastrin-induced secretion of gastric acid. It has a maturational effect on duodenal mucosal cells and increased lactase activity and net calcium transport in suckling rats. EGF has been identified in plasma, saliva, urine, amniotic fluid, and milk. Human milk is known to be mitogenic for cultured cells. EGF is active when administered orally, stable in acid, and resistant to trypsin digestion.

Newborn puppies fed their mother's milk were found to have hyperplasia of the enteric mucosa as compared with formula-fed littermates. Furthermore, the intestinal weight, length, and DNA and RNA content were greater in the puppies fed their mother's milk.

Previous studies specified the presence of EGF in the aqueous portion of human milk only; however, Gullett et al.<sup>59</sup> have established that EGF and its receptor are found in all human milk compartments: aqueous, liposomal, and membranes (milk fat globule membranes [MFGMs]).

Studies of EGF in human milk first reported that human milk stimulates DNA synthesis in cell cultures in which growth had been arrested. The mitogenic activity of the milk was neutralized by the addition of an antibody to human EGF. These findings support the concept that EGF is a major growth-promoting agent in breast milk. Actual measurements of EGF in the milk of 11 mothers who delivered at term and 20 who delivered prematurely were also done. EGF concentrations were  $68 \pm 19$  ng/mL (mean  $\pm$  SEM) in those who delivered at term and  $70 \pm 5$  ng/mL (mean  $\pm$  SEM) in the milk of those who delivered prematurely. No significant change throughout 7 weeks and no diurnal variation were observed. The total EGF content was closely correlated with the volume of milk expressed, suggesting to the authors that EGF has

a passive transport from the circulation as a function of plasma concentration.

Given that EGF has significant healing effects on injured GI tract mucosa and decreasing gestational age of neonates is associated with higher risk of developing GI disorders, the amount of EGF in milk is significant. Concentrations of EGF in human milk from extremely preterm (23 to 27 weeks) mothers were significantly higher than values obtained from preterm and full term mothers throughout the first month postpartum according to studies done by Dvorak et al.<sup>42</sup> They also noted that transforming growth factor (TGF- $\alpha$ ) was also elevated in this group of mothers with extremely premature infants.

Using various techniques for assay, Iacopetta et al.<sup>73</sup> found 30 to 40 ng/mL EGF in human milk, less than 2 ng/mL in bovine milk, and none in several bovine milk-based formulas. Little change occurred with refrigeration or freezing. The role of EGF in promoting normal growth and functional maturation of the intestinal tract continues to be under study.

## CHAPTER 5

# *Host-Resistance Factors and Immunologic Significance of Human Milk*

---

Some of the most dramatic and far-reaching advances in the understanding of the immunologic benefits of human milk have been made using newer techniques to demonstrate the specific contribution of the numerous "bioactive factors" contained in human milk (Table 5-1). The multifunctional capabilities of the individual factors, the interactive coordinated functioning of these factors, and the longitudinal changes in the relative concentrations of them for the duration of lactation make human milk unique. The immunologically active components of breast milk make up an important aspect of the host defenses of the mammary gland in the mother; at the same time, they complement, supplement, and stimulate the ongoing development of the infant's immune system.<sup>130–132</sup>

The explosion of research on all the immunologic properties and actions of breast milk in the last 10 years makes it impossible to summarize all the important aspects of what we now know about the immunologic benefits of breast milk. The recently developed technologies of genomic studies using microarrays and proteomics promise to continue this rapid expansion of knowledge on the biology of the mammary gland, human milk, and the infant's developing immune system.

The common comment about the immunologic benefits of breast milk, "It has antibodies," is a huge understatement. Antibodies in human milk play a relatively small role in the immune protection for the infant produced by breastfeeding. The intestinal microbiome, mucosal immunity, nucleotides, probiotics and prebiotics, oligosaccharides, and

glycans related to the ingestion of human milk are much more important components of the infant's immune protection.\* The developing immunity of infants is a dynamic process. It is made all the more complex by the contextual nature of the interactions of various components in human milk with the developing gastrointestinal (GI) tract. This directly affects both local and systemic immunity over time. This chapter emphasizes the important concepts of these immunologic benefits and refers the interested reader to the most recent literature for more extensive information on the many specific components.

### *Overview*

---

The immunologic benefits of human milk can be analyzed from a variety of perspectives:

1. Reviewing the published information on the protection of infants from specific infections that compares breastfed and formula-fed infants.
2. Comparing documented deficiencies in infants' developing immune systems and the actions of bioactive factors provided in breast milk.
3. Examining the proposed function of the active components contained in human milk: antimicrobial, antiinflammatory, and immunomodulating.
4. Considering the nature of the different factors: soluble, cellular, and hormone-like.
5. Examining the contribution of breast milk to immune protection of the mammary gland.

---

**TABLE 5-1** Immunologically and Pharmacologically Active Components and Hormones Observed in Human Colostrum and Milk

Soluble	Cellular	Hormones and Hormone-Like Substances
Immunologically specific	Immunologically specific	Epidermal growth factor
Immunoglobulin	T-lymphocytes	Prostaglandins
sIgA (11S), 7S IgA, IgG, IgM IgE, IgD, secretory component	B-lymphocytes	Relaxin
		Neurotensin
	<b>Accessory cells</b>	Somatostatin
	Neutrophils	Bombesin
<b>T cell products</b>	Macrophages	Gonadotropins
<b>Histocompatibility antigens</b>	Epithelial cells	Ovarian steroids
		Thyroid-releasing hormone
	<b>Additional cells</b>	Thyroid-stimulating hormone
<b>Nonspecific factors</b>	Stem cells	Thyroxine and triiodothyronine
Complement		Adrenocorticotropin
Chemotactic factors		Corticosteroids
Properdin (factor P)		Prolactin
Interferon		Erythropoietin
$\alpha$ -Fetoprotein		Insulin
Bifidus factor		Cytokines
Antistaphylococcal factor(s)		Interleukins
Antiadherence substances		
Epidermal growth factor		
Folate uptake enhancer		
Antiviral factor(s)		
Migration inhibition factor		
Gangliosides		
Nucleotides		
Antisecretory factor		
Spermine		
Soluble CD14		
<b>Carrier proteins</b>		
Lactoferrin		
Transferrin		
Vitamin B <sub>12</sub> -binding protein		
Corticoid-binding protein		
<b>Enzymes</b>		
Lysozyme		
Lipoprotein lipase		
Leukocyte enzymes		

Modified from Ogra PL, Fishaut M: Human breast milk. In Remington JS, Klein JO, editors: *Infectious diseases of the fetus and newborn infant*, ed 4, Philadelphia, 1995, Saunders.

6. Determining the site of the postulated action of the specific factors (e.g., in the breast or in the infant) at the mucosal level (respiratory tract or GI tract) or at the systemic level.
7. Classifying the factors relative to their contribution to the constitutive defenses (innate immunity) versus the inducible defenses (adaptive immunity) of the infant's immune system.
8. Clarifying the mechanism of action of the proposed immunologic benefit (e.g., the mucosal-associated lymphoid tissue [MALT] forms bioactive factors at the level of the mucosa, which migrate to the breast and breast milk, activating cells at those sites).
9. Considering the contribution of human milk to the development of an infant's immune system relative to potential long-term immunologic benefits,

such as protection against allergy, asthma, autoimmune disease, or inflammatory bowel disease.

## Protective Effect of Breast Milk

The protective effect of breast milk against infection was documented as early as 1892 in the medical literature. Data proved that milk from various species, including humans, was protective for offspring, containing antibodies against a vast number of antigens.<sup>329</sup>

Veterinarians have long known the urgency of offspring receiving the early milk of the mother. Death rates among human newborns not suckled at the breast in the Third World are at least five times higher than among those who receive colostrum and the mother's milk. The evidence that a lack of breastfeeding and poor environmental sanitation have a pernicious synergistic effect on infant mortality rate has been presented by Habicht et al.,<sup>123</sup> after studying 1262 women in Malaysia.

The evidence that breastfeeding protects against infections in the digestive and respiratory tracts has been reported for several decades.<sup>326</sup> However, many of the older studies were criticized for flawed methodology, and because they were performed in "developing countries," where the risk for infection due to poor sanitation was expected to be higher.<sup>15,123,143</sup> Various researchers have proposed specific criteria for assessing the methodology of studies reporting on the protective effects of breast milk, clearly identifying measurable outcomes and the definition of breastfeeding, with other methods to limit bias and to control for confounding variables.<sup>15,59,180,182</sup> More recent studies, which have incorporated many of the proposed methodologic criteria, continue to document that breastfeeding protects infants against diarrhea, respiratory infections,

and otitis media.\* Individual papers report protection against urinary tract infections and neonatal sepsis.<sup>7,132,266,333</sup> Several papers document the decreased risk for dying in infancy associated with exclusive or predominant breastfeeding in Pakistan, Peru, Ghana, India, Nepal, and Bangladesh.<sup>5,7,10,80,218</sup> A systematic review by the Bellagio Child Survival Study Group predicted that exclusive breastfeeding for 90% of all infants through 6 months of age could prevent 13% of the childhood deaths occurring younger than 5 years of age.<sup>165</sup> Recent reviews on human breast milk document the evidence for protection against infectious diseases from breastfeeding, for resource-rich and resource-poor countries.<sup>77,155,187</sup>

## Dose-Response Relationship

One of the important considerations relative to measuring the immunologic benefits of breast milk is the exclusivity and duration of breastfeeding. The basic concept is identifying a dose-response relationship between the amount of breast milk received by an infant during the period of observation and the immunologic benefit gained. This is equatable to the dose-response relationship for a medication and a specific measurable effect of that medication. In the case of breast milk, the "dose" or volume of breast milk consumed by the infant will be increased by the greater exclusivity and the longer duration of breastfeeding. Dr. Labbok and Krasovec<sup>182</sup> have carefully defined breastfeeding in terms of the patterns of breastfeeding relative to the amount of supplementation with formula or other fluids or foods (full/nearly full, medium or equal, low partial, or token) to standardize the use of equatable terms in different studies. Box 5-1 outlines these definitions

\*3,8,18,54,64,70,150,202,243,252,269,273,292,338

### BOX 5-1. Breastfeeding Definitions

Any breastfeeding	Full breastfeeding	Exclusive human breast milk only	Infant ingests no other nutrients, supplements, or liquids
		Almost exclusive	No milk other than human milk; only minimal amounts of other substances such as water, juice, tea, or vitamins
Partial breastfeeding	High partial Medium partial Low partial	High partial	Nearly all feeds are human milk (at least 80%)
		Medium partial	A moderate amount of feeds are breast milk, in combination with other nutrient foods and nonhuman milk (20%-80% of nutritional intake is human breast milk)
		Low partial	Almost no feeds are breast milk (less than 20% of intake is breast milk)
Never breastfed	Token		Breastfeeding primarily for comfort; nonnutritive, for short periods of time, or infrequent
	Infant never ingested any human milk		

of the "amount" of breastfeeding.<sup>187</sup> Raisler et al.<sup>274</sup> referred to a dose-response relationship when they studied the effect of "dose" of breast milk on preventing illness in more than 7000 infants. "Full breastfeeding" was associated with the lowest rates of illness (diarrhea, cough, or wheeze), and even children with "most" or "equal" breastfeeding had evidence of lower odds ratios of ear infections and certain other illnesses. A number of other long-term studies demonstrated greater protection from infection with increased exclusivity of breastfeeding and durations of at least 3 months. A couple of papers demonstrated a "dose" effect relative to decreased occurrence of late onset sepsis in very-low-birth-weight (VLBW) infants<sup>95</sup> and premature infants<sup>294</sup> associated with the infants' receiving at least 50 mL/kg per day of the mother's milk, compared with receiving other nutrition. The current recommendations from the American Academy of Pediatrics reinforce the importance of the dose-response relationship between breastfeeding and the benefits of breastfeeding. The AAP recommends exclusive breastfeeding for the first 6 months of life and at least partial breastfeeding after the introduction of solid foods for an additional 12 months or longer.\* Another important consideration, relative to exclusive breastfeeding, is the potential effect of other foods and fluids in an infant's diet that could negatively influence immunologic benefits and infection-protective effects at the level of the GI mucosa.

## *Developmental Deficiencies in Infants' Immune Systems*

The human immune system begins forming and developing in the fetus. Newborn infants' immune systems are immature and inadequate at birth. Immune systems rapidly adapt in the postnatal period. These are related to the natural maturation of the skin and mucosal barriers and in response to the exposure of infants to inhaled and ingested antigens and microbial agents in the extrauterine environment. Infants' immune systems develop throughout at least the first 2 years of life. Overall, infants have limited abilities to respond effectively and quickly to infectious challenges, which explains infants' ongoing susceptibility to infections.\*\* Box 5-2 lists most of the better understood deficiencies in infants' immune systems. An extensive discussion of these developmental immune deficiencies affecting infants is presented by Lawrence and Pane.<sup>187</sup> The B-lymphocytes and immunoglobulin production are deficient in the amount and

### **BOX 5-2. Developmental Defects in Newborns**

**Phagocytes (function matures over the first 6 months of life):**

Limited reserve production of phagocytes in response to infection

Poor adhesion molecule function for migration

Abnormal transendothelial migration

Inadequate chemotactic response

Qualitative deficits in hydroxyl radical production

Decreased numbers of phagocytes reaching the site of infection

**Cell-mediated immunity:**

Limited numbers of mature functioning (memory) T cells (gradual acquisition of memory T cells throughout childhood)

Decreased cytokine production: IFN- $\alpha$ , IL-2, IL-4, IL-10

Diminished NK cell cytolytic activity (matures by 6 months of age)

Limited antibody-dependent cytotoxic cell activity

Poor stimulation of B-cells (subsequent antibody production, isotype switching)

**B-lymphocytes and immunoglobulins:**

Limited amounts and repertoire of active antibody production

Poor isotype switching (primarily IgM and IgG1 produced in neonates)

IgG1 and IgG3 production is limited (matures at 1 to 2 years of age)

IgG2 and IgG4 production is delayed (matures at 3 to 7 years of age)

Serum IgA levels are low (less than adult levels through 6 to 8 years of age)

Deficient opsonization by immunoglobulins

Poor response to T cell independent antigens (polysaccharides) (matures at 2 to 3 years of age)

**Complement cascade:**

Decreased function in both the classical and the alternative pathways

Insufficient amounts of C5a

specificity of antibodies produced. There is limited isotype switching and slow maturation of the antibody response to specific antigens (polysaccharides).<sup>140,216</sup> The systemic cell-mediated immune response, including effector and memory T cells, is functionally limited in its response in infants.<sup>304,331,341</sup> Neutrophil activity in infants is also developmentally delayed, which directly contributes to infants' susceptibility to invasive bacterial infections during the first months of life.<sup>192,209,300,309,342</sup> The complement system in infants is characterized by low levels of complement components, and both the "classical" and alternative pathways have limitations for complement activation.<sup>2,81,302,335</sup> Numerous immune components are produced in limited amounts in infancy, including complement, interferon- $\gamma$ , secretory immunoglobulin

\*3,17,64,70,75,78,150,202,252,269,292,338

\*\*56,106,107,109,148,339

A(slgA), interleukins (IL-3, IL-6, IL-10), tumor necrosis factor (TNF)- $\alpha$ , lactoferrin, and lysozyme.<sup>56,109</sup>

Relative to these various immune deficits in infants, one can find various bioactive and immuno-modulating factors in breast milk that are potentially capable of complementing and enhancing the development of infants' mucosal and systemic immune systems.<sup>109,133</sup> This concept of bioactive and immunomodulating factors in breast milk is an important area of evolving research that has been extensively reviewed in the literature.<sup>109,110,133,176</sup> The most intense focus of this research centers on the effects of human milk on infants' GI tract.<sup>107,245</sup>

## Bioactive Factors

The bioactive factors being studied are as diverse as proteins (lactoferrin, lysozyme, etc.), hormones (erythropoietin, prolactin, insulin, etc.), growth factors (epithelial growth factor, insulin-like growth factor, etc.), neuropeptides (neurotensin, somatostatin, etc.), cytokines (TNF- $\alpha$ , IL-6, etc.), antiinflammatory agents (enzymes, antioxidants, etc.), and nucleotides (see Table 5-1). In the past, it was adequate to point to the lists of factors (especially immunoglobulins) to "explain" the immunologic benefit of breast milk. Today, it is necessary to understand not only the "actions" of the specific factors but to understand how they interact with and affect the action of multiple other factors acting on the same process or system. For example, it is important to understand how secretory IgA (slgA) interacts with or affects the actions of other bioactive factors (lactoferrin, complement and mucins) at the level of the intestinal mucosa. The specific effects of the dynamic interactions of the numerous bioactive factors on mucosal immunity, the development of the infant's immune system, and local inflammation are only beginning to be understood.

From an evolutionary perspective, maternal antibodies are transmitted to the fetus by different pathways in different species.<sup>109,193,313</sup> An association has been recognized between the number of placental membranes and the relative importance of the placenta and the colostrum as sources of antibodies. By this analysis, horses, with six placental membranes, pass little or no antibodies transplacentally and rely totally on colostrum for protection of foals. Humans and monkeys, having three placental membranes, receive more of the antibodies via the placenta and less from the colostrum. The transfer of IgG in humans is accomplished by the active transport mechanism of the immunoglobulin across the placenta. Secretory IgA (slgA) immunoglobulins are found in human milk and provide local protection to the mucous membranes of the GI tract. Other investigations have established that the

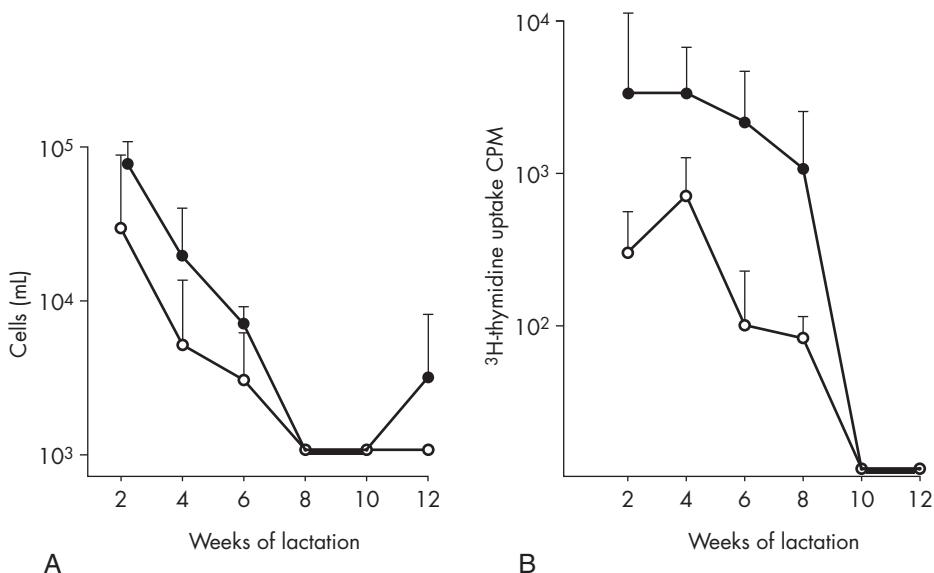

mammary glands and their secretion of milk are important in protecting the infant not only through the colostrum, but also through mature milk from birth through the early months of life.

Although the predominance of IgA in human colostrum and milk had long been described, the importance of this phenomenon was not fully appreciated until the discovery that IgA is a predominant immunoglobulin. It is present in mucosal secretions of other glands, in addition to the breast.

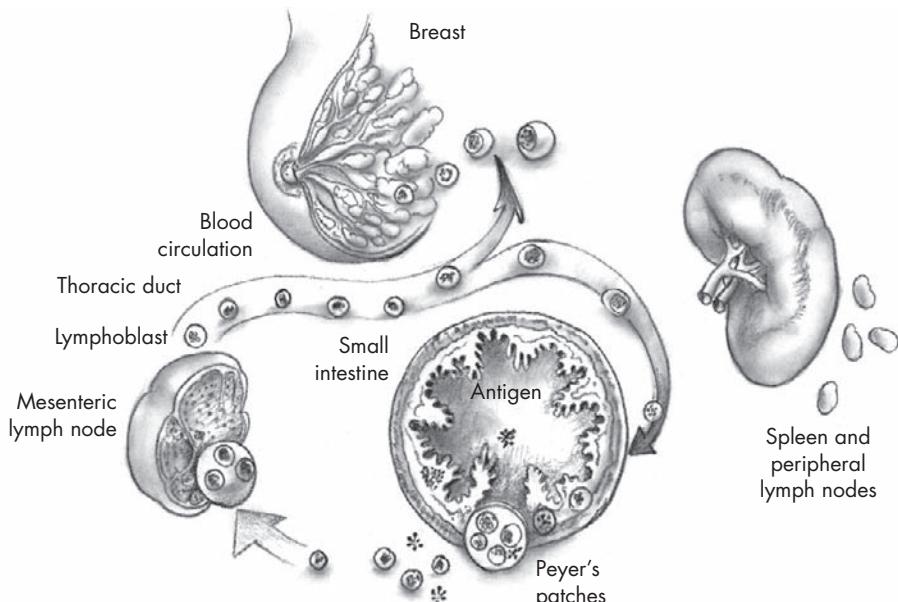

## Mucosal Immunity

Mucosal immunity has become the subject of extensive research.<sup>28,29,148,245</sup> It is clear that considerable traffic of cells occurs between mucosal, epithelial, and secretory, or lymphoid, tissue sites.<sup>263</sup> The data support the concept of a general system of MALT, which includes the gut, lung, mammary gland, salivary and lacrimal glands, and the genital tract (Figure 5-2). Through the immune response of MALT, a reaction to an immunogen at a mucosal site may be an effective means of producing immunity at distant sites. Antibodies against specific antigens found in milk have also been found in the saliva, which is evidence for transfer of protection to two different distant sites simultaneously. Evidence suggests that the mammary glands may act as extensions of the gut-associated lymphoid tissue (GALT) and possibly the bronchiole-associated lymphoid tissue. The ability of epithelial surfaces exposed to the external environment to defend against infectious agents has been well documented for the GI, genitourinary, and respiratory tracts.<sup>174</sup> The slgA and secretory IgM (slgM) produced through the adaptive response of the mucosal-lymphoid immune system act by blocking colonization with pathogens and limiting the passage of harmful antigens across the mucosal barrier. Activated B-cells and cytokines pass to the mammary gland, where they contribute to the production of slgA in breast milk. Direct contact between the antigen and the lymphoid cells of the breast is unlikely.<sup>246</sup> Peyer's patches, tonsils, and other MALT structures appear to be well developed at birth.<sup>39</sup> Even with the Peyer's patches, tonsils, and lymphoid tissue at the mucosal level being well developed at birth, there is inadequate production of slgA and serum IgA in infancy. A breastfeeding infant, as part of the maternal-infant dyad exposed to the same antigens via their mucosal services, can receive protective slgA and slgM in the mother's breast milk, produced by the mother's MALT (Figure 5-2).

The protective properties of human milk can be divided into cellular factors and humoral factors for facility of discussion, although they are closely related *in vivo*. A wide variety of soluble and cellular components and hormone-like agents have been

**Figure 5-1.** A, Longitudinal study of numbers of leukocytes. B, Longitudinal study of uptake of  $^{3}\text{H}$ -thymidine in lymphocytes. Same subjects were examined during second through twelfth week of lactation. Data are presented as mean  $\pm$  SD of macrophages-neutrophils (●) and lymphocytes (○) in A and of stimulated (●) and unstimulated (○) lymphocytes in B. (From Goldman AS, Garza C, Nichols BL, et al: Immunologic factors in human milk during the first year of lactation, *J Pediatr* 100:563, 1982.)

**Figure 5-2.** Schema of mechanism by which progeny of specifically sensitized lymphocytes originating from gut-associated lymphoid tissue may migrate to and infiltrate mammary gland and its secretions, supplying breast with immune cells. (Modified from Head JR, Beer AE: The immunologic role of viable leukocytic cells in mammary exoscretions. In Larson BL, editor: *Lactation, vol 4, mammary gland/human lactation/milk synthesis*, New York, 1978, Academic Press.)

identified in human milk and colostrum (see Table 5-1). Although the following discussion separates these elements, it is important to emphasize that the constituents of human milk are multifunctional and their functioning *in vivo* is interactive and probably coordinated and complementary.

## Cellular Components of Human Colostrum and Milk

Cells are an important postpartum component of maternal immunologic endowment. More than

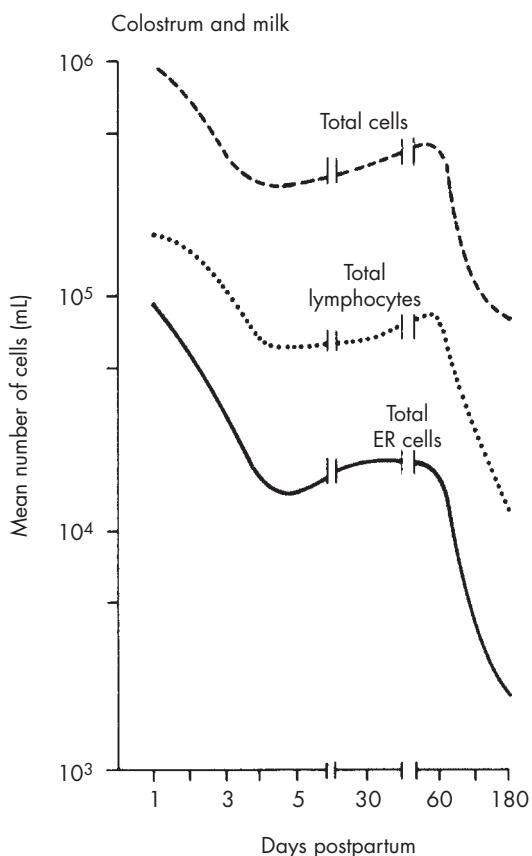

100 years ago, cell bodies were described in the colostrum of animals. As with much lactation research, further study of colostral corpuscles was undertaken by the dairy industry for commercial reasons in the early 1900s. This research afforded an opportunity to make major progress in the understanding of cells in milk. Initially, it was thought that these cells represented a reaction to infection in the mammary gland and were even described as "pus cells."

It has become clear that the cells of milk are normal constituents of colostrum in all species. Cells include macrophages, lymphocytes, neutrophils, and epithelial cells, and they total approximately  $4000/\text{mm}^3$ . Cell fragments and epithelial cells were examined by electron microscope in fresh samples from 30 women by Brooker.<sup>35</sup> He found that the membrane-bound cytoplasmic fragments in the sedimentation pellet outnumbered intact cells. The fragments were mostly from secretory cells that contained numerous cisternae of rough endoplasmic reticulum, lipid droplets, and Golgi vesicles containing casein micelles. Secretory epithelial cells were found in all samples and, after the second month postpartum, began to outnumber macrophages. Ductal epithelial cells were about 1% of the population of cells for the first week or so and then disappeared. All samples contained squamous epithelial cells, originating from galactophores and the skin of the nipple.

## LEUKOCYTES

Living leukocytes are normally present in human milk.<sup>174</sup> The overall concentration of these leukocytes is of the same order of magnitude as that seen in peripheral blood, although the predominant cell in milk is the macrophage rather than the neutrophil. Macrophages compose about 90% of the leukocytes, and  $2000$  to  $3000/\text{mm}^3$  are present. Lymphocytes make up about 5% to 10% of the cells ( $200$  to  $300/\text{mm}^3$ ), which is a much lower concentration than in human blood.<sup>113</sup> The number of cells found in human milk increases with mastitis. Both large and small lymphocytes are present. By indirect immunofluorescence with anti-T cell antibody to identify thymus-derived lymphocytes, it has been shown that 50% of human colostral lymphocytes are T cells, and up to 80% of the lymphocytes in human milk are T cells.<sup>334</sup> Immunofluorescence procedures to detect surface immunoglobulins characteristic of B-lymphocytes identified 34% as B-lymphocytes.

The number of leukocytes and the degree of mitogenic stimulation of lymphocytes sharply decline during the first 2 or 3 months of lactation to essentially undetectable levels, according to Goldman et al. (Figure 5-1).<sup>247</sup> Enumeration of

**Figure 5-3.** Geometric mean concentration of total cells, lymphocytes, and erythrocyte rosette-forming cells (ER) in colostrum and milk of 200 lactating women. (Modified from Ogra SS, Ogra PL: Immunologic aspects of human colostrum and milk. I. Distribution characteristics and concentrations of immunoglobulins at different times after the onset of lactation, *J Pediatr* 92:546, 1978.)

the total cell numbers in milk has been difficult, but when various techniques are compared (Coulter electronic particle counter, visual cell counting with special stains, filter trapping with fluorescent detection, and automated fluorescent cell counting), stains for deoxyribonucleic acid (DNA) were superior to the other techniques.

## MACROPHAGES

Macrophages are large-complex phagocytes that contain lysosomes, mitochondria, pinosomes, ribosomes, and a Golgi apparatus. The monocytic phagocytes are lipid laden and were previously called the colostral bodies of Donne. They have the same functional and morphologic features as phagocytes from other human tissue sources. These features include ameboid movement, phagocytosis of microorganisms (fungi and bacteria), killing of bacteria, and production of complement

components C3 and C4, lysosome, and lactoferrin. Other milk macrophage activities include the following:<sup>265</sup>

- Phagocytosis of latex, adherence to glass
- Secretion of lysozyme, complement components
- C3b-mediated erythrocyte adherence
- IgG-mediated erythrocyte adherence and phagocytosis
- Bacterial killing
- Inhibition of lymphocyte mitogenic response
- Release of intracellular IgA in tissue culture
- Giant cell formation
- Interaction with lymphocytes

Data suggest these macrophages also amplify T cell reactivity by direct cellular cooperation or by antigen processing. The colostral macrophage has been suggested as a potential vehicle for the storage and transport of immunoglobulin. A significant increase in IgA and IgG synthesis by colostral lymphocytes, when incubated with supernatants of cultured macrophages, has been reported.<sup>267</sup>

The macrophage may also participate in the biosynthesis and excretion of lactoperoxidase and cellular growth factors that enhance growth of intestinal epithelium and maturation of intestinal brush-border enzymes.

The mobility of macrophages is inhibited by the lymphokine migration inhibitor factor, which is produced by antigen-stimulated sensitized lymphocytes. The activities of macrophages have been demonstrated in both fresh colostrum and colostral cell culture. Certain functions are altered compared with their counterpart in human peripheral blood.

## POLYMORPHONUCLEAR LEUKOCYTES

The highest concentration of cells occurs in the first few days of lactation and reaches more than a million per milliliter of milk.

Colostrum (1 to 4 days postpartum) contains  $10^5$  to  $5 \times 10^6$  leukocytes/mL, and 40% to 60% are polymorphonuclear cells (PMNs). Mature milk (i.e., after 4 days) has fewer cells (see Figure 5-3), approximately  $10^5$ /mL with 20% to 30% PMNs. After 6 weeks, few PMNs are present. The functions of the PMNs normally include microbial killing, phagocytosis, chemotactic responsiveness, stimulated hexose monophosphate shunt activity, stimulated nitroblue tetrazolium dye reduction, and stimulated oxygen consumption.<sup>41</sup> When milk PMNs are compared with those in the serum, their activity is often less than that of serum PMN cells. Whether milk PMNs actually perform a role in the protection of the infant has been studied by many investigators using many techniques. Briefly, animal studies have shown that (1) the mammary gland is susceptible to infection in early lactation,

(2) a dramatic increase in PMNs occurs with mammary inflammation, and (3) in the presence of peripheral neutropenia during chronic mastitis, severe infection of the gland occurs. This implies, according to Buescher and Pickering,<sup>41</sup> that the primary function of milk PMNs is to defend the mammary tissue, *per se*, and not to impart immunocompetence to the newborn. This may explain the presence of large numbers of PMNs that are relatively hypofunctional early and then disappear over time. Evidence shows that neutrophils found in human milk demonstrate signs of activation, including increased expression of CD11b (an adherence glycoprotein), decreased expression of L-selectin, spontaneous production of granulocyte-macrophage colony-stimulating factor (GM-CSF), and the ability to transform into CD1<sup>+</sup> dendritic cells (DCs).<sup>154</sup> Human milk macrophages have the morphology and motility of activated cells. The movement of these cells in a three-dimensional system is greater than that of monocytes, their counterparts in peripheral blood. Such activated neutrophils may play a role in phagocytosis at the level of the mucosa of the GI tract, supplementing infants' poor ability to recruit phagocytes to that site.<sup>169</sup>

## LYMPHOCYTES

Both T and B lymphocytes are present in human milk and colostrum and are part of the immunologic system in human milk. T cells are 80% of the lymphocytes in breast milk. Human milk lymphocytes respond to mitogens by proliferation, with increased macrophage-lymphocyte interaction and the release of soluble mediators, including migration inhibitor factor. Cells destined to become lymphopoietic cells are derived from two separate influences, the thymus (T) and the bursa (B) or bursal equivalent tissues. The population of the B cells makes up the smaller part of the total. They synthesize IgA antibody. The term B cell is derived from its origination in a different anatomic site from the thymus; in birds, it has been identified as the bursa of Fabricius. The B cells can be identified by the presence of surface immunoglobulin markers. The B cells in human milk include cells with IgA, IgM, and IgG surface immunoglobulins. B cells transform into plasma cells and remain sessile in the tissues of the mammary gland.

## T CELL SYSTEM

More rapid mitotic activity occurs in the thymus gland than in any other lymphatic organ, yet 70% of the cells die within the cell substance. The thymus is the location for much of the T cell differentiation and selection and plays a major role

in the development of infants' immune systems. Thymosin has been identified as a hormone produced by thymic epithelial cells to expand the peripheral lymphocyte population. After emergence from the thymus gland, T cells acquire new surface antigen markers. The T cells circulate through the lymphatic and vascular systems as long-lived lymphocytes, which are called the "recirculating pool." They then populate restricted regions of lymph nodes, forming thymic-dependent areas.<sup>334</sup> It is interesting to note that exclusively breastfed infants have a significantly larger thymus than formula-fed infants at 4 and 10 months.<sup>134</sup> The significance of the lymphocytes in human milk in affording immunologic benefits to breastfed infants continues to be investigated. It is suggested that lymphocytes can sensitize, induce immunologic tolerance, or incite graft-versus-host reactions. According to Head and Beer,<sup>142</sup> lymphocytes may be incorporated into sucklings' tissues, achieving short-term adoptive immunization of the neonate.

Studies of the activities of lymphocytes have been carried out by a number of investigators who collected samples of milk from lactating women at various times postpartum, examined the number of cell types present, and then studied the activities of these cells in vitro.<sup>170,174</sup> Ogra and Ogra<sup>247</sup> collected samples from 200 women and measured the cell content from 1 through 180 days (see Figure 5-3). They then compared the response of T lymphocytes in colostrum and milk with that of the T cells in the peripheral blood. T cell subpopulations have also been shown by surface epitopes to be similar to those in the peripheral blood.

The greatest number of cells appeared on the first day, with the counts ranging from 10,000 to 100,000/mm<sup>3</sup> for total cells. By the fifth day, the count had dropped to 20% of the first day's count. In addition, the number of erythrocyte rosette-forming cells was determined by using sheep erythrocyte-rosetting technique. The erythrocyte rosette formation lymphocytes constituted a mean 100/mm<sup>3</sup> on the first day and one tenth of that by the fifth day.

At 180 days, total cells were 100,000/mm<sup>3</sup>, lymphocytes were 10,000/mm<sup>3</sup>, and erythrocyte rosette formation lymphocytes were 2000/mm<sup>3</sup>. The investigators compared the values with those in the peripheral blood of each mother; the levels remained essentially constant.<sup>246</sup> In a similar study, Bhaskaram and Reddy<sup>24</sup> sampled milk over time from 74 women and found comparable cell concentrations. They examined the bactericidal activity of the milk leukocytes and found it to be comparable with that of the circulating leukocytes in the blood, irrespective of the stage of lactation or state of nutrition of the mother.

Ogra and Ogra<sup>247</sup> also studied the lymphocyte proliferation responses of colostrum and milk to

antigens. Their data show response to stimulation from the viral antigens of rubella, cytomegalovirus (CMV), and mumps. Analysis of cell-mediated immunity to microbial antigens shows milk lymphocytes are limited in their potential for recognizing or responding to certain infectious agents compared with cells from the peripheral circulation. This is thought to be an intercellular action and not caused by lack of external factors. In contrast, the T cells and B cells have been shown to have unique reactivities not seen in peripheral blood.

Colostral lymphocytes are derived from mature rather than immature T cell subsets. The distribution of T cell subsets in colostrum includes both CD4<sup>+</sup> and CD8<sup>+</sup> cells.<sup>278</sup> The distribution of CD4 cells in colostrum and human milk is lower than in the serum, and fewer CD4 cells exist than CD8 cells.<sup>334</sup> The percentage of CD4 cells is higher than in the serum of either postpartum donors or normal control subjects. No correlation exists with length of gestation and number of cells (normal blood usually contains twice as many CD4<sup>+</sup> as CD8<sup>+</sup> lymphocytes).<sup>166</sup>

Parmely et al.<sup>256</sup> partially purified and propagated milk lymphocytes in vitro to study their immunologic function. Milk lymphocytes responded in a unique manner to stimuli known to activate T lymphocytes from the serum. The authors found milk lymphocytes to be hyporesponsive to nonspecific mitogens and histocompatibility antigens on allogenic cells in their laboratory. They found them unresponsive to *Candida albicans*. Significant proliferation of lymphocytes occurred in response to the K<sub>1</sub> capsular antigen of *Escherichia coli*.<sup>146</sup> Lymphocytes from blood failed to respond to the same antigen. This supports the concept of local mammary tissue immunity at the T lymphocyte level.

More recent experiments in rodents have provided evidence that T lymphocytes that are reactive to transplantation alloantigens can adoptively immunize a suckling newborn. Foster nursing experiments performed in rodents have shown that newborn rats exposed to allogenic milk manifested alterations in their reactivity to skin allografts of the foster mother's strain. In animals, mothers may give their suckling newborn immunoreactive lymphocytes. The influence of maternal milk cells on the development of neonatal immunocompetence has been demonstrated in several different immunologic contexts. Congenitally, athymic nude mice nursed by their phenotypically normal mothers or normal foster mothers had increased survival. The mothers contributed their T-cell-helper activity to the suckling newborn.

Colostral lymphocytes proliferate in response to various mitogens, alloantigens, and conventional antigens. Colostral cells survive in the neonatal

stomach and in the gut of experimental animals, some remaining viable in the upper GI tract for a week. No evidence, however, indicates that trans-epithelial migration takes place when neonatal mice are foster-nursed by newly delivered animals whose colostral cells were tagged with  $^3\text{H}$ -thymidine.<sup>41</sup>

Cells in human milk have been studied using the same markers employed with cells in the peripheral blood; 80% of the lymphocytes are T cells that are equally distributed between CD4 $^+$  and CD8 $^+$  subpopulations, and their T cell receptors are principally of the  $\alpha/\beta$  type. CD4 $^+$  cells are common leukocyte cells of the helper and suppressor-inducer subsets, and CD8 $^+$  cells are leukocytes of the cytotoxic and noncytotoxic subsets. T cells in human milk are presumed activated because they display increased phenotypic markers of activation, including HLA-DR and CD25 (IL-2 receptor). The majority of T cells in human milk are CD45RO $^+$  consistent with effector and memory T cells.<sup>284,334</sup> These cells are effective producers of interferon- $\gamma$ , which is consistent with their phenotypic features. Here again, human milk may supplement the infant with a functioning immune cell to compensate for an identified deficiency in the infant, a paucity of memory T cells.

## B CELL SYSTEM

Juto<sup>166</sup> studied the effect of human milk on B-cell function. Cell-free, defatted, filtered colostrum, as well as mature breast milk, showed an enhancing effect on B-cell proliferation and generation of antibody secretion. This was not seen with formula. Juto suggested that this could represent an important immunologic mechanism. Goldblum et al.<sup>104</sup> were able to show a B-cell response in human colostrum to *E. coli* given to the mother orally, which was not accompanied by a systemic response in the mother. This suggests that the breast and breast milk reflect sites of local, humoral, or cell-mediated immunity, which were initially induced at a distant site such as the gut and transferred via reactive lymphoid cells migrating to the breast. Head and Beer<sup>142</sup> provided a scheme to describe this mechanism (see Figure 5-2). The diagram depicts the progeny of specifically sensitized lymphocytes that originated in GALT, specifically Peyer's patches, as they migrate to the mammary gland. As they infiltrate the mammary gland and its secretion, they supply the breast with immune cells capable of selected immune responses. Ogra and Ogra<sup>246,247</sup> suggest that the cells may selectively accumulate in the breast during pregnancy. The responses of milk cells and their antibodies are not representative of an individual's total immunity.<sup>256</sup> Most of these immunocompetent cells, initially stimulated in GALT, recirculate to the external mucosal surface and populate the lamina

propria as antibody-producing plasma cells. A substantial number of these antigen-sensitized cells selectively home-in to the stroma of the mammary glands and initiate local IgA antibody synthesis against the antigens initially encountered in the respiratory or intestinal mucosa.<sup>24</sup> More recent work on human milk-derived B-cells demonstrates that breast milk contains activated memory B-cells, different than those in the blood. These cells express mucosal adhesion molecules ( $\alpha_4\beta_7^{-/+}$ ,  $\alpha_4\beta_1^+$ , CD44 $^+$ , CD62L $^-$ ), suggesting an origin in the mammary gland, but similar to GALT-associated B-cells.<sup>320</sup> The mucosae-associated epithelial cytokine CCL28 may contribute to migration of and retention of these cells in the mammary gland.<sup>332</sup> This information supports the concept of the mammary gland as an effector site of the mucosal immune system.

The accumulated epidemiologic research supports the concept that colostrum and milk provide human infants with immunologic benefits. Both T- and B-lymphocytes found in breast milk are reactive against organisms invading the intestinal tract. However, the proof of specific viral or bacterial protection, secondary to the action of immunologically active B-cells, has not been demonstrated.

## Survival of Maternal Milk Cells

Although it is clear that cells are provided in the colostrum and milk, the effectiveness and impact of these cells on the neonate depend on their ability to survive in the GI tract. It has been demonstrated in several species, including humans, that the pH of the stomach can be as low as 0.5, but the output of hydrochloric acid is minimal for the first few months, as is the peptic activity. Immediately after a feeding begins, the pH rises to 6.0 and returns to normal in 3 hours. The cells from milk tolerate this. Studies in rats have also shown that intact nucleated lymphoid cells are found in the stomach and intestines.<sup>19</sup> These cells, when removed from rat stomachs, are capable of phagocytosis. Lymphoid cells in milk have been shown to traverse the mucosal wall.

When human milk is stored, however, the cellular components do not tolerate heating to 63°C (145.4°F), cooling to -23°C (-9.4°F), or lyophilization. Although a few cells may be identified in processed milk, they are not viable.<sup>105</sup>

## STEM CELLS

Interest in mammary stem cells (MaSCs) has blossomed since Cregan et al.<sup>62</sup> reported the presence of MaSCs in human breast milk. Their research was based on the demonstration of the cytokeratin 5 MaSC marker on cells isolated from human breast milk. Additional analysis showed cells from human

milk with both the multipotent stem cell marker, nestin, and the cytokeratin 5 marker. There are several areas of interest relative to these MaSCs in humans: the potential ready availability of multipotent mesenchymal stem cells for autologous stem cell therapies; the identified cell markers and signaling pathways on these cells, which could lead to more targeted breast cancer therapies; the role of stem cells in the dynamic states of the breast, especially lactation; the potential correlation between MaSCs and transplantation tolerance; and the state of microchimerism of MaSCs in the infant and the potential effects on the infant.\*

The mammary gland is an attractive target in the search for stem cells, in that it is a dynamic, metabolically active tissue. It has the capacity to proliferate and hypertrophy through adolescent development, pregnancy, lactation, and the subsequent involution phase of the breast. Embryonic stem cells have a tremendous differentiation potential, in that they can develop into every cell type in the body. Adult stem cells constitute a small portion of organ cells that can mature into multiple specific cell types. Adult stem cells can also produce new stem cells to maintain the population of these cells in the organ. They are said to remain quiescent within "stem cell niches" within an organ.<sup>336</sup> DeOme et al. noted the existence of adult stem cells in mammary tissue in 1959. Other investigators investigated the renewal capacity of these cells and considered them to be a multipotent stem cell.<sup>69</sup> The search for such pluripotent stem cells continued, using a variety of markers (Sca 1) and characteristics (Hoechst dye efflux), which led to the identification of mammary gland stem cell progenitors (MG-SP). These are able to differentiate into both the K18+ luminal and K14+ myoepithelial cell lineages.<sup>58</sup> Dontu et al. demonstrated that MaSCs grown in "mammospheres" (under anchorage independent conditions) expressed the surface cell markers CD49f, K5, and CD10. Some additional markers, characteristic of luminal and myoepithelial cells, were expressed. Some of these same cells were treated with prolactin and developed into functional alveolar cells, secreting beta-casein. Other investigators demonstrated that these progenitor cells, raised in mammospheres, were capable of differentiating in three types of cells (luminal, myoepithelial, and alveolar). They were clonally derived and could retain multipotent capacity after propagation through several passages.<sup>72</sup> Others have employed label-retention studies to characterize MaSCs as label-retention cells (LRCs) and been able to demonstrate asymmetric division in their nonquiescent

states.<sup>301</sup> Subsequent research has identified signaling pathways related to stem cell propagation including Wnt/beta-catenin, Notch, Hedgehog (Hh) transforming growth factor (TGF)-beta, phosphatase and tensin homologue, and Bmi.<sup>336</sup> Stem cells have many of the features of tumor cells, including self-renewal and the ability to replicate indefinitely.<sup>337</sup> The question is what might distinguish normal progenitor cells from tumorigenic progenitor cells. Other investigators searching for such tumorigenic mammary gland stem cells identified MaSCs with the surface markers Lin<sup>-</sup>CD29hiCD24<sup>+</sup>, which were capable of generating a functional mammary gland in the mouse.<sup>299</sup>

The exact mechanism of acquired tolerance to noninherited maternal antigens (NIMA) is unknown. It has been suggested that exposure of the fetus during pregnancy and exposure during breastfeeding to NIMA may be the explanation for transplantation tolerance in breastfed persons.<sup>4,214</sup> Breast milk contains a variety of major histocompatibility complex antigens from the mother. Molitor et al. demonstrated high levels of NIMA HLA proteins in both the cord blood and breast milk, emphasizing the potential role of human breast milk in exposing the infant to NIMAs. The existence of mammary derived stem cells in the infant suggests a degree of microchimerism in infants directly from maternal breast cells in breast milk. Dutta and Burlingham propose that stem cell microchimerism in infants is related to tolerance to NIMAs.<sup>79</sup>

Human milk contains a heterogeneous cell population. Early lactation milk and colostrum contain larger numbers of leukocytic origin cells, and mature breast milk contains more cells of epithelial origin. There also exists variability in the breast milk cell content and composition between breastfeeding women and within an individual woman over the time period of lactation.<sup>136</sup> Hassiotou et al. have proposed a broad degree of differentiation of breast milk stem cells (hBSCs) found in human milk. The proposed lineage includes differentiation in breast cells (myoepithelial, ductal, alveolar, and secretory), stromal type cells (osteoblast, chondrocytes, and adipocytes), neural progenitor type cells, and endodermal cell types (hepatocytes and pancreatic cells).<sup>135,137</sup> There remains much more to be understood about the existence of human breast stem cells in human milk and their possible role in health in the infant and later in life.

## Humoral Factors

### IMMUNOGLOBULINS

All classes of immunoglobulins are found in human milk. The study of immunoglobulins has been

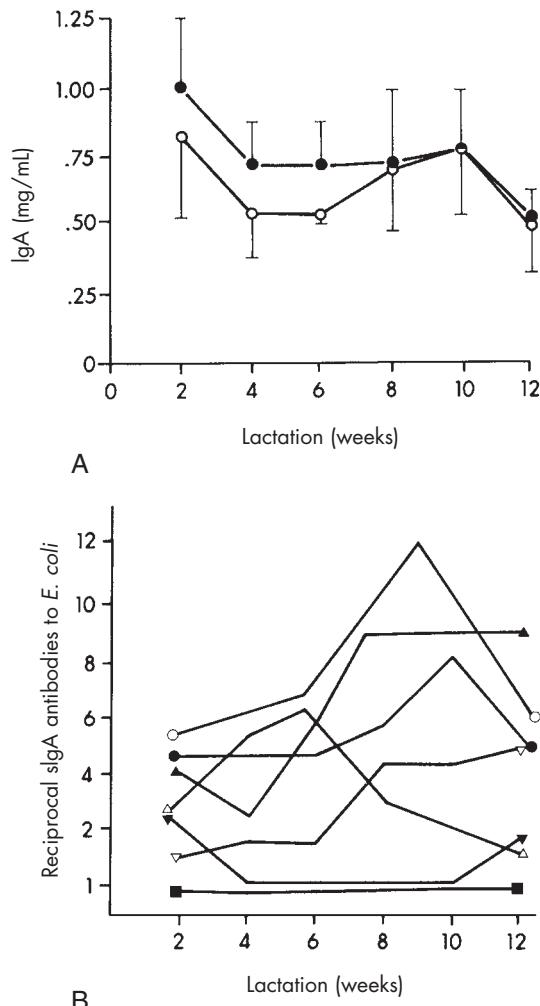

\*16,85,135,136,203,257,290,299,318,336

enhanced through the techniques of electrophoresis, chromatographics, and radioimmunoassay. More than 30 components have been identified; of these, 18 are associated with proteins in the maternal serum, and the others are found exclusively in milk. The concentrations are highest in the colostrum of all species, and the concentrations change as lactation proceeds.<sup>210</sup> IgA, principally sIgA, is highest in colostrum. Although postpartum levels fall throughout the next 4 weeks, substantial levels are maintained throughout the first year, during gradual weaning between 6 and 9 months, and even during partial breastfeeding (when the infant receives solid foods) in the second year of life (Figure 5-4 and Table 5-2). Specific sIgA antibodies to *E. coli* persist through lactation and may even increase (see Figure 5-4).

The main immunoglobulin in human serum is IgG; IgA content is only one fifth the level of IgG. In milk, however, the reverse is true. IgA is the most important immunoglobulin in milk, not only in concentration but also in biologic activity. sIgA is likely synthesized in the mammary alveolar cells<sup>307</sup> or by lymphocytes that have migrated from Peyer's patches in the GI tract or from lymphoid tissue in the respiratory tract via the lymphatics to the breast. Cytokines cause isotype switching of local IgM<sup>+</sup> B-cells to become IgA<sup>+</sup> B-lymphocytes.<sup>107,297,330</sup> These isotype switched cells travel to the breast, where they are transformed into plasma cells producing secretory, dimeric IgA. It is through this "enteromammary" pathway that the mother provides increased amounts of sIgA to the infant against the microorganisms present in the mother's and infant's environment.<sup>313</sup>

Brandtzaeg<sup>29</sup> has proposed a model for the transport of IgA (polymeric) and IgM (pentameric), produced by plasma cells, across the secretory epithelium. The model involves the formation of sIgA and IgM, through binding, with the secretory component attached to the epithelial membrane. This occurs in the membrane of mammary epithelial cells during lactation.<sup>30,115</sup>

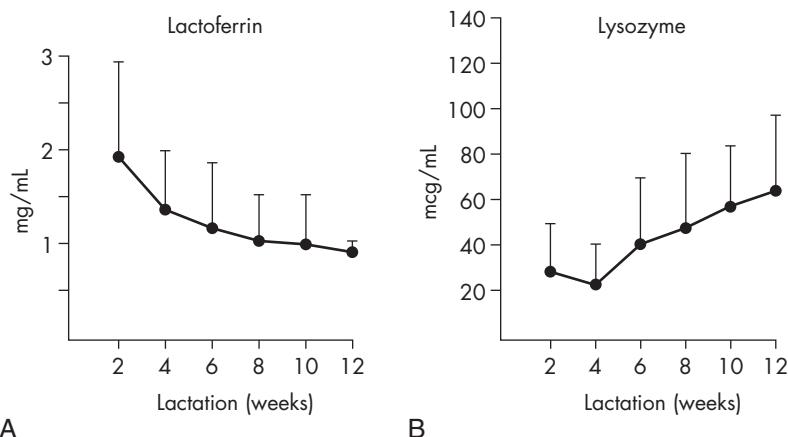

Quantitative determinations of immunoglobulins in human milk were made from milk collected at birth to as long as 27 months postpartum by Petersen et al.<sup>259</sup> and by Goldman et al.<sup>114</sup> The IgA content was high immediately after birth, dropping in 2 to 3 weeks, and then remaining constant. Similar observations were made on IgG levels and IgM levels. Ogra and Ogra<sup>246,247</sup> have compared serum and milk levels at various times postpartum. Samples obtained separately from the left and right breasts showed similar values. The levels remained constant during a given feeding and throughout a 24-hour period. In all quantitative determinations, IgA is the predominant immunoglobulin in breast milk, constituting 90% of all the immunoglobulins in colostrum and milk.

**Figure 5-4.** Same subjects in Figure 5-3 were examined during second through twelfth week of lactation. **A**, Longitudinal study of total IgA and sIgA. Total (●) and secretory IgA (○). **B**, Longitudinal study of reciprocal of sIgA antibody titers to *E. coli* somatic antigens in human milk. The sIgA antibody titers to *E. coli* somatic antigens from each subject are represented by a different symbol (open and closed circles, diamonds, and squares). (From Goldman AS, Garza C, Nichols BL, et al: Immunologic factors in human milk during the first year of lactation, *J Pediatr* 100:563, 1982.)

Ogra and Ogra<sup>246–248</sup> studied the serum of postpartum lactating mothers and nonpregnant matched control subjects. They noted that the individual and mean concentrations of all Ig classes were lower in the postpartum subjects. The levels were statistically significant for IgG; they were 50 to 70 mg higher in the nonpregnant women.

Immunoglobulin levels, particularly IgA and IgM, are very high in colostrum and drop precipitously in the first 4 to 6 days, but IgG does not show this decline. The volume of mammary secretion, however, increases dramatically in this same period; thus the absolute amounts of immunoglobulins

**Figure 5-5.** Same subjects in Figure 5-3 were examined during second through twelfth week of lactation. Data in longitudinal studies are presented as mean  $\pm$  SD. **A**, Concentration of lactoferrin progressively decreased through first 8 weeks ( $r=0.69$ ) (2 vs. 8 weeks;  $p<0.02$ ), but not thereafter. **B**, In contrast, lysozyme levels steadily increased from fourth through twelfth week ( $r=0.76$ ) (4 vs. 12 weeks;  $p<0.01$ ). (From Goldman AS, Garza C, Nichols BL, et al: Immunologic factors in human milk during the first year of lactation, *J Pediatr* 100:563, 1982.)

Concentrations of Immunologic Components in Human Milk Collected During Second Year of Lactation			
Component	Duration of Lactation (mo)		
	12	13-15	16-24
IgA (mg/mL)			
Total	0.8 $\pm$ 0.3	1.1 $\pm$ 0.4	1.1 $\pm$ 0.3
Secretory (sIgA)	0.8 $\pm$ 0.3	1.1 $\pm$ 0.3	1.1 $\pm$ 0.2
Lactoferrin (mg/mL)	1.0 $\pm$ 0.2	1.1 $\pm$ 0.1	1.2 $\pm$ 0.1
Lysozyme (mcg/mL)	196 $\pm$ 41	244 $\pm$ 34	187 $\pm$ 33
sIgA antibodies (reciprocal titers to <i>E. coli</i> somatic antigens)	5 $\pm$ 6	9 $\pm$ 10	6 $\pm$ 3

Data are presented as the mean  $\pm$  SD.

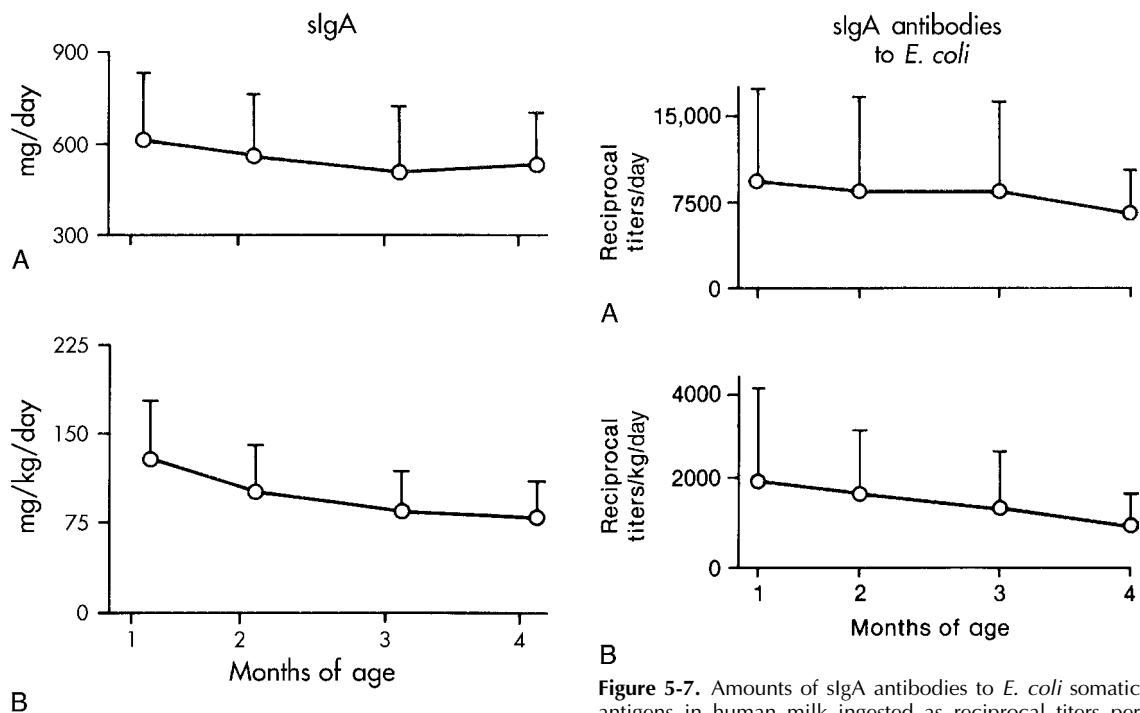

From Goldman AS, Goldblum RM, Graza C: Immunologic components in human milk during the second year of lactation, *Acta Paediatr Scand* 72:461, 1983.

remain more nearly constant than it would first appear. Local production and concentration of IgA, and probably IgM, may take place in the mammary gland at delivery.

IgE and IgD have also been measured in colostrum and milk. Using radioimmunoassay techniques, colostrum was found to contain concentrations of 0.5 to 0.6 IU/mL IgE in 41% of samples and less in the remainder.<sup>11</sup> IgD was found in all samples in concentrations of 2 to 2000 mg/dL. Plasma levels were poorly correlated. The findings suggest possible local mammary production rather than positive

transfer. The question of whether IgE or IgD antibodies in breast milk have similar specificities for antigens as the IgA antibodies in milk remains unanswered.<sup>208</sup> Keller et al.<sup>171</sup> examined the question of local mammary IgD production, and its possible participation in a mucosal immune system, by comparing colostrum and plasma levels of total IgD with specific IgD antibodies. From their work comparing colostrum/plasma ratios for IgG, IgD, and albumin and measuring IgD against specific antigens, the authors reported evidence for IgD participation in the response of the mucosal immune system, with increases in total IgD and IgD against specific antigens found in colostrum.

Butte et al.<sup>45</sup> addressed the question of total quantities of immunologic components secreted into human milk per day and available to an infant. They did so by measuring the amounts of sIgA, sIgA antibodies to *E. coli*, lactoferrin, and lysozyme ingested per day and per kilogram per day in the first 4 months of life (Figures 5-6 through 5-10). Lactoferrin, sIgA, and sIgA antibodies gradually declined in amount ingested per day and per kilogram per day. Lysozyme, in contrast, rose during the same period in total amount available and amount per kilogram per day. The authors<sup>45</sup> suggest that production and secretion of these immunologic factors by the mammary gland may be linked to the catabolism of the components at an infant's mucosal tissues. When the concentrations of sIgA, IgG, IgM,  $\alpha_1$ -antitrypsin, lactoferrin, lysozyme, and globulins C3 and C4 were compared in relationship to parity and age of the mother, no consistent trend was observed. When maturity of the pregnancy was considered, however, mean concentrations of all these proteins were higher, except for IgA, when the delivery was premature. Because

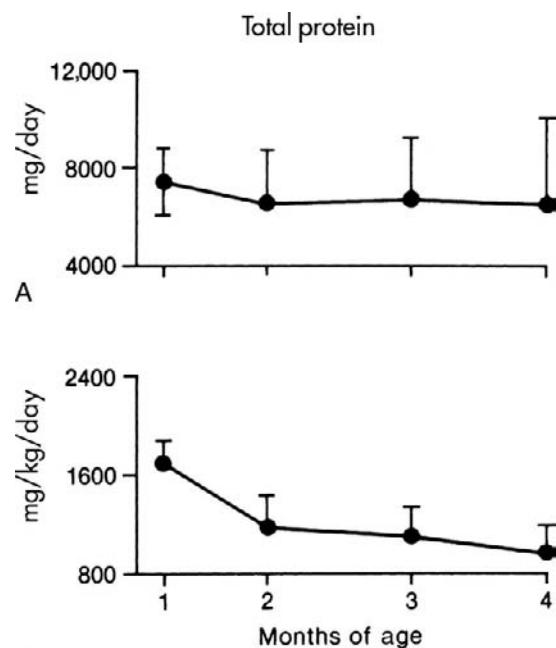

**Figure 5-6.** Amounts of sIgA and sIgA antibodies to *E. coli* somatic antigens in human milk ingested per day (A). Per kilogram per day (B). Data are presented as mean $\pm$ SD. (From Butte NF, Goldblum RM, Fehl LM, et al: Daily ingestion of immunologic components in human milk during the first four months of life, *Acta Paediatr Scand* 73:296, 1984.)

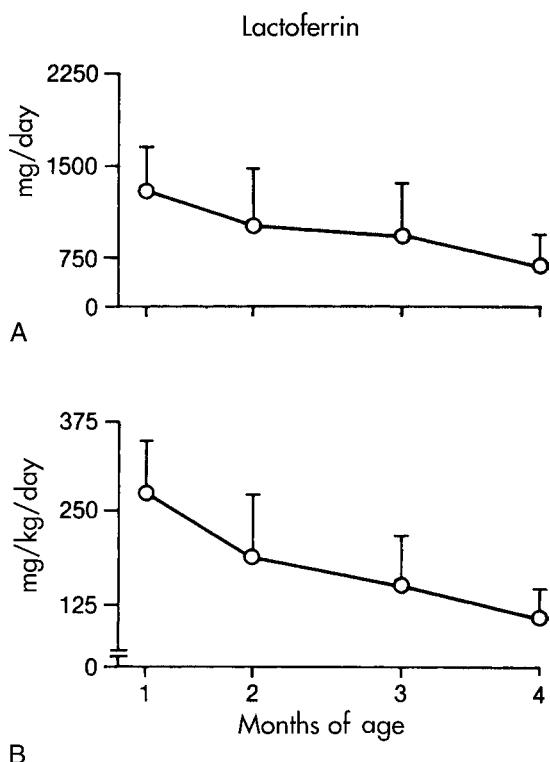

**Figure 5-7.** Amounts of sIgA antibodies to *E. coli* somatic antigens in human milk ingested as reciprocal titers per day (A). Per kilogram per day (B). Data are presented as mean $\pm$ SD. several proteins in human milk have physiologic functions in infants. Davidson and Lönnerdal<sup>66</sup> examined the survival of human milk proteins through the GI tract. Crossed immuno-electrophoresis showed that three human milk proteins transversed the entire intestine and were present in the feces: lactoferrin, sIgA, and  $\alpha_1$ -antitrypsin.

Miranda et al.<sup>213</sup> reported on the effect of maternal nutritional status on immunologic substances in human colostrum and milk. Maternal malnutrition was characterized as lower weight-to-height ratio, creatine/height index, total serum proteins, and IgG and IgA. In malnourished mothers, the colostrum contained one third the normal concentration of IgG, less than half the normal level of albumin, and lower IgA and complement C4. Lysozyme, complement C3, and IgM levels were normal. Levels improved with development of mature milk and improvement in maternal nutrition. According to one report in 2003, moderate exercise during lactation does not affect the levels of IgA, lactoferrin, or lysozyme in breast milk.<sup>199</sup> Immunologic components contained in human milk during the second year of lactation become a significant point as more infants are nursed longer. For a longitudinal study of lactation into the second year by Goldman

**Figure 5-9.** Amount of lactoferrin in human milk ingested per day (A). Per kilogram per day (B). Data are presented as mean $\pm$ SD. (From Butte NF, Goldblum RM, Fehl LM, et al: Daily ingestion of immunologic components in human milk during the first four months of life, *Acta Paediatr Scand* 73:296, 1984.)

et al.,<sup>111</sup> women were included who had fully breastfed their infants for 6 months to a year and were continuing to partially breastfeed. Samples were collected by fully emptying the breast by electric pump. Table 5-2 summarizes the concentrations of the measured factors. No leukocytes were detected. Concentrations of total IgA and sIgA, lactoferrin, and lysozyme were similar to those 7 to 12 months postpartum and during gradual weaning. sIgA antibodies to *E. coli* were produced in the second year, demonstrating significant immunologic benefit to the infant with continued breastfeeding.<sup>111</sup> IgA, IgM, and IgG were measured in nursing women from the beginning of lactation and simultaneously in the feces of their children by Jatsky et al.<sup>161</sup> at the Academy of Medicine in Moscow. They reported IgA to be very high in the milk and rapidly increasing in the feces. IgG and IgM levels, however, were low in both milk and feces. In normal full-term bottle-fed infants, IgA appeared in the feces at 3 to 4 weeks of age, but at much lower levels than in breastfed infants. Koutras and Vigorita<sup>179</sup> reported that in the first 8 weeks of life increased amounts of sIgA were found in the stools

**Figure 5-10.** Amount of lysozyme in human milk ingested per day (A). Per kilogram per day (B). Data are presented as mean $\pm$ SD. (From Butte NF, Goldblum RM, Fehl LM, et al: Daily ingestion of immunologic components in human milk during the first 4 months of life, *Acta Paediatr Scand* 73:296, 1984.)

of breastfed infants compared with formula-fed infants. The authors ascribed this phenomenon to the presence of sIgA in human milk and a stimulation of the local GI production of immunoglobulin.

Savilahti et al.<sup>291</sup> measured serum levels of IgG, IgA, and IgM in 198 infants at 2, 4, 6, 9, and 12 months of age. By 9 months, the exclusively breastfed infants had IgG and IgM levels significantly lower than those who had been weaned early (before 3.5 months) to formula. Six infants were still exclusively breastfed at 12 months, and their IgA levels had also lowered to levels found at 2 months with bottle feeders. Infection rates were similar. Two months after the children were weaned to formula, the IgG and IgM levels were comparable. Iron and zinc levels were the same in all children.

## SPECIFICITY OF IMMUNOGLOBULINS

sIgA antibodies have been identified in human milk that recognize a large variety of microorganisms. The sIgA antibodies that recognize bacteria, viruses, parasites, and fungi are listed in Table 5-3. Some sIgA antibodies recognize various bacteria, including

**TABLE 5-3** Antibodies in Human Milk

Factor	Shown, In Vitro, to Be Active Against:	Assay	Effect of Heat
Secretory IgA	Enteroviruses		
	Poliovirus types 1, 2, 3	ELISA, NA, Precipitin	Stable at 56°C for 30 min; some loss (0%-30%)
	Coxsackievirus types A <sub>9</sub> , B <sub>3</sub> , B <sub>5</sub>	NA	Stable at 62.5°C for 30 min; destroyed by boiling
	Echovirus types 6 and 9	NA	
	Herpesvirus		
	CMV	ELISA, IFA, NA	
	Herpes simplex virus	NA	
	HIV		
	Semliki Forest virus	IFA	
	Respiratory syncytial virus	IFA	
	Rubella	IFA, HAI	
	Reovirus type 3	ELISA, NA	
	Rotavirus		
	Measles		
	Norovirus		
	<i>Escherichia coli</i> (EIEC, EAEC, EPEC)		
	<i>Shigella</i>		
	<i>Salmonella</i>		
	<i>Campylobacter</i>		
	<i>Vibrio cholerae</i>		
	<i>Haemophilus influenzae</i> type b		
	<i>Streptococcus pneumoniae</i>

Some sIgA antibodies recognize *Entamoeba histolytica*, *Giardia*, *Strongyloides stercoralis*, and *C. albicans*.<sup>107,240</sup> The list of viruses for which sIgA antibodies exist in human milk is equally long, including enteroviruses (poliovirus, coxsackie, and echovirus), CMV, herpes simplex virus, human immunodeficiency virus (HIV), Semliki Forest virus, respiratory syncytial virus (RSV), rubella, reovirus type 3, rotavirus, measles, Norovirus, and porcine coronavirus. IgG and IgM antibodies also exist in human milk against CMV, RSV, and rubella, as well as IgE antibodies against parvovirus B19. Noguera-Obenza and Cleary<sup>240</sup> reviewed the role of breast milk sIgA in providing protection for infants against various agents specifically causing bacterial enteritis.

## STABILITY OF IMMUNOGLOBULINS

Preservation of human milk at  $-20^{\circ}\text{C}$  for up to 3 months does not decrease significantly the levels of IgA, IgG, IgM, C3, C4, lactoferrin, or lysozyme.<sup>84,91,194,249</sup> The preservation of sIgA, IL-6, and TNF- $\alpha$  with freezing at  $-4^{\circ}\text{C}$  or  $-20^{\circ}\text{C}$  was recently confirmed by Hines et al.<sup>145</sup>

A variety of different heat treatments have been applied to milk to protect against bacterial contamination or to protect against infection with specific infectious agents (especially HIV and CMV). Heat treatments include low-temperature, short-time at  $56^{\circ}\text{C}$  for 15 minutes; Holder pasteurization at  $62.5^{\circ}\text{C}$  for 30 minutes; high-temperature, short-time at  $70$  to  $73^{\circ}\text{C}$  for 15 seconds; boiling at  $100^{\circ}\text{C}$  for greater than 1 minute; sterilization, variable time periods; Pretoria pasteurization at  $56$  to  $62.5^{\circ}\text{C}$  for approximately 15 minutes<sup>162</sup>; flash heating at  $56^{\circ}\text{C}$  for approximately 6 minutes with a peak temperature at  $72^{\circ}\text{C}$ <sup>156,157</sup>; and microwave heating, with milk temperatures of  $20$  to  $77^{\circ}\text{C}$  for 30 seconds.<sup>272</sup> Boiling or sterilization essentially destroys 100% of immunologic activity. sIgA and lysozyme activities drop by 20% with Holder pasteurization and by 50% at  $65^{\circ}\text{C}$ . Neither low-temperature, short-time nor high-temperature, short-time reduces the sIgA or lysozyme content markedly. IgG and IgM are greatly reduced by Holder pasteurization.

sIgA differs antigenically from serum IgA. IgA can be synthesized in the nonlactating, as well as in the lactating, breast. It is a compact molecule and resistant to proteolytic enzymes of the intestinal tract and the low pH of the stomach. The sIgA present in human milk is primarily manufactured by plasma cells in the mammary gland, modified in its translocation across the mammary epithelia, and only minimally produced by the cellular

lymphocytes in milk. Levels in milk are 10 to 100 times higher than in serum. Levels in cow milk are very low, that is, a tenth of the level in mature human milk (0.03 mg/dL). Later in life, the human intestinal tract's subepithelial plasma cells secrete IgA. The intestinal secretion of sIgA does not occur in the neonatal period but increases between 4 and 12 months of life.

Discussion continues as to whether any antibodies are absorbed from the intestinal tract, although probably 10% are absorbed. Almost 75% of ingested IgA from milk survives passage through the intestinal tract and is excreted in the feces. All immunoglobulin classes have been identified in the feces.<sup>277</sup> A large body of evidence demonstrates the activity of the immunoglobulins, especially IgA, at the mucosal level of the GI and respiratory tracts. These antibodies provide local intestinal protection against microorganisms, which may infect the mucosa or enter the body through the gut or respiratory tract.

## Other Bioactive Factors

### BIFIDUS FACTOR

It is well established that the predominant bacteria found in breastfed infants are bifid bacteria. Bifid bacteria are gram-positive, nonmotile, anaerobic bacilli. Many observers have shown the striking difference between the flora of the guts of breastfed and bottle-fed infants. Gyorgy<sup>122</sup> demonstrated the presence of a specific factor in colostrum and milk that supported the growth of *Lactobacillus bifidus*. Bifid factor has been characterized as a dialyzable, nitrogen-containing carbohydrate that contains no amino acid.

In vitro studies by Beerens et al.<sup>20</sup> showed the presence of a specific growth factor for *Bifidobacterium bifidum* in human milk, which they called BB. Other milks, including cow milk, sheep milk, pig milk, and infant formulas, did not promote the growth of this species but did show some activity supporting *B. infantis* and *B. longum*. This growth factor was found to be stable when the milk was frozen, heated, freeze-dried, and stored for 3 months. Growth-promoting factors were present for the six strains studied, which varied in their resistance to physical change. Because all these factors were active in vitro, they did not require the presence of intestinal enzymes for activation. It has not been possible to show the presence of this growth factor in other mammalian milks; thus it may contribute to the implantation and persistence of *B. bifidum* in a breastfed infant's intestine.

*Lactobacillus* has been described as one of a number of probiotic bacteria, which provide an immune

protective benefit to their host. *Lactobacillus* reportedly stimulates antibody production and improves phagocytosis by blood leukocytes.<sup>167,261</sup> The use of probiotic bacteria has reportedly produced benefits in a variety of situations associated with infections. The addition of such bacteria to formula is another example of trying to make formula better by making it more like breast milk. Hatakka et al.<sup>138</sup> examined the possible effect of adding probiotic bacteria to formula on the occurrence of infection in children attending daycare. They reported modest reductions in the number of children with complicated respiratory infections or lower respiratory tract infections, as well as the number of children receiving antibiotics for a respiratory infection, in the group of children receiving formula supplemented with *Lactobacillus rhamnosus* GG compared with children receiving unsupplemented formula.

## RESISTANCE FACTOR

It was well known in the preantibiotic era that human milk protects human infants throughout lactation against staphylococcal infection. Gyorgy<sup>122</sup> identified the presence of an "antistaphylococcal factor" in experiments with young mice that had been stressed with staphylococci. This factor, with no demonstrable direct antibiotic properties, was termed resistance factor and described as nondialyzable, thermostable, and part of the free-fatty acid part of the phosphide fraction, probably C18:2, but distinct from linoleic acid.

## LYSOZYME

Human milk contains a nonspecific antimicrobial factor, lysozyme, which is a thermostable, acid-stable enzyme. This enzyme is a 130-amino-

acid-containing glycoprotein that can hydrolyze the 1 to 4 linkage between *N*-acetylglucosamine and *N*-acetylmuramic acid in bacterial cell walls. It is found in large concentrations in the stools of breastfed infants and not in stools of formula-fed infants; thus it is thought to influence the flora of the intestinal tract.

Goldman et al.<sup>114</sup> describe an initial fall in lysozyme levels from 85 to 90 mg/mL to 25 mg/mL at 2 to 4 weeks and then an increase during 6 months to 250 mg/mL (see Figure 5-5). Lysozyme levels show an increase over time during lactation; this finding is more apparent in Indian women than in those of the Western world. Reddy et al.<sup>276</sup> studied the levels of lysozyme in well-nourished and poorly nourished women in India and found no difference between them (Table 5-4). As shown in this study, lysozyme levels increase during lactation. Levels in human milk are 300 times the level in cow milk. Lysozyme is bacteriostatic against Enterobacteriaceae and gram-positive bacteria.<sup>265</sup> It is secreted by neutrophils and some macrophages and is present in many body secretions in the adult.

In a study of immunologic components in human milk in the second year of lactation, Goldman et al.<sup>97</sup> reported that concentrations of lysozyme, lactoferrin, and total IgA and sIgA were similar to those in uninterrupted lactation and in gradual weaning at 6 to 9 months. sIgA antibodies to *E. coli* were also produced during the second year. The authors state that "this supports the idea that the enteromammary lymphocyte traffic pathway, which leads to the development of lymphoid cells in the mammary gland that produce IgA antibodies to enteric organisms, operates throughout lactation."<sup>111</sup> When cow milk formula is added to human milk, it reduces the effect of lysozyme; however, powdered human milk fortifier (Enfamil) did not inhibit the antiinfective properties.<sup>173</sup>

**TABLE 5-4** Antibacterial Factors in Colostrum and Mature Milk in Well-Nourished and Undernourished Indian Women

Group	Hemoglobin (g/dL)	Serum Albumin (g/dL)	Immunoglobulins (mg/dL)			Lysozyme (mg/dL)	Lactoferrin (mg/dL)
			IgA	IgG	IgM		
<b>Colostrum (1-5 days)</b>							
Well-nourished women	11.5±0.37	2.49±0.065	335.9±37.39 (17)*	5.9±1.58 (17)	17.1±4.29 (17)	14.2±2.11 (15)	420±49.0 (28)
Undernourished women	11.3±0.60	2.10±0.081	374.3±42.13 (10)	5.3±2.30 (10)	15.3±2.50 (10)	16.4±2.39 (21)	520±69.0 (19)
<b>Mature milk (1-6 months)</b>							
Well-nourished women	12.8±0.43	3.39±0.120	119.6±7.85 (12)	2.9±0.92 (12)	2.9±0.92 (12)	24.8±3.41 (10)	250±65.0 (17)

## LACTOFERRIN

Lactoferrin is an iron-binding protein closely related to the serum iron transport protein, transferrin, and is part of the larger transferrin protein family. Lactoferrin is found in mucosal secretions (tears, saliva, vaginal fluids, urine, nasal and bronchial secretions, bile, GI fluids) and, notably, in milk and colostrum. A bacteriostatic effect of lactoferrin is well established for a wide range of microorganisms, including gram-positive and gram-negative aerobes, anaerobes, viruses, parasites, and fungi. The original proposed mechanism of action for its bacteriostatic effect was depriving the microorganism of iron. A second antibacterial action, involving direct action with bacterial surfaces, binds negatively charged molecules (lipoteichoic acid) on the surface of gram-positive bacteria. This neutralizes the surface charge, allowing the action of other antibacterial factors (like lysozyme or binding lipid A) on gram-negative bacteria, which releases the lipid, producing damage to the cell membrane. Another antibacterial action is binding bacterial adhesions blocking host cell interaction.<sup>116</sup> Lactoferrin can kill *C. albicans* and *C. krusei* by changing the permeability of the fungal cell surface. Lactoferrin now is considered a multifunctional, immunoregulatory protein.

The biologic role of lactoferrin has been reviewed in several studies.<sup>197,198,242,289</sup> They point out that lactoferrin reversibly binds two ferric ions and that its affinity for iron is 300 times greater than that of transferrin, retaining iron down to a pH of 3. Human lactoferrin is strongly basic. Lactoferrin is normally unsaturated with iron,<sup>44</sup> and it is usually less than 10% saturated with iron in human milk.<sup>93,289</sup> Oral iron therapy for an infant can interfere with the bacteriostatic action of lactoferrin, which depends on its unsaturated state for some portion of its bacteriostatic function. Reddy et al.<sup>276</sup> showed that giving iron to the mother did not interfere with the saturation of lactoferrin in the milk or, thus, its potential bacteriostatic effect. Protein energy malnutrition, rather than iron supplies, influences lactoferrin synthesis in the mammary gland. Malnourished but noniron-deficient mothers are lactoferrin deficient.

The concentration of lactoferrin is high in colostrum—600 mg/dL—then progressively declines over the next 5 months of lactation, leveling at about 180 mg/dL. Breast milk also contains small amounts of transferrin (10 to 15 mg/mL). Lactoferrin is 10% to 15% of the total protein content of human milk.<sup>197</sup> Lactoferrin is resistant to proteolysis, especially in its iron-saturated form. Intact lactoferrin is detectable in the stool of infants, with higher proportions of lactoferrin measurable in the stool of premature infants.<sup>71</sup> Both intact lactoferrin

and fragments have been detected in the urine of premature infants, although absorption is less likely in full-term infants.<sup>130</sup> The absorption of iron from breast milk is directly enhanced by lactoferrin.<sup>198</sup>

Many bacteria require iron for normal growth, and one bacteriostatic effect of lactoferrin has been ascribed to its iron-binding action. In neutrophils, lactoferrin within neutrophilic granules tightly binds iron, but neutrophils with excessive iron are inefficient at destroying bacteria. Lactoferrin does not limit the growth of all microorganisms; *Helicobacter pylori* and *Neisseria*, *Treponema*, and *Shigella* species all have receptors for lactoferrin, directly binding iron and allowing adequate growth.

Some evidence supports various other proposed mechanisms of action for lactoferrin's antimicrobial effect. Lactoferrin has been shown to limit the formation of biofilms by specific organisms, inhibit adhesion to host cells by other organisms, and directly bind to viral particles of herpes simplex virus, HIV, and adenovirus. A proteolytic action of lactoferrin appears to inactivate virulence factors of some organisms. Separately, lactoferrin binds directly to glycosamino glycans (GAGs) and integrins interrupting the binding of various viruses (herpes simplex virus, HIV, adenovirus, CMV, hepatitis B virus [HBV]) to host cells. Pepsin hydrolysate products of lactoferrin (B or H) may exert a direct bactericidal effect by binding to lipopolysaccharide of gram-negative organisms and disrupting bacterial membranes.<sup>317</sup> Lactoferrin may cause an increased release of cytokines by cells including antiinflammatory cytokines such as IL-10.<sup>63,191</sup> Others have shown that lactoferrin suppresses the release of IL-1, IL-2, IL-6, IL-8, and TNF- $\alpha$ , all proinflammatory cytokines, which would be more of an immune-modulating effect.<sup>191</sup> Other investigators using a recombinant human lactoferrin (talactoferrin) demonstrated evidence of lactoferrin causing increased maturation of DCs<sup>303</sup> and talactoferrin causing the recruitment and activation of neutrophils and macrophages<sup>281</sup> as other examples of how lactoferrin affects the innate immune protection of the growing infant. Several other effects have been proposed for lactoferrin, including inhibition of hydroxyl radical formation, decreasing local cell damage; lipopolysaccharide binding, also leading to a diminished inflammatory response; and DNA binding, affecting transcription and possibly regulation of the production of cell products.<sup>242</sup> Activation of natural killer (NK) cells, modulation of complement activity, and blocking of adhesion of enterotoxigenic *E. coli* and *Shigella flexneri*<sup>103</sup> are other proposed actions of lactoferrin.

A specific region of lactoferrin, near the N-terminus of the molecule, is strongly basic and is reported to mediate some of lactoferrin's antimicrobial activity. "Lactoferricins," small peptides

containing this basic region and produced by proteolytic cleavage, reportedly bind to lipopolysaccharide, leading to disruption of the bacterial cell wall and cytoplasmic membrane.<sup>317</sup>

In another area of immune protection, lactoferrin may limit cancer development.<sup>191</sup> The proposed mechanisms of its anticancer effects include increasing NK cell cytotoxicity, increased production of IL-18 and inhibition of angiogenesis, augmented apoptosis of cancer cells, and initiation of cell cycle arrest in growing tumor cells.<sup>191</sup>

The multiple roles and proposed mechanisms of action of lactoferrin in breastfed infants continue to be more specifically elucidated.

## INTERFERON

Colostral cells in culture have been shown to be stimulated to secrete an interferon-like substance with strong antiviral activity up to 150 National Institutes of Health units/mL.<sup>265</sup> This property has not yet been identified in the supernatant of colostrum or milk. Interferon- $\gamma$  has been produced by T cells from human milk when stimulated in vitro.<sup>265</sup> The T cells isolated from human milk were the CD45RO phenotype and have been identified as a source of interferon. Srivastava et al.<sup>305</sup> have measured low levels of interferon- $\gamma$  in not only colostrum, but also transitional and mature milk. They postulated that the low level of interferon- $\gamma$  (0.7 to 2 pg/mL) might be adequate to protect against infection without hyperactivation of T cells. Interferon is produced by NK cells and by T cells, phenotypically Thy0 and Thy1. It can cause increased expression of major histocompatibility complex molecules, increase macrophage function, inhibit IgE and IL-10 production, and produce antitumor and antiviral activity. The exact role of interferon- $\gamma$  in breast milk has not been delineated.

## COMPLEMENT

The C3 and C4 components of complement, known for their ability to fuse bacteria bound to a specific antibody, are present in colostrum in low concentrations compared with their levels in serum. IgG and IgM activate complement. C3 proactivator has been described, and IgA and IgE have been identified as stimulating the system. Activated C3 has opsonic, anaphylactic, and chemotactic properties and is important for the lysis of bacteria bound to a specific antibody. No functional role for complement in breast milk has been identified.

## VITAMIN B<sub>12</sub>-BINDING PROTEIN

Unsaturated vitamin B<sub>12</sub>-binding protein of high molecular weight has been found in very high levels

in human milk, and in the meconium and stools of breastfed infants, compared with its levels in infant formulas and infants who are formula fed. The protein binding renders the vitamin B<sub>12</sub> unavailable for bacterial growth of *E. coli* and *Bacteroides*.<sup>121</sup>

## GLYCANS AND OLIGOSACCHARIDES

Glycans are complex carbohydrate structures attached to various other structures (a lactose moiety, a lipid component, peptides, proteins, or aminoglycans) that are present in large amounts in human milk.<sup>233</sup> They include glycoproteins, glycolipids (gangliosides), glycosaminoglycans, mucins, and oligosaccharides. Oligosaccharides are composed of a basic core structure derived from glucose, galactose, or N-acetylglucosamine. They are linked to a variety of terminal fucose linkages or sialic acid linkages to create numerous different compounds. Oligosaccharides compose the major portion of glycoconjugates in milk and are present in the milk-fat globule membrane and in skim milk.<sup>229,233,235</sup> Gangliosides are glycolipids found in the plasma membrane of cells, especially in cells in the gray matter of the brain. More specifically, gangliosides are glycosphingolipids that contain sialic acid, hexoses, or hexose amines as the carbohydrate component and ceramide as the lipid component of the molecule. Human milk oligosaccharides (HMO) are poorly absorbed and poorly digested and remain in the gut. Their probable functions are antipathogenic, immunomodulatory, antiinflammatory, and prebiotic.<sup>236</sup>

The predominant gangliosides in human milk are GM1, GM2, GM3, and GD3, as reported by Newburg.<sup>231</sup> A diverse abundance of these complex carbohydrates are synthesized by the many glycosyltransferases contained in the mammary gland. Mucin and lactadherin are two glycoproteins included in this group that have antimicrobial effects.<sup>286</sup> Some of these carbohydrate molecules are structurally similar to glycans on the surface of small intestine epithelial cells that act as receptors for microorganisms. One proposed mechanism for the antimicrobial effect of these soluble substances is direct binding with the potential pathogenic organisms.<sup>230,231</sup> After studying the adhesion of S-fimbriated *E. coli* to buccal epithelial cells, Schrotten et al.<sup>296</sup> proposed that mucins contained in the human milk-fat globule membrane can block bacterial adhesion throughout the intestine.

Gangliosides appear to be responsible for blocking the activity of heat-labile enterotoxin from *E. coli* and the toxin from *V. cholerae* in rat intestinal loop preparations.<sup>251</sup> Another toxin from *Campylobacter jejuni*, with similar binding specificity, also seems to be inhibited by GM1.<sup>184,283</sup> Globotriaosylceramide, another glycolipid in human milk, is

the natural cell surface receptor for the toxin from *Shigella dysenteriae* and verotoxin released by enterohemorrhagic *E. coli*.<sup>232</sup> The proposed mechanism of action of these glycolipids is that, by binding to the toxin, they form a stable complex that prevents the toxin from binding to the appropriate receptors on intestinal cells. However, Crane et al.<sup>61</sup> proposed, from their studies, that the oligosaccharide binds to the toxin receptor to block the action of the heat-stable enterotoxin of *E. coli*. Human milk gangliosides may be important in protecting infants against toxin-induced diarrhea, but this has not been specifically demonstrated *in vivo* in controlled trials.<sup>232,251</sup> Evidence exists that human milk glycans inhibit a broad range of pathogens (Table 5-5).<sup>229–234</sup> Newberg et al.<sup>232</sup> document the constitutive expression of various fucosylated glycans in human milk and secretions and present "typical" concentrations of these active agents in human milk from the literature. Their secretion is related to the "secretor" and Lewis genes, which control the individual differences in expression of Lewis blood group types.

Chaturvedi et al.<sup>55</sup> have recently examined the survival of oligosaccharides from human milk in infants' intestines. They demonstrated that the concentrations of oligosaccharides were higher in the infants' feces than in mothers' milk and higher in feces than urine. The profile of oligosaccharides found in the infants was similar to that found in their mothers' milk. The formula-fed infants had lower concentrations of oligosaccharides, and the profiles of the oligosaccharides were different from those found in the breastfed infants. The oligosaccharides remained intact passing through the intestine. A small percentage are absorbed and excreted intact in the urine. The oligosaccharides were available at these sites to block intestinal and urinary pathogens. Two other groups of researchers have documented variation of the composition of glycans in human milk over the first 4 months of lactation<sup>60</sup> and variations in the composition of glycans in diverse populations.<sup>83</sup> Others have analyzed the oligosaccharide composition of donor human milk (Holder pasteurized) and compared that to samples of human milk obtained directly from the mothers.<sup>204</sup> The total amount of HMO was lower in donor human milk. The concentrations of specific oligosaccharides (lacto-*N*-tetraose, lacto-*N*-neotetraose, lacto-*N*-fucopentaose I, and disialyllacto-*N*-tetraose) were significantly lower in donor milk. The concentrations of 3'-sialyllactose and 3-fucosyllactose were higher in human milk obtained directly from the mothers.<sup>204</sup> Therefore, a diverse repertoire of glycans are present in large amounts in human milk, which persist intact in the intestine and reach the urine, and have demonstrated inhibitory effects on a variety of pathogens.

Antipathogen	Pathogen
Ganglioside GM <sub>1</sub>	Cholera toxin
	Labile toxin of <i>Escherichia coli</i>
	Toxin of <i>Campylobacter jejuni</i>
Globotriaosylceramide	<i>Shigella</i> toxin I
	Shigella-like toxin of <i>E. coli</i>
GM3	Enteropathogenic <i>E. coli</i>
Fatty acids	Enveloped viruses <i>Giardia lamblia</i>
Chondroitin sulfate	HIV
Sulfatide	HIV
Glycoprotein (mucin)	Inhibition: rotavirus <i>in vitro</i> and <i>in vivo</i>
Glycoprotein (mucin, glycosaminoglycan)	HIV
Lactadherin	Rotavirus
Mucin	Adherence: S-fimbriated <i>E. coli</i>
MUC 1	Poxviruses, HIV
Glycoprotein (mannosylated)	<i>E. coli</i> intestinal adherence
Large macromolecule	Respiratory syncytial virus
Macromolecule-associated glycans	Norovirus, <i>Pseudomonas aeruginosa</i>
Oligosaccharides	Adherence: <i>Streptococcus pneumoniae</i> and <i>Haemophilus influenzae</i> , enteropathogenic <i>E. coli</i> <i>Listeria monocytogenes</i>
Fucosylated oligosaccharide	Adherence, invasion, <i>C. jejuni</i> , stable toxin of <i>E. coli</i> stable toxin <i>in vivo</i> , <i>Vibrio cholera</i>
Sialyllactose	Cholera toxin, <i>E. coli</i> , <i>Pseudomonas aeruginosa</i> , Influenza virus <i>Aspergillus fumigates</i> , Polyomavirus, <i>Helicobacter pylori</i>

GM, Granulocyte-macrophage; HIV, human immunodeficiency virus.

Modified from Newburg DS, Ruiz-Palacios GM, Morrow AL: Milk glycans protect infants against enteric pathogens, *Ann Rev Nutr* 25:37–58, 2005.

These components constitute a major contribution of human milk to innate immunity at the level of an infant's gut. There is variability in the amounts of specific HMO in the milk of different mothers, at different times through each mother's period of lactation and in human donor milk. The importance of the "match" of the mother-infant dyad based on HMO composition and quantity and the benefits to the infant still need to be elucidated.

Other authors propose that the gangliosides GD3 and GM3 may play an immunomodulatory role early in lactation by affecting DCs, decreasing the production of ILs (IL-10 and IL-12), and suppressing the expression of various cluster designation (CD) markers and major histocompatibility complex class II on DCs.<sup>34</sup>

## INTERLEUKINS

ILs are considered a "subgroup" of cytokines.<sup>195</sup> Originally, when cytokines were first hypothesized, it was thought that they were primarily produced by leukocytes and acted on other leukocytes, and therefore they could be called ILs. Although much of their effect is on lymphocyte activation and differentiation, it is now known that ILs act on and are produced by a variety of cells.<sup>113</sup>

Goldman et al.<sup>113</sup> identified IL-1 $\beta$ , IL-6, IL-8, and IL-10 in breast milk (Table 5-6). Srivastava et al.<sup>305</sup> reported measuring moderate amounts of IL-6, IL-8, and IL-10 in the different stages of breast milk. Very low amounts of IL-1 $\beta$  were detected, especially in comparison with the amount of IL-1 receptor antagonist (RA), which presumably could block the activity of the small amount of IL-1.

Agents	Bioactivity in Milk	Concentrations*
IL-1 $\beta$	$\pm$	1130 $\pm$ 478
IL-6	+	151 $\pm$ 89
IL-7	?	79-100 $\pm$ 19†
IL-8	?	3684 $\pm$ 2910
IL-10	+	3400 $\pm$ 3800
TNF- $\alpha$	+	620 $\pm$ 183
G-CSF	?	$\sim$ 358
M-CSF	+	17,120
Interferon- $\gamma$	?	?
EGF	+	$\sim$ 200,000
TGF- $\alpha$	+	$\sim$ 2200-7200
TGF- $\beta_2$	+	130 $\pm$ 108

CSF, Colony-stimulating factor; EGF, epidermal growth factor; G, granulocyte; IL, interleukin; M, macrophage; TGF, transforming growth factor; TNF, tumor necrosis factor.

\*The concentrations of these agents were determined by enzyme-linked immunosorbent assay (ELISA) except for IL-1 $\beta$  and EGF by radioimmunoassay. Concentrations are expressed as pg/mL except for M-CSF (U/mL).

†From Ngom PT, Collinson AC, Pido-Lopez J, et al: Improved thymic function in exclusively breastfed infants is associated with higher interleukin 7 concentrations in their mothers' breastmilk, *Am J Clin Nutr* 80:722-728, 2004.

From Goldman AS, Chheda S, Garofalo R, Schmalstieg FC: Cytokines in human milk properties and potential effects upon the mammary gland and the neonate, *J Mammary Gland Biol Neoplasia* 1:251, 1996.

Hawkes et al.<sup>139</sup> reported on the amount of cytokines in breast milk over the first 12 weeks of lactation. The proposed "proinflammatory" cytokines, IL-1 $\beta$ , IL-6, and TNF- $\alpha$ , were present in only 7 of 36 mothers who donated samples at each point throughout the study. A broad range of concentrations of each of these cytokines was seen during the course of the study. The "antiinflammatory" cytokines, TGF- $\alpha_1$  and TGF- $\beta_2$ , were present in significant amounts in all samples. IL-2 has also been reported in breast milk in 81% of the mothers tested, with milk (aqueous) levels correlating with plasma IL-2 levels. IL-2 was constitutively produced from 57% of milk cell samples, and IL-2 production was markedly increased by stimulation of the cells with Con A.<sup>37</sup>

IL-6 has been identified in breast milk by other investigators, especially in the first 2 days of life.<sup>253,282</sup> The authors suggest that IL-6 in human milk may augment the newborn's immune functions before the body can begin full production of cytokines. Specifically, this is accomplished by increasing antibody production, especially IgA, enhancing phagocytosis, activating T cells, and increasing  $\alpha_1$ -antitrypsin production by mononuclear phagocytes. IL-7 is a chemokine known to improve thymic output in animals and appears related to the proliferation and survival of T cells in all stages of development.<sup>238</sup> Ngom et al.<sup>238</sup> have described improved thymic function in exclusively breastfed infants associated with higher IL-7 concentrations in the mother's breast milk. The breast milk of Gambian mothers contained variable levels of IL-7, but the geometric mean levels were higher in the first 8 weeks postpartum in mothers whose infants were born in the "harvest-season" (January to June) compared with those mothers whose infants were born in the "hungry-season." The authors postulate that IL-7 in breast milk enhances T cell proliferation and survival and overall thymic development in the infant, leading to long-term benefits in protection from infection.

IL-8 is a chemokine capable of attracting and activating neutrophils and attracting CD45RA $^+$  T cells. IL-8 is produced by mammary epithelial cells.<sup>253</sup> Srivastava et al.<sup>305</sup> also detected messenger ribonucleic acid (mRNA) for IL-8, suggesting that cells in breast milk were capable of producing IL-8. The exact function of IL-8 in breast milk remains to be elucidated.

IL-10 is thought to have antiinflammatory effects, including decreasing the production of interferon- $\gamma$ , IL-12, and other proinflammatory cytokines. It has been reported to enhance IgA, IgG, and IgM synthesis.

IL-18 has been identified in colostrum, early milk, and mature milk, with the highest levels occurring in colostrum and in association with

preterm deliveries and complications of pregnancy in the mothers.<sup>312</sup> The levels of IL-18 were correlated with soluble Fas ligand in colostrum. IL-18 was detected by immunohistochemical staining in actively secreting epithelial cells in a lactating breast. IL-18 has been shown to be produced by intestinal epithelial cells and activated macrophages. It leads to the production of other chemokines (GM-CSF, IL-2, TNF- $\alpha$ ). It induces the expression of Fas ligand on lymphocytes. The authors suggested that IL-18, present in colostrum, may play a role in stimulating a systemic T<sub>H</sub>1 response and causing NK cell and macrophage activation in neonates.

The interaction and the direct effect of these ILs in breast milk must be clarified. The amount of T cells bearing markers of recent activation is increased in human milk compared with the results in peripheral blood of adults. Wirt et al.<sup>334</sup> have described a marked shift from virginal to antigen-primed (memory) T cells in human milk, which suggests certain functional capacities for these cells. The phenotypic pattern of T cells may result from T-cell-activating substances or selective homing of T cells to the breast. These activated T cell populations are transferred to the infant through breast milk, along with a variety of ILs at a time when infants are capable of only limited production of ILs. A complex interaction of ILs and cells in human milk and at the mucosal level may provide antimicrobial and antiinflammatory benefits to the infant.

## CYTOKINES

Of the many bioactive substances that have been identified in human milk, cytokines are some of the most recently identified and investigated agents. Their existence has long been suspected in attempts to explain certain immunologic and protective effects of breast milk on infants. More than 40 cytokines have been described,<sup>200</sup> and more than 10 of these have been identified in human milk.<sup>113,305</sup> Cytokines are small proteins or glycoproteins that, through binding to receptors on immune and nonimmune cells, produce a broad range of effects (many still unidentified) through autocrine, paracrine, and endocrine actions. Cytokines are produced predominantly by immune cells and function in complex associations with other cytokines to stimulate and control the development and normal functioning of the immune system. The nomenclature and abbreviations used are complicated and confusing. Newer systems of classification have been established according to which cells produce them or what their general functions are<sup>195</sup> or based on the relative position of their cysteine residues or their receptor types (CCR, CXCR,

### BOX 5-3. Nomenclature and Abbreviations for Various Cytokines

Interferon Alpha, Beta, Gamma	IFN- $\alpha$ , - $\beta$ , - $\gamma$
Granulocyte colony-stimulating factor	G-CSF
Macrophage colony-stimulating factor	M-CSF
Stem cell factor	SCF
Interleukins 1, 2, 4, 6, 8, 10	IL-1, -2, -4, -6, -8, -10
Interleukin 1 beta	IL-1 $\beta$
Interleukin 1 receptor antagonist	IL-1RA
Soluble interleukin 2 receptor	sIL-2R
Transforming growth factor beta <sub>2</sub>	TGF- $\beta_2$
Tumor necrosis factor alpha	TNF- $\alpha$
Transforming growth factor alpha	TGF- $\alpha$
Macrophage inflammatory protein	MIP
Regulated on activation, normal T cell expressed and secreted	RANTES
Epidermal growth factor	EGF
Growth-regulated oncogene	GRO
Monocyte chemoattractant protein 1	MCP-1
Leukocyte inhibitory factor	LIF

and CX3CR).<sup>200</sup> Box 5-3 provides a simplified list with abbreviations.

Little evidence demonstrates specific *in vivo* activity of the different cytokines. Based on general information on the function and interaction of the particular cytokines, as well as consideration of as yet unexplained effects of breast milk, proposed functions of the cytokines include initiation of development of host defense, stimulation of host defenses, prevention of autoimmunity, antiinflammatory effects in the upper respiratory tract and GI tract, and stimulation of the development of the digestive system, especially the mucosal immune system of the alimentary tract and the proximal respiratory tract. The maternal breast may respond to feedback stimulation or suppression by secreted cytokines, influencing the growth, differentiation, and secretory function of the breast. As shown in other situations, cytokines may enhance receptor expression on cells in the respiratory and GI tracts for major histocompatibility complex molecules or immunoglobulins. Various cell types in the mucosal immune system may be activated or attracted to specific sites in the GI tract by the action of cytokines.

Beyond these proposed beneficial effects of cytokines, newer studies are identifying specific immunologic and protective roles for different cytokines in developing infants. For example, extensive work has been done on epidermal growth factor (EGF), and other growth factors (HB-EGF,

G-CSF, EPO, and EPO-like growth factors) have been studied relative to their role in preventing necrotizing enterocolitis (NEC) and gut homeostasis.<sup>223</sup> A number of potential roles for EGF in gut homeostasis have been proposed and studied, including intestinal development, proliferation and adaptive response to damage, repair, and regeneration and diminishing inflammatory responses to various stimuli. TGF- $\beta$  has been studied for its role in initiating and stimulating IgA production early on in infancy.<sup>244</sup>

The actual measurement of cytokines in breast milk has been complicated by a number of factors, including different assays used (bioassays, enzyme-linked immunosorbent assay [ELISA], radioimmunoassay), binding to proteins, their existence in monomeric or polymeric forms, the presence of antagonists, and their varying presence in colostrum, early milk, or mature milk.<sup>9</sup> Goldman et al.<sup>113</sup> reported on the bioactivity and concentration of cytokines in breast milk from their own work and that of others (see Table 5-6). Srivastava et al.<sup>305</sup> obtained some conflicting results using different assays in colostrum, early milk, and mature milk. They confirmed the presence of M-CSF throughout lactation, as well as TGF- $\beta_1$  and - $\beta_2$ , IL-1RA, GRO- $\alpha$ , MCP-1, RANTES, and IL-8, but reported insignificant amounts of GM-CSF, stem cell factor, LIF, MIP-1 $\alpha$ , IL-2, IL-4, IL-11, IL-12, IL-13, IL-15, sIL-2R, and IFN- $\alpha$  (see Box 5-3 for nomenclature). Srivastava et al.<sup>305</sup> also used reverse transcriptase (RT) polymerase chain reaction (PCR) to measure the production of cytokine mRNA by cells in breast milk. They reported the presence of mRNA for MCP-1, IL-8, TGF- $\beta_1$ , TGF- $\beta_2$ , M-CSF, IL-6, and IL-1 $\beta$ , which may be another source of these cytokines in breast milk. Hawkes et al.<sup>139</sup> demonstrated that human milk cells from lactating women at 5 weeks postpartum are capable of active cytokine production in vitro (IL-1 $\beta$ , IL-6, and TNF- $\alpha$ ), with and without exposure to lipopolysaccharide. Continued cytokine production by human milk cells is another explanation for the variable amounts of cytokines identified in breast milk and is further evidence that the cells are capable of responding to an infectious stimulus.

In their investigations of the possible antiinflammatory effects of breast milk, Buescher and Malinowska<sup>40</sup> examined milk for the presence of soluble receptors and cytokine antagonists. They demonstrated soluble intercellular adhesion molecule 1, soluble vascular cell adhesion molecule 1, and soluble E-selectin in colostrum and at lower levels in mature milk, as well as high levels of soluble TNF- $\alpha$  receptor I (sTNF- $\alpha$ RI), sTNF- $\alpha$ RII, and IL-1RA. Also, they identified that most TNF- $\alpha$  did not exist "free" in breast milk, but was associated with TNF receptors. The in vivo significance of these findings remains to be assessed.

Given the complex interaction and regulation of cytokine production and cytokines' relation to coordinated inflammatory and antiinflammatory responses in tissues, one should assume that the interaction of cytokines in breast milk and the effect of cytokines, cytokine receptors (soluble and expressed on various cell types), and cytokine antagonists on the infant will be equally complex. A new methodology, antibody-based protein arrays, has been applied to identify cytokines in human milk.<sup>181</sup> Kverka et al.<sup>181</sup> analyzed colostrums and milk samples from the first 4 days postpartum, using two different arrays capable of detecting 42 and 79 cytokines. Three cytokines (EGF, IL-8/CXCL8, and GRO/CXCL1-3) were detected in all of the tested samples. Nineteen cytokines were present in more than 50% of the samples. An additional 32 cytokines were identified in human milk for the first time. The concentration of cytokines varied in the different women and varied over time. Continued investigation with this and other assays will be essential to understanding the significance and specific effects of these substances in breast milk.

## Nucleotides

Nucleotides, nucleosides, nucleic acids, and related metabolic products are essential to many biologic processes. Although they are not essential nutrients, because they can be synthesized endogenously and recovered from in vivo "salvage" sources, their presence in the diet may carry significant benefits under various conditions (i.e., "conditionally essential").<sup>53,224,322,344</sup> In situations of disease, stress, rapid growth, or limited dietary intake, supplementation of the diet with nucleotides may decrease energy expenditure to synthesize or salvage nucleotides, which optimizes the host response to these adverse situations.<sup>344</sup>

Nucleotides exist in relatively large amounts in human milk (15% to 20% of the nonprotein nitrogen), suggesting that they have some nutritional significance, although no clinical syndromes have been associated with nucleotide deficiency to date. Nucleotides are present in the natural milk of different species in varying amounts and composition. The nucleotide content and composition of bovine milk are particularly less and different from human milk. Infant formulas supplemented with nucleotides contain roughly the same amounts of nucleotides as human milk, from 20 to 70 mg/L.<sup>50,51,188</sup> Unsupplemented formulas contain lesser amounts of nucleotides.

Mammalian cells contain a large variety of nucleotides and related products, which have many metabolic functions, including the following<sup>51-53</sup>:

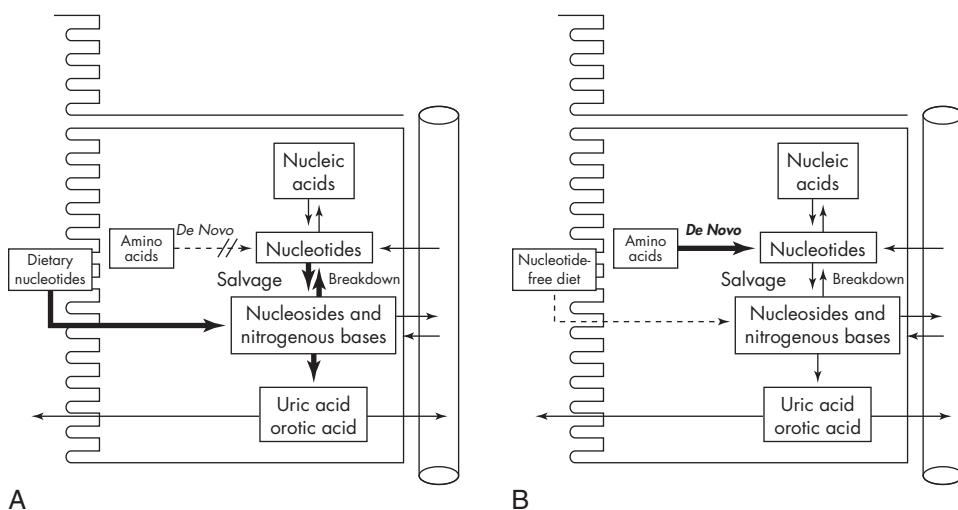

1. Energy metabolism: adenosine triphosphate is a major form of available cellular energy.
2. Nucleic acid precursors: the monomeric units for RNA and DNA are present.
3. Physiologic mediators: cyclic adenosine monophosphate and cyclic guanosine monophosphate serve as "messengers" for cellular processes; adenosine diphosphate is necessary for platelet aggregation; and adenosine has been shown to affect vasodilatation.
4. Related products function as coenzymes in metabolic pathways: nicotinamide-adenine dinucleotide, flavin adenine dinucleotide, and coenzyme A.
5. Related products function as intermediate carrying molecules in synthetic reactions: uridine diphosphate glucose in glycogen synthesis and guanosine diphosphate mannose, guanosine diphosphate-fucose, uridine diphosphate-galactose, and cytidine monophosphate sialic acid in glycoprotein synthesis.
6. Allosteric effectors: the intracellular concentrations of nucleotides influence the progression of certain steps of metabolic pathways.
7. Cellular agonists: extracellular nucleotides influence intracellular signal transduction (e.g., cyclic adenosine monophosphate and inositol-calcium pathway).

Nucleotide concentrations in cells and tissues are maintained by de novo synthesis and salvage from intermediary metabolism and diet (Figure 5-11).<sup>271</sup> Nucleosides are the predominant product absorbed in the small intestine. Nucleosides are probably transported by passive diffusion and a carrier-mediated process; purines and pyrimidines are transported by

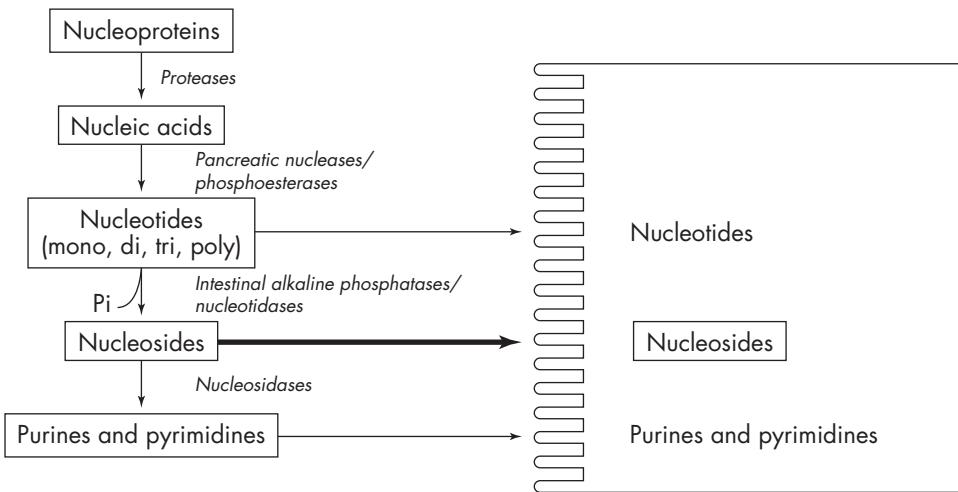

passive diffusion at high concentrations and by a sodium-dependent active mechanism at low concentrations (Figure 5-12).<sup>271</sup> The digestion and absorption of nucleotides, nucleosides, and pyrimidines and purines also involve polymeric and monomeric nucleotides and other adducts (nucleosides in a biologically active moiety).

In early reports on the nucleotide and nucleoside content of milk, various methods of measurement were used, and the amounts were described as either the monomeric fraction of nucleotides or the total RNA. Leach et al.,<sup>188</sup> recognizing the complex nature of digestion and absorption of nucleotides and related products, attempted to measure the total potentially available nucleosides (TPANs) in human milk. They used solid-phase extraction, high-performance liquid chromatography analysis, and enzymatic hydrolysis of the various fractions. They analyzed breast milk samples at various stages throughout lactation (colostrum, transitional, early, and late mature milk) from 100 European women and 11 American women. They used an aqueous TPAN-fortified solution containing ribonucleosides, 5'-mononucleotides, polymeric RNA, and nucleoside-containing adducts to estimate the accuracy of their process.

The mean ranges of TPAN values were similar for European women from different countries and American women, although broad ranges were seen and the composition of individual nucleotides varied.<sup>188</sup> The mean TPAN value was lowest in colostrum but did not show a consistent upward or downward trend in transitional, early, or late mature milk. The mean ranges of TPAN values were 82 to 164 mmol/L for colostrum, 144 to 210 mmol/L for transitional milk, 172 to 402 mmol/L for early

**Figure 5-11.** Metabolic regulation of cellular nucleotide pools in presence and absence of nucleotide in diet. **A,** Effect of dietary nucleotide activating salvage pathway. **B,** De novo nucleotide synthesis is enhanced with nucleotide-free diet. (From Quan R, Barness LA: Do infants need nucleotide supplemented formula for optimal nutrition? *J Pediatr Gastroenterol Nutr* 11:429, 1990.)

**Figure 5-12.** Digestion and absorption of nucleic acids and their relational products. (From Quan R, Barness LA: Do infants need nucleotide supplemented formula for optimal nutrition? *Pediatr Gastroenterol Nutr* 11(4):429, 1990.)

mature milk, and 156 to 259 mmol/L for late mature milk (Table 5-7). Monomeric and polymeric nucleotides were the predominant forms of TPAN in pooled samples. Cytidine, guanosine, and adenosine were found mainly in these fractions, whereas uridine was found primarily as free nucleotide and adduct (Table 5-8). The methods used recovered 90% to 95% of the true TPAN values compared with the TPAN-fortified solution, although the uridine and guanosine content was underestimated. Tressler et al.<sup>319</sup> measured the TPAN in pooled breast milk samples from Asian women demonstrating average levels in colostrum, transitional milk, and mature milk and found it to be similar to the levels in European and American women.

Leach et al.<sup>188</sup> concluded that their process of estimating TPANs, including sequential enzymatic hydrolyses, and measuring the entire nucleotide fraction provides a reasonable estimate of the in vivo process and the nucleotides available to the infant from human milk.

Proposed effects of dietary nucleotides include effects on the immune system, iron absorption, intestinal flora, plasma lipoproteins, and growth of intestinal and hepatic cells. Effects on the immune system, related to nucleotide supplementation to the diet, have mainly been reported from animal studies. They include increased mortality rate from graft-versus-host disease; improved delayed-type cutaneous hypersensitivity and alloantigen-induced lymphoproliferation; reversal of malnutrition and starvation-induced immunosuppression; increased resistance to challenge with *S. aureus* and *C. albicans*; and enhanced T cell maturation and function.<sup>264</sup> Spleen cells of mice fed a nucleotide-free diet produce lower levels of IL-2, express lower levels of IL-2 receptors, and have

decreased NK cell activity and macrophage activity.<sup>51,52</sup> Presumably, these nucleotide-associated changes are related to T-helper/inducer cells and the initial phases of antigen processing and lymphocyte proliferation.<sup>52,53,322</sup>

In vitro and in vivo experiments documented that ingested nucleotides increased iron absorption, perhaps affecting xanthine oxidase.<sup>271</sup> Although in vitro studies showed that added nucleotides enhanced the growth of bifidobacteria, conflicting results have been obtained on the influence of dietary nucleotides on the fecal flora of infants receiving breast milk or nucleotide-supplemented formula.<sup>12,271</sup> Clinical studies in infants receiving nucleotide-supplemented formula demonstrated increased high-density lipoprotein cholesterol, lower very-low-density lipoprotein cholesterol, increased long-chain polyunsaturated fatty acids (PUFA), and changes in red blood cell membrane phospholipid composition.<sup>12</sup> Supplementation studies in animals have shown enhanced GI tract growth and maturation, improved intestinal repair after diarrhea, stimulation of hepatic growth, and augmented recovery from hepatectomy.<sup>264</sup>

A recent review discusses the effects of dietary nucleotides on the immune system and protection against infection reported in studies in the literature.<sup>293</sup> Carver et al.<sup>52</sup> compared infants receiving breast milk to those receiving commercially available infant formula and formula supplemented with nucleotides at a level of 32 mg/L. At 2 and 4 months, NK cell activity and IL-2 production were higher in the breastfed and nucleotide-supplemented groups compared with those receiving formula without nucleotide supplements. Infections occurred infrequently in all groups, but slightly less in the breastfed group. No differences were noted in

hematologic profiles and plasma chemistry values, and no toxicity or intolerance was associated with nucleotide supplementation. The sample size was small, marked variability was seen in the IL-2 measurements, and the differences noted at 4 months were less than at 2 months. Therefore, the authors concluded that dietary nucleotides may contribute to improved immunity in breastfed infants.

Brunser et al.<sup>36</sup> examined the effect of a nucleotide-supplemented formula on the incidence of diarrhea in 392 infants in Chile, studied through 6 months of age. Although the infants receiving the supplemented formula (20 mg/L) experienced less diarrhea, the difference in the duration of diarrhea was small. The numbers were too small to comment on the causative agents of diarrhea, although no apparent protection against any one agent was seen. The beneficial effect of nucleotides against diarrhea was proposed to be secondary to enhanced immune response to intestinal pathogens or improved intestinal integrity or a combination of both. In a larger study of 3243 infants younger than 6 months of age, the severity of the diarrhea (duration and number of bowel movements), as well as the incidence of diarrhea, was lower in the nucleotide-supplemented group.<sup>185</sup>

Two groups of premature infants fed either nucleotide supplemented (20 mg/L) or unsupplemented formula were followed, and the concentration of plasma immunoglobulins throughout the first 3 months of life was measured.<sup>224</sup> IgG plasma concentrations were not different in the two groups during the study period. IgM plasma levels were higher in the nucleotide-supplemented group at 20 to 30 days and 3 months of life, while IgA plasma levels were significantly higher at 3 months of age in the supplemented group.

Pickering et al.<sup>264</sup> published a 12-month, controlled, randomized study of 311 infants to examine the effect of added nucleotides at levels comparable to human milk on infants' immune responses to various vaccine antigens; 103 nonrandomized infants received breast milk for at least 2 months and then either human milk or a standard infant formula. Another 208 infants were randomized to receive either a standard infant formula or one supplemented with nucleotides. The amount and actual nucleotide content added were based on TPANs, as measured by Leach et al.,<sup>188</sup> equaling 72 mg/L. Overall growth and nutrition tolerance were similar in each group. The nucleotide group had significantly higher geometric mean titers of *H. influenzae* type b antibody and diphtheria antibody than the control group or the breastfed infants. No significant difference was seen between the nucleotide and control groups for the IgG response to oral poliovirus vaccine or tetanus. Infants who were breastfed for longer than 6 months had significantly higher antibody responses to oral poliovirus

vaccine than children breastfed for less than 6 months, or either of the two formula-fed groups. No significant differences were found between the different groups with respect to total IgG, IgA, or IgE. Differences were seen in the number of children who experienced at least one episode of diarrhea: the nucleotide group (4/27, 15%), versus the control group (13 of 32, 41%,  $p < 0.05$ ), and the breastfed group (6 of 27, 22%). Notably, the breastfed group was heterogeneous, relative to the amount of breast milk received and the duration of feeding, whereas the nucleotide group received supplementation for the entire 12 months.

Questions that remain concerning nucleotides and their proposed beneficial effects in an infant's diet include the following:

- What are the proven mechanisms of action of these proposed benefits?
- What form and concentration of nucleotides are necessary to affect these benefits?
- Is adequate information available to justify using nucleotides in infant formula in higher amounts and different compositions than are currently used?

Debate and research to answer these and other questions concerning nucleotides will continue.

## Mucosal Immune System

A primary function of each of the body's different mucosal surfaces is immunologic. Each distinct mucosal surface has multiple other physiologic functions including gas exchange (in the lungs), nutrient absorption (in the gut), sensory detection (in the eyes, nose, and mouth), and reproduction (in the uterus and vagina). The thin, permeable nature of these barrier mucosal surfaces, their large surface area, and the constant exposure to microorganisms, foreign proteins, and chemicals predispose the mucosal membranes to damage and infection. During the first year(s) of life, when the infant's immune system is developing and maturing, it is doing so on a systemic and a mucosal basis, as well as involving both innate and adaptive immune mechanisms. That development must include the ability to respond to and protect against invasive pathogens, and at the same time "tolerate" or "ignore" the multitude of commensal organisms that reside at these surfaces. During this early development, breast milk contains numerous bioactive factors that supplement the immune protection at the mucosal level, while limiting inflammation. Additionally, these factors contribute to the immune modulation and growth stimulation of infants' mucosal and systemic immune defenses.\*

\*<sup>106,107,108,109,110,133</sup>

The mucosal immune system involves both innate mechanisms and adaptive immune mechanisms functioning in concert. The development of the mucosal immune system occurs in the prenatal period and continues in the postnatal period. The functional mucosal barrier includes the action of enzymes, chemicals, acidity or pH, mucus, immune globulins, and indigenous flora. In as early as 8 weeks of gestational age, researchers have identified changes in the intestinal barrier with the development of enterocytes, goblet cells, and enterochromaffin cells, along with evidence of development of tight junctions between the epithelial cells.<sup>255,268</sup> Mucus production, which can block adherence of pathogens to epithelial cells, demonstrates both pre- and postnatal development, beginning with evidence of expression of the *muc2* gene as early as 12 weeks' gestational age.<sup>43</sup> This is approximately the same time that Paneth cells appear in intestinal crypts. These cells secrete various products, including  $\alpha$ -defensin, lysozyme, secretory phospholipase A<sub>2</sub>, and TNF- $\alpha$ , which contribute to protection from pathogens, enhance stem cell protection within the epithelial layer, and influence the selection and number of commensal organisms.<sup>219,288</sup> Secretory immune globulins slgA and IgM act at the epithelial surface, largely without inflammation, by limiting adherence and transmigration and facilitating phagocytosis of potential pathogens.

## Mucosal-Associated Lymphoid Tissue

The well-recognized MALT is present in localized areas beneath the mucosal surfaces: tonsils and adenoids in the nasopharynx, and Peyer patches and isolated lymphoid follicles in the intestine. Overlying the isolated lymphoid follicles of the gut are specialized epithelial cells called M-cells. M-cells (membrane, microfold, or multifenestrated cells) come in direct contact with microorganisms and antigens due to a lack of a surface glycocalyx covering. These remarkable cells endocytose, phagocytose, and transcytose molecules and antigens, from their luminal surface to their basal surface. Antigen-presenting cells and lymphocytes process the transcytosed molecules, presenting them to submucosal aggregates of lymphocytes. The activated lymphocytes that have responded to the specifically presented antigens migrate via the lymphatics to the thoracic duct and into the blood. These lymphocytes circulate in the blood, until they return to mucosal tissues, predominantly the same ones they originated from, where they now function as effector lymphocytes in the lamina propria. This process of "directed migration" to specific sites occurs due to the influence of cytokines and adhesion molecules, such as chemokine CCL28 (mucosal epithelia chemokine), expressed in the colon

and salivary glands, and CCL25 (thymus-expressed chemokine), which effects the site-specific migration.<sup>263</sup> The immune response of lymphocytes in the submucosa, and the subsequent directed migration to the same and other mucosal sites, produces a focused response to a selected repertoire of antigens at those sites. The lactating mammary gland is an essential component of MALT. A mother makes a mature effective immune response to microorganisms in her and her infant's environment through antigenic stimulation of MALT in the mother's gut and respiratory mucosa. The maternal immune response produces activated lymphocytes, cytokines, immunoglobulins, and other factors against the specific microorganism. There is a subsequent "directed migration" of these activated lymphocytes, immunoglobulins, cytokines, and bioactive factors to the breast and into the breast milk. These specific factors in the breast milk add to the protective effect of breast milk against specific microorganisms in the mother's and infant's environment. This is a well-recognized example of how breast milk can provide additional immune protection to the infant. It is also one of the reasons to continue breastfeeding when a mother or the infant has a possible infection.

The mucosal immune system undergoes significant postnatal development, in part due to the dramatic exposure of the mucosa to large numbers of microorganisms in early postnatal life. Peyer patches are rudimentary, and few immunoglobulin-producing intestinal plasma cells are present until several weeks after birth.<sup>31</sup> After several weeks, germinal centers within the lymphoid follicles develop, and the number of IgM- and IgA-producing cells in the intestine increase. Immunoglobulin-producing intestinal plasma cells (primarily IgA-producing cells) in the lamina propria increase in number from 1 to 12 months of age.<sup>308</sup> With normal maturation of the mucosal immune system, large numbers of immunoglobulin-producing cells locate in the intestinal lamina propria. The monomeric IgA produced by these plasma cells is transported through epithelial cells to the mucosal lumen. Attachment of an epithelial glycoprotein, the membrane secretory component to two IgA molecules, leads to the formation of a dimeric molecule. The slgA molecule is "secreted" at the mucosal surface. IgM, in the form of a pentamer, contains a polypeptide J-chain and is transported by the same mechanism.<sup>32</sup> A portion of the secretory component remains attached to the slgA and IgM, which protects these molecules against proteolysis and contributes to their stability. Large amounts of slgA and IgM are produced, in a similar fashion, by the mammary glands and delivered to the infant via breast milk. The slgA and IgM remain stable in saliva and feces<sup>128</sup> and provide specific protection by blocking adherence and entry. They also facilitate inactivation, neutralization, and agglutination of a wide variety of microorganisms.

Distinct from the action of immunoglobulins, a large number of bioactive factors in breast milk act at the mucosal level to supplement the innate defenses.<sup>126</sup> These include lactoferrin, lysozyme, casein, oligosaccharides, glycoconjugates, and lipids. Mucin-1, lactadherin, and a glycosaminoglycan are antimicrobial components, which are part of the milk-fat globule. Free-fatty acids and monoglycerides, digested components of the milk-fat globule, can cause lysis of enveloped viruses, bacteria, fungi, and protozoa. Lauric and linoleic acids, which constitute a large percentage of the FFE in human milk, are two such acids produced by lipolysis in the stomach.<sup>127</sup>

Additional factors contained in breast milk with demonstrated activity at the level of the mucosa include cytokines, hormones, and growth factors. IL-10 and IFN- $\gamma$  act by influencing the epithelial barrier.<sup>96</sup> Other factors that are considered to contribute to mucosal growth and development are TGF- $\alpha$ , EGF, and hormones (insulin and insulin-like growth factor).<sup>71</sup> Many other factors contained in breast milk have the potential for activity at the level of the mucosa, including nutrients, vitamins, nucleotides, enzymes, and soluble molecules with receptor-like structures (soluble CD14, soluble toll-like receptor (TLR) 2).<sup>183,189,324</sup>

## Toll-Like Receptors

TLRs and the complex interaction between indigenous bacterial flora and the intestine are important aspects of research into the development of the mucosal immune system. Forchielli and Walker<sup>90</sup> have reviewed many of these immune mechanisms acting at the mucosal level. TLRs are transmembrane receptors (pattern recognition receptors) that are capable of detecting and discriminating among various groups of potential pathogens and initiate different immune responses to them. TLRs "recognize" pathogen-associated molecular patterns, or conserved features in the pattern of molecules expressed by pathogens and commensal organisms. Specific TLRs recognize a particular repertoire of patterns: TLR2 identifies bacterial lipoproteins and peptidoglycan molecules; TLR3 recognizes double-stranded DNA; and TLR4 identifies lipopolysaccharide. Ten TLRs are recognized in humans to date; some have identified legends (pathogen-associated molecular patterns from viruses, bacteria, and protozoa) to which they bind. TLRs are present on some epithelial cells, but are predominantly expressed on macrophages and DCs.<sup>275</sup> Intestinal epithelial cells are influenced by gut flora and local immune response to express specific TLRs. The recognition of specific antigen patterns by epithelial cells, macrophages, and dendritic cells within the gut via the different toll-like receptors on these cells leads to the different T-lymphocyte immune

responses. It has been postulated that the ongoing immune stimulation elicited by the microbial flora in the gut "programs" the host to predominately express different T-helper cell responses: T<sub>H</sub>1-like, T<sub>H</sub>2-like, and T<sub>H</sub>3-like. This is referred to as "cross-talk" between the indigenous intestinal flora and the body's immune system. The T<sub>H</sub>1-like response is described as delayed-type hypersensitivity or cellular immunity. It is characterized by the predominant release of IL-2, IL-12, and interferon- $\gamma$ . The T<sub>H</sub>2-like response is primarily involved with humoral immunity and antibody production (especially IgE) associated with ILs: IL-4, IL-5, and IL-6. The T<sub>H</sub>3-like response is related to oral tolerance and antiinflammatory effects in association with the release of IL-10 and TGF-10. A theoretical "ideal" for this system is the ability of the host to respond to various stimuli with balanced protection against the microbial invasion, without excessive inflammation or damage to the host. An imbalanced (or poorly regulated) response of this system could result in an allergic reaction against food proteins (T<sub>H</sub>2 excess) or an autoimmune inflammatory response against self-antigens (T<sub>H</sub>1 excess).<sup>90</sup>

Ongoing research continues to explore these molecular mechanisms, and their potential contribution to allergy, autoimmune disease, and normal immune function development within a fetus, infant, and young child. The role of breast milk in the development of the systemic and mucosal immune systems takes on new significance when considering these concepts and mechanisms. This is especially true when examining the role of breast milk in adding to the innate and adaptive immune response at the level of the mucosa. The postulated effects of breast milk on the intestinal microbiota and the inflammatory state within the intestine must also be considered when considering the issues of allergy, autoimmune disorders, and normal immune function development. Vorbach et al.<sup>327</sup> postulated that the mammary gland evolved from a protective immune gland as part of the innate immune system. They present a list of various protective molecules that are part of both mucosal secretions and human milk. They discuss how specific nutritional factors in human milk have dual functions: nutritional and protective. This highlights the dual role of the breast as a nutritional and immune organ and should stimulate further research into the breast's role in innate immunity, as a component of the mucosal immune system.

## Microbiota, Probiotics, and Prebiotics

Investigation into the microbial colonization of the intestinal tract has exploded. Much of this investigation has been driven by new molecular techniques

involving the analysis of ribosomal RNA sequences of microbes that might not have been identified by traditional culture techniques. The diversity of the microbiota (all the microbes which colonize the GI tract) can be viewed from different perspectives, based on the technical methods used.<sup>306</sup> Culture independent methods for identifying breast milk microbiota and the human infant intestinal microbiome are expanding our understanding of the complex nature of human microbiota and their role in the developing infant. Probiotics have been broadly defined as microorganisms that can exist within a host while affording benefits for the organisms and the host. Prebiotics are substances that (through different mechanisms) increase the growth and survival of probiotic bacteria within the host. Commonly recognized probiotic bacteria are *L. rhamnosus* GG, *B. infantis*, *Streptococcus thermophilus*, *Bacillus subtilis*, *Saccharomyces boulardii*, and *Bifidobacteria bifidus*. Many more organisms are considered to be probiotic, some of which are commercially available.<sup>68,217</sup> Prebiotics are predominantly nondigestible oligosaccharides that ferment within the colon, changing the ambient pH and producing small-chain fatty acids. Breast milk, with its significant composition of oligosaccharides, functions as a prebiotic source for an infant, facilitating the growth of bifidobacteria and lactobacilli.<sup>65,298</sup>

Ongoing research is exploring the potentially mutually beneficial relationship between the microbes and the host. Researchers are paying particular attention to nutrition (the availability of nutrients, energy sources, and synthesis of vitamins as influenced by the microbes),<sup>227</sup> the developing GI tract (including angiogenesis and mucosal barrier repair),<sup>97,147,226,254</sup> the maturation of mucosal immunity,<sup>172,262</sup> both the innate system<sup>147</sup> and adaptive system,<sup>147,314</sup> and the bioavailability and metabolism of drugs and chemicals in the GI tract.<sup>73,149</sup> Specific proposed mechanisms of how probiotic bacteria and prebiotic substances<sup>220</sup> contribute to an infant's developing immune system include competition with pathogenic bacteria for colonization; strengthening the tight junctions to enhance the mucosal barrier; producing antimicrobial bacteriocins; stimulating mucus production; stimulating peristalsis; influencing the secretion of IgA; stimulating the crosstalk interaction between intestinal cells; colonizing bacteria to affect the mucosal immune development; and increasing the production of certain cytokines (IL-10 and interferon- $\gamma$ ).<sup>97,172,260,262</sup>

The complex role of the infant's intestinal microbiota in immunity, inflammation, and intestinal homeostasis continues to be explored. Various authors have summarized the current concepts surrounding the microbiota and immunity and intestinal homeostasis.<sup>21,108,110,158,328</sup> The relationship between the bacteria that constitute the microbiota within the infant host can be commensal,

mutualistic, and parasitic. This depends on the timing, location, and situation, in addition to the nutritional status of the infant, co-infection with other specific organisms, and the genetic make-up of the infant. The homeostatic balance (eubiosis) is associated with the normal development of the infant's immunity and intestinal maturity. Imbalances of the homeostasis (dysbiosis) seem to contribute to pathologic conditions such as allergy, autoimmunity, and inflammatory conditions. Jain and Walker have eloquently described the maturation of the intestinal mucosal barrier and mucosal immune system as related to the effect of human milk on the microbiota and nutritional balance of the infant.<sup>158</sup> They discuss the influence of human milk on the interactions between nutrition, intestinal microbiota, and developing mucosal and systemic immunity. They consider the effects of microbiota on epithelial cell proliferation and how the development of the intestinal mucosa villi and crypts affect the mucosal barrier. Jain and Walker discuss probable mechanisms of these effects being the modulation of occludin and caludin proteins, as well as the epithelial cell signaling to enhance mucosal integrity. The microbiota is also essential to the development of the intestinal lymphoid tissue, in particular, the isolated lymphoid tissue and cryptopatches in the lamina propria. The next line of lymphoid defense, Peyer's patches and mesenteric lymph nodes, is also affected. DCs, lymphoid cells, and effector cytokines and chemokines are influenced by the complex interactions of intestinal microbiota. This leads to combating infection, dampening inflammation, and aiding in tissue repair of the barrier function more effectively. Breast milk's direct effect on the microbiota and the nutritional milieu is both conditioning and developmental. This is mediated through the effect on the intestinal cell expression and activity of toll-like and C-type lectin receptors. These affect the detection of microbe associated molecular patterns (MAMPs), leading to further development of isolated lymphoid follicles and Peyer's patches, which are essential to the maturation of B-cell response and IgA production. Specific actions of bacteria have been identified with specific effects on the immune system. *Bacteroides fragilis* produces polysaccharide A (PSA), which induces and expands Treg cells, which produce IL-10. Other intestinal bacteria produce quantities of short-chain fatty acids (SCFA) as a fermentation product, which includes butyrate as a well-known SCFA. Butyrate contributes to the induction of and function of the Treg cell network and its activity in the gut.<sup>21</sup> Some commensal bacteria contribute to "colonization resistance,"<sup>42</sup> which is the direct competition with pathogenic organisms for the same nutrients. Thus colonization by

pathogenic organisms is limited. Other commensals produce specific antimicrobial peptides that can limit the growth or survival of particular pathogens.<sup>125</sup> In addition to the intestinal microbiota affecting local immune responses, there are data suggesting that alterations in intestinal commensal organism spectrum and amount can diminish systemic T and B cell response to influenza. Alternatively, this may improve neutrophil killing of *S. pneumoniae* and *S. aureus*.<sup>22,57</sup> Separately, there are data suggesting that any alteration of the microbiota or alteration of the local inflammatory environment can lead to bacterial translocation and systemic infection. Conversely, an intestinal infection or inflammatory state can lead to disruption of the local microbiota (dysbiosis).<sup>33,215</sup> There is a large amount of research on the role of intestinal microbiota in combination with genetics and the host immune system contributing to the development of inflammatory bowel disease.<sup>201</sup> Cystic fibrosis is another chronic illness that has been ascribed to a genetic defect leading to dysbiosis and ongoing activation of the immune system leading to chronic inflammation and infections.<sup>26</sup> Intestinal cancer is associated with inflammation of the GI tract and microbiota activated inflammation.<sup>82</sup> There is ample and growing evidence that eubiosis is associated with the normal development of the infant's immunity and intestinal maturity and that dysbiosis plays a role in chronic inflammatory diseases.

## Gastrointestinal Commensal Organisms

The microbial colonization of an infant's intestinal tract begins at birth; organisms from the maternal flora are the first colonizers. Numerous additional factors directly influence the composition of the intestinal microbiota in early infancy, including gestational age, ingestion of breast milk or formula, initiation of solid foods, mode of delivery, the route of delivery of food, the time of onset of feeding, exposure to other microbes through contact (with family, animals, persons from other environments), antibiotics, and intercurrent or chronic illness.<sup>86,121,149,261</sup>

Breast milk is known to transmit bacteria, fungi, parasites and viruses to the infant. Human milk has been analyzed by both culture and molecular techniques to identify its microbiota, which predominately includes organisms associated with the skin or the intestine.<sup>46,87,153,163,262</sup> Next-generation sequencing is the newest method and involves direct extraction of bacterial DNA from the milk and pyrosequencing to identify particular

### BOX 5-4. Bacteria Commonly Found in Breast Milk

Phyla	Genera
Firmicutes	<i>Staphylococcus</i> , <i>Streptococcus</i> , <i>Leuconostoc</i> , <i>Lactococcus</i> , <i>Enterococcus</i> , <i>Clostridia</i> , <i>Veillonella</i> , <i>Gemella</i> , <i>Bifidobacterium</i> , <i>Lactobacillus</i>
Actinobacteria	<i>Corynebacterium</i> , <i>Propionibacterium</i> , <i>Actinomyces</i>
Proteobacteria	<i>Pseudomonas</i> , <i>Serratia</i> , <i>Sphingomonas</i> , <i>Ralstonia</i> , <i>Escherichia</i> , <i>Enterobacter</i> , <i>Acinetobacter</i> , <i>Bradyrhizobium</i>
Bacteroidetes	<i>Prevotella</i>

Bolded bacteria are most prevalent populations detected.

Derived from Cabrera-Rubio et al. (2012), Fernandez et al. (2012), and Hunt et al. (2011).

species. Despite the broad diversity of bacteria in human milk<sup>87</sup> there are four dominant phyla in the human intestine: Actinobacteria, Bacteroides, Firmicutes, and Proteobacteria.<sup>47</sup> (See Box 5-4. Bacteria Commonly Found in Breast Milk.) The microbiota of human milk changes from being very diverse in colostrum to becoming less diverse, with organisms similar to the oral and skin flora of infants over the period of lactation.<sup>46,153</sup> There has been discussion of the potential mechanisms of entry of bacteria into human milk: from the mother's skin (nipple and surrounding areola); retrograde passage from the infant's mouth into the breast; migration of leukocytes and/or DCs; with intracellular bacteria, which move from the mother's intestine to the mammary gland and into the milk; and from the maternal breast tissue/cells into the milk (Fernandez L: Pharm Res 2013,<sup>87</sup> LaTuga MS: Semin Reprod Medicine 2014<sup>186</sup>). There has even been a distinct microbiota of human breast tissue identified with Proteobacteria and Firmicutes, also in high abundance in the breast as noted for human milk.<sup>321,340</sup>

The predominant flora of breastfed infants are *L. bifidus* and *Bifidobacterium* spp., which constitute up to 95% of the culturable organisms. The remaining minority of bacteria include *Streptococcus*, *Bacteroides*, *Clostridium*, *Micrococcus*, *Enterococcus*, *E. coli*, and other uncommon organisms in small numbers.<sup>217,226,343</sup> *L. bifidus* metabolizes milk saccharides, producing large amounts of acetic acid, lactic acid, and some formic and succinic acids, which create the low pH of the stool of breastfed infants. *L. bifidus* also produces SCFA in the course of colonization. Large numbers of bifidobacteria can lower the pH of the intestine, which limits the growth of some pathogens such as *E. coli*, *Bacteroides*, and staphylococci. The flora of bifid bacteria is inhibitory to certain pathogenic bacteria. Substantial clinical

evidence is available to demonstrate protection against intestinal infections from *S. aureus*, *Shigella*, *Salmonella*, *V. cholerae*, *E. coli*, rotavirus, *Campylobacter*, and protozoa.<sup>103</sup> Two facilitory actions of breast milk are apparent. The first encourages the growth of *L. bifidus* and thus crowds out the growth of other bacteria. In the second, the number of pathogens is also kept low by the direct action of lysozyme and lactoferrin. When the number of pathogenic bacteria is kept low, multiple other factors can contribute to keeping the growth of potentially pathogenic bacteria under control and limit the invasion of bacteria through the gut wall into the bloodstream. These other potentially beneficial factors and mechanisms include intestinal motility, gastric acid secretion, intestinal mucin, oligosaccharides, intestinal integrity as a permeability barrier, subepithelial cells in lymphoid follicles (phagocytic and non-phagocytic [DCs]), cytokines, chemokines, and, potentially, immuno-modulatory nutrients (glutamine, arginine, nucleotides, and PUFA).<sup>227</sup>

The intestinal flora of formula-fed infants is made up of predominantly gram-negative bacteria, especially coliform organisms, *Bacteroides*, and *Clostridium*, *Enterobacter*, and *Enterococcus*.<sup>343</sup>

Studies have demonstrated that potentially four distinctly different "microhabitats" for microflora exist; within the GI lumen, within the mucus layer, separately within crypt mucus, and directly on the surface of the intestinal epithelium. The significance of these microhabitats and the effect of specific microorganisms have yet to be determined.<sup>97</sup> At weaning, the facultative anaerobes decline in number, and obligate anaerobes (*Bacteroides*) become the predominant organisms in the intestine. Preterm infants are colonized with different types and numbers of bacteria than are full-term infants. The environment of neonatal intensive care units (NICUs) influences the microbial colonization. Factors of the NICU environment include incubators, widespread use of antibiotics and parenteral nutrition, and illness. The short- and long-term effects of the different and changing GI microbiota are a concern.<sup>227,250</sup> This is particularly true when one considers the contributing factors or causes for sepsis, NEC, chronic lung disease, or poor neurologic outcome in NICUs.

The question of a causal role of intestinal microflora and the development of NEC in premature and VLBW infants has been proposed.<sup>151,211</sup> Gewolb et al.<sup>101</sup> suggested that a low percentage of *Bifidobacterium* and *Lactobacillus* in the stool of VLBW infants within the first month of life is a risk factor for infection. Some studies on the use of probiotics and the occurrence of NEC have demonstrated a lower incidence of NEC in infants receiving probiotics.<sup>25,152,196</sup> Here again, the use of the mothers' breast milk for premature infants

and VLBW infants decreases the risk to the infant of sepsis, NEC, and infection-related events.<sup>73,245</sup> In a controlled prospective study of high-risk, low-birth-weight infants in India using donor human milk, significantly fewer infections and no major infections were found in the group receiving human milk. The control infants experienced diarrhea, pneumonia, septicemia, and meningitis.<sup>225</sup> There is evidence that probiotics or a human milk diet can prevent NEC in preterm infants.<sup>144,258,280,311</sup>

It is clear that the intestinal microbiota is essential to the maturation of the GI tract and the developing immune system. Human breast milk is an important determining factor in the make-up of the microbiota. The microbiota, in combination with many of the bioactive factors in breast milk, is crucial to maintaining a eubiotic state in the intestinal tract and programming both the local GI immune milieu and a normal systemic immune response.\*

## Genetics and Epigenetics

As research pushes to identify all the benefits of human breast milk for the developing infant and corroborate the etiologic effect of factors in breast milk that lead to specific outcomes in neonates, the how and why of these effects become more important. The high level of variability in breast milk composition, and the potential link between breast milk variation and neonatal outcomes, suggests genetic or epigenetic effects or both. Baumgartel and Conley presented a systematic review of publications of genetic studies that utilized RNA and DNA found in human breast milk and the potential effects on BM compositional variability and neonatal outcomes.<sup>16</sup> They identified 13 articles which focused on gene expression and three articles on epigenetics. A number of methods for the analyses of genes were utilized in these studies: Northern blot, RT-PCR, spectrophotometry, microarrays, and Western blots. Bisulfite conversion, PCR amplification, and pyrosequencing were used for epigenetic analysis. In addition to "cataloging" these studies, the authors outlined the limitations of these studies. They made recommendations for the methodology of future studies on breast milk, concerning gene expression and epigenetic effects. The related gene products examined in these studies included important proteins contained in breast milk ( $\beta$ -casein,  $\alpha$ -lactalbumin, M-ficolin, and parathyroid hormone-related protein), transporter proteins, cytokines, and ILs. The epigenetic studies examined methylation of specific genes, for

\*14,21,141,158,159,314,328

example: kallikrein-related peptidase 6 (KLK6), retinol binding protein (RBP1), and glutathione S-transferase (GSTP1), among others. This small collection of studies only emphasizes how much work there is to do to understand the genetics and epigenetics of breast milk and breastfeeding.

The complexity of the breast, its various stages of development, the stages of lactation, and the variable composition of human breast milk suggest a complex interplay between genetic, epigenetic, environmental, and lifestyle factors. These all affect milk production and influence the benefits of lactation for the mother and infant. Epigenetics may play a pivotal role in our understanding of the benefits of breastfeeding. The word "epigenetics" means "atop" or "surrounding" genetics. Various definitions of epigenetics enhance our understanding of its essential features: (a) "changes in gene function which do not alter the underlying structure of DNA but result in genes being switched on or off in a reversible way"<sup>270</sup> and (b) "stable heritable phenotype resulting from changes in a chromosome without alterations in the DNA sequence."<sup>23</sup> Broadly, this implies any mitotically or meiotically heritable change that leads to different gene expression without actually changing the DNA sequence. The true implication is that each individual "adapts" to their environment through some of these epigenetic mechanisms, leading to potentially different health outcomes for the individual.

Berger et al. discuss three "categories of signals" leading to the epigenetic change, which becomes a stably heritable state: epigenator, epigenetic initiator, and epigenetic maintainer. The epigenator is an external or environmental signal, which affects the cell, leading to the activation of the initiator. The intracellular epigenetic initiator "selects" the location of chromosomal/chromatin change, which leads to a change in gene expression. The epigenetic maintainer preserves the new epigenetic chromatin state. The major epigenetic mechanisms for changing gene expression and maintaining it are DNA methylation, histone modification, chromatin remodeling, and noncoding RNAs (ncRNA) [microRNA (miRNA) is one of the ncRNAs]. DNA methylation and histone modification can influence the transcription of specific genes. ncRNAs can affect either transcription (production of an RNA copy of specific genes) or interference with translation (the production of an amino acid sequence from messenger RNA [mRNA]). DNA methylation often results in the "silencing" of the affected gene. Methylation in humans happens at a cytosine next to a guanine nucleotide (CpG site). The critical periods for the occurrence of DNA methylation are early in gestation and early in infancy. "Genomic imprinting" is a specific example of DNA methylation. Imprinting is the inactivation

of one of the two copies of a gene inherited from one's parents, leading to the expression of the other copy of the gene. Imprinting has been described in a percentage of children with Beckwith-Wiedemann syndrome (BWS); a change in DNA methylation leads to genomic imprinting and, subsequently, the disorder. As noted in adults and children, there are genes involved in DNA methylation regulation that are mutated in acute myeloid leukemia.<sup>270</sup> Histone modification changes how the DNA and proteins are "packaged" to form chromatin. Either the chromatin is formed in the "inactive form," leading to transcriptional repression, or in the "active form," leading to active transcription and gene expression.

Verduci et al. summarized a number of possible epigenetic effects of human breast milk components on specified health outcomes.<sup>323</sup> They describe in vitro animal studies correlating specific breast milk components with variable gene expression and potential health outcomes. These include lactoferrin reducing NF- $\kappa$ B expression and leading to less NEC; prostaglandin J decreasing the expression of cholesterol biosynthesis enzymes and prevention of nonalcoholic fatty liver disease (NAFLD); and long-chain PUFA  $n$ -3 (LCPUFA  $n$ -3) causing diminished expression of hepatic hydroxymethyl glutaryl coenzyme A (HMGCoA) reductase, limiting the development of high total blood cholesterol in adult mice. They also note several epigenetic effects hypothesized in humans: prostaglandin J, which leads to increased peroxisome proliferator-activated receptor  $\gamma$  (PPAR $\gamma$ ) and less obesity in adolescents; and undigestible oligosaccharides, which promote the growth of various commensal bacteria and lead to diminished inflammation through the inhibition of nuclear factor kappa-light-chain (NF- $\kappa$ B) activation of B-cells. Each of these is an example of the types of epigenetic changes that could occur in humans due to exposure to specific factors in human breast milk. Verduci et al. refer to dietary factors leading to changes in gene expression as "nutritional epigenetics."<sup>323</sup>

Kosaka et al. have described the existence of microRNA in breast milk and its potential as an immune regulatory agent through transfer from mother to infant (Kosaka N et al. Silence 2010<sup>178</sup>). After the extraction of RNA from human breast milk, they performed a miRNA microarray analysis. They identified specific miRNAs as abundant in human milk. These were related to T and B cell maturation and regulation, neutrophil proliferation, and activation and regulation of TLRs. They also demonstrated that extracted human milk miRNA was resistant to degradation by low pH (pH 1), freezing and thawing, and RNase digestion. As a result, it is highly likely that infants ingest a good amount of miRNA. Thus this miRNA in

human breast milk could function in cell-to-cell communication from mother to infant, affecting the expression of specific genes in the infant. Understanding the role of genetics and epigenetics in the explanation of specific benefits of breast milk for the infant and mother remains in the future, with the success of ongoing research.

## *Effectiveness of Human Milk in Controlling Infection*

The properties of human milk do appear to control or limit infections in infants. Hundreds of articles<sup>205,225</sup> have been written about the protective effect of breastfeeding, including the recent Agency for Healthcare Research and Quality publication *Breastfeeding and Maternal and Infant Health Outcomes in Developed Countries from 2007*.<sup>155</sup> Using evidence-based analyses, the report documents the decreased risk for acute otitis media, GI infections, and lower respiratory tract diseases in breastfed infants in developed countries.<sup>155</sup>

### **PROTECTION AGAINST BACTERIAL INFECTION**

Breast milk IgA has antitoxin activity against enterotoxins of *E. coli* and *V. cholerae* that may be significant in preventing infantile diarrhea. Antibodies against O antigen of some of the most common serotypes of *E. coli* were found in high titers in breast milk samples collected from healthy mothers in Sweden. The infants who had consumed reasonable amounts of breast milk with high titers of *E. coli* antibodies had antibodies in their stool.<sup>129</sup> Protection against cholera in breastfed children by antibodies in breast milk was studied by Glass et al.<sup>103</sup> A prospective study in Bangladesh showed cholera antibody levels to vary in the colostrum and milk. The correlation among colonization, disease, and milk antibodies led the authors to conclude that breast milk antibodies against cholera do not protect children from colonization with *V. cholerae*, but they do protect against disease.

*Salmonella* infection was similarly studied by France et al.<sup>92</sup> to evaluate the immunologic mechanisms in host colostrum and milk specific for salmonellae. Vigorous responses of colostral and milk cells against these organisms and nonspecific opsonizing capacity of the aqueous phase of colostrum and milk were demonstrated.

Gotheffors et al.<sup>117</sup> showed that *E. coli* isolated from stools of breastfed infants differed from strains found in formula-fed infants in two respects. First, *E. coli* strains were more sensitive to the bactericidal effect of human serum. Second, and more often,

spontaneously agglutinated bacteria from other sites, such as the prepuce or periurethral area, were less sensitive in breastfed infants. These findings support the theory that breast milk favors proliferation of mutant strains, which have decreased virulence. This mutation of bacterial strains is another way breastfeeding may protect against infection.

It has been suggested that "milk immunization" is a dynamic process, because a mother's milk has been found to contain antibodies to virtually all her infant's strains of intestinal bacteria. The mother, exposed to the infant's microorganisms through either the breast or the gut, responds immunologically to those microorganisms. Thus she directly provides protection for her immunologically immature infant.

The orderly review of data on the presence of antibodies in human milk has produced a substantial list of affected organisms. In addition to *E. coli*, antibodies to *B. fragilis*, *Clostridium tetani*, *Haemophilus pertussis*, *Diplococcus pneumoniae*, *Corynebacterium diphtheriae*, *Salmonella*, *Shigella*, *Chlamydia trachomatis*, *V. cholerae*, *S. aureus*, and several strains of *Streptococcus* (Table 5-3) have been identified. Noguera-Obenza and Cleary<sup>240</sup> have summarized the contribution of sIgA in breast milk to protecting infants from bacterial enteritis.

A study in Oslo by Hanson<sup>129</sup> of an outbreak of severe diarrhea caused by *E. coli* strain 0111 showed that six severely ill children were formula fed. Two infants who were breastfed had *E. coli* strain 0111 in their stools but showed few symptoms. Their mothers had no detectable antibodies for strain 0111 in their milk, which would suggest that other factors in human milk protect the infant from serious illness when no antibodies are in the milk. Hanson<sup>129</sup> also reported the results of another study in which, after colonization with a specific strain of *E. coli*, mothers had large numbers of lymphoid cells in their milk with antibodies to that *E. coli*. The mothers' serum showed no such response. This supports the concept that antigen-triggered lymphoid cells from Peyer's patches seek out lymphoid-rich tissue, producing IgA in the mammary gland. The mother is immunized in the gut at the same time as her milk. It has also been shown that *E. coli* enteritis can be cured by feeding human milk. Others have reviewed the nonantibody antimicrobial factors in human milk.<sup>183,240</sup> (Tables 5-9, 5-10 and 5-11).

Schlesinger and Covelli<sup>295</sup> studied possible cell-mediated immunity in breastfed infants. They showed that tuberculin-positive nursing mothers had reactive T cells in their colostrum and early milk. Furthermore, 8 of 13 infants nursed by tuberculin-positive mothers had tuberculin-reactive peripheral blood T cells after 4 weeks. Cord blood had no such activity. No clinical or research data suggesting a protective effect of this apparently induced tuberculin reactivity in infants are available.

**TABLE 5-9**

Nonantibody, Antibacterial Protective Factors in Human Milk

Factors	Proposed Mechanisms of Action	Organisms Affected	Effect of Heat
Bifidus factor	Inhibits replication of certain bacteria in GI tract by causing proliferation of lactobacilli	Enterobacteriaceae, including shigellae, salmonellae, and some <i>E. coli</i>	Stable to boiling
Complement components	Opsonic, chemotactic, and bacteriolytic activity	<i>E. coli</i>	Destroyed by heating at 56°C for 30 min
Lysozyme	With IgA, peroxide, or ascorbate, causes lysis of bacteria	<i>E. coli</i> , Salmonellae	Some loss (0%-23%) at 62.5°C for 30 min; essentially destroyed by boiling for 15 min
Lactoferrin (nutrient binders)	Binds ferric iron	<i>E. coli</i>	Two thirds destroyed at 62.5°C for 30 min
		<i>Candida albicans</i>	
Lactoperoxidase	Oxidizes bacteria	<i>E. coli</i>	Presumably destroyed by boiling
		<i>Salmonella typhimurium</i>	
Nonantibody proteins: receptor-like glycolipid or glycoprotein	Inhibit bacterial adherence	<i>Vibrio cholerae</i>	Stable to boiling for 15 min
Gangliosides (GM1-like)	Interfere with attachment of enterotoxin to GM1 cell membrane ganglioside receptors	<i>E. coli</i> and <i>V. cholerae</i> enterotoxins	Stable to boiling
Nonlactose carbohydrate factors	Prevent action of stable toxin	<i>E. coli</i> stable toxin	Stable at 85°C for 30 min
Milk cells (macrophages, polymorphonuclear leukocytes, B- and T-lymphocytes)	By phagocytosis and killing: <i>E. coli</i> , <i>S. aureus</i> , <i>S. enteritidis</i>		
	By sensitized lymphocytes: <i>E. coli</i>		Destroyed at 62.5°C for 30 min
	By phagocytosis: <i>C. albicans</i> lymphocyte stimulation by <i>E. coli</i> K antigen

## PROTECTION AGAINST VIRAL INFECTION

Protection against viruses has been the subject of similar studies. Breast milk contains antibodies against poliovirus, coxsackievirus, echovirus, enterovirus, influenza virus, reovirus, RSV, rotavirus, and rhinovirus.<sup>228,285</sup> It has been confirmed that human milk inhibits the growth of these viruses in tissue culture. Nonspecific substances in human milk are active against arbovirus and murine leukemia virus, according to work by Fieldsteel.<sup>88</sup>

A high degree of antiviral activity against Japanese B encephalitis virus, as well as the two leukemia viruses, has been found in human milk. The factor was found in the fat fraction and was not destroyed by extended heating, which distinguishes it from antibodies. May<sup>205</sup> believes the

nonimmunoglobulin macromolecule antiviral activity in human milk is caused by specific fatty acids and monoglycerides (Table 5-10). It is important to recognize that factors other than immunoglobulins are contained in breast milk, which can play a role in the protection of the breastfeeding infant from viral infections.<sup>124,127</sup>

Specimens of human colostrum have been found to contain neutralizing activity against RSV. RSV has become a major threat in infancy and is the most common reason for hospitalization in infancy in some developed countries. It has a high mortality rate. Epidemics have occurred in special care nurseries. Statistically significant data collected by Downham et al.<sup>74</sup> showed that, compared with uninfected control subjects who were breastfed (46 of 167), few breastfed babies (8 of 115) were among the infants hospitalized for RSV infection.

**TABLE 5-10** Nonantibody, Antiviral, and Antiprotozoan Factors in Human Milk

Factors	Proposed Mechanisms of Action	Organisms Affected	Effect of Heat
Lipids (unsaturated fatty acids and monoglycerides)	Inactivate lipid-enveloped virus	Herpes simplex	Stable to boiling for 30 min
		Semliki Forest virus	
		Influenza	
Macromolecules	Inhibit attachment and penetration	Ross River virus	
		Herpes simplex	Most stable at 56°C for 30 min
		Coxsackievirus B <sub>4</sub>	Destroyed by boiling for 30 min
$\alpha_2$ -Macroglobulin protein	Inhibits hemagglutinin activity	CMV	
		Rotavirus	
		Influenza	Stable to boiling for 15 min
$\alpha_1$ -Antitrypsin	Trypsin-dependent inhibition	Parainfluenza	
		Rotavirus	Stable to boiling for 10 min
Bile salt-stimulated lipase	May generate fatty acids and monoglycerides that inactivate organisms	<i>Giardia lamblia</i>	
Nonlipase macromolecule	Unknown	<i>Entamoeba histolytica</i>	
		<i>G. lamblia</i>	
			Destroyed at 62.5°C for 30 min
Milk cells	Induce interferon by virus or phytohemagglutinin; induce lymphokine by phytohemagglutinin; induce cytokine by herpes simplex virus; lymphocyte stimulation by rubella, CMV, herpevirus, measles, mumps		

Modified from May JT: Antimicrobial properties and microbial contaminants of breast milk: an update, *Aust Paediatr J* 20:265, 1984; Pickering LK, Kohl S: Human milk humoral immunity and infant defense mechanisms. In Howell RR, Morris RH Jr, Pickering LK, editors: *Human milk and infant nutrition and health*, Springfield, Ill., 1986, Charles C Thomas.

Fishaut et al.<sup>89</sup> studied the immune response to RSV prospectively in 26 nursing mothers during several months. Antiviral IgM and IgG were rarely found in colostrum or milk. RSV-specific IgA, however, was identified in 40% to 75% of specimens. Two mothers with the disease had specific IgG, IgM, and IgA antibodies in serum and nasopharyngeal secretions, but only IgA was found in their milk. This confirms that IgA antibodies to specific respiratory tract pathogens are present in the products of lactation. Because RSV appears to replicate only in the respiratory tract, the authors suggest that viral-specific antibody activity in the mammary gland may be derived from the bronchiole-associated lymphoid tissue.

## ANTIPROTOZOAN FACTORS

In human milk, bile salt-stimulated lipase has been found to be the major factor inactivating

protozoans (Table 5-11).<sup>205</sup> The mechanism by which lipase acts is not known, although it may generate fatty acids and monoglycerides, which inactivate enveloped bacteria, viruses, or protozoa. A nonimmunoglobulin, nonlipase, heat-stable factor has been identified in human milk that can inactivate *Giardia lamblia*.

## Antiinflammatory Properties

Human milk protects against many intestinal and respiratory pathogens with minimal evidence of inflammation. Goldman et al.<sup>112</sup> hypothesize that human milk is poor in initiators and mediators of inflammation, but rich in antiinflammatory agents. Several major biochemical pathways of inflammation, including the coagulation system, the fibrinolytic system, and complement, are poorly represented in human milk. Box 5-5 outlines the

TABLE 5-11 Antiprotozoan Factors in Human Milk		
Factor	Organisms Affected (In Vitro)	Effect of Heat
Bile salt-stimulated lipase	<i>Giardia lamblia</i>	Destroyed at 62.5°C for 1 min
	<i>Entamoeba histolytica</i>	
	<i>Trichomonas vaginalis</i>	
Nonimmunoglobulin, nonlipase macromolecule	<i>G. lamblia</i>	Stable to boiling for 20 min

Modified from May JT: Antimicrobial properties and microbial contaminants of breast milk: an update, *Aust Paediatr J* 20:265, 1984.

antiinflammatory properties of various constituents and the paucity of certain proinflammatory mediators in breast milk.

The interaction of factors in the milk with one another, or with host defenses, cannot be entirely predicted by examining each factor separately. When the decreased response of human milk leukocytes to chemoattractant peptides was demonstrated by Thorpe et al.,<sup>315</sup> the failure of the response of human milk leukocytes was not caused by alterations in maternal peripheral blood leukocytes. This suggests that inhibitors are in the milk, and that human milk leukocytes may be modified in the mammary gland to protect through noninflammatory mechanisms.<sup>315</sup> Only low numbers of basophils, mast cells, eosinophils, and cytotoxic T cells are present in breast milk. Many other studies have documented the decreased function of milk

#### BOX 5-5. Antiinflammatory Features of Human Milk

##### Paucity of initiators and mediators

Foreign antigens

IgG antibodies

Complement system

Fibrinolytic system

Coagulation system

Kallikrein system

##### Antiinflammatory agents

Lactoferrin

Secretory IgA

Lysozyme

Catalase

α-Tocopherol

Cysteine

Ascorbic acid

Histaminase

Arylsulfatase

α<sub>1</sub>-Antichymotrypsin

α<sub>1</sub>-Antitrypsin

Prostaglandins (E<sub>2</sub>, F<sub>2</sub>α)

Pregnancy-associated α<sub>2</sub>-glycoprotein

Oligosaccharides

Epidermal growth factors

##### Special features of leukocytes

No basophils, mast cells, eosinophils, or platelets

T-lymphocytes respond poorly to allogeneic cells

Low natural killer cell activity or antibody-dependent cytotoxicity

Poor response of neutrophils and macrophages to chemoattractants

Inhibits complement

Prevents bacterial adherence

Inhibits neutrophil chemotaxis

Limits antigen penetration

Inhibits neutrophil chemotaxis, generation of toxic oxygen radicals

Destroys hydrogen peroxide

Scavengers of oxygen radicals

Degradates histamine

Degradates leukotrienes

Neutralizes enzymes that act in inflammation

Cytoprotective: inhibit neutrophil degranulation, lymphocyte activation

Inhibits lymphocyte blastogenesis

Inhibits microbial attachment

Strengthens mucosal barriers

polymorphonuclear leukocytes and macrophages in both colostrum and mature milk.<sup>38</sup>

The antioxidant properties of human colostrum were demonstrated by Buescher and McIlheran<sup>39</sup> using aqueous human colostrum on human PMNs. The colostrum significantly interfered with PMN oxygen metabolic and enzymatic activities that are important in the mediation of acute inflammation.

Antioxidants in breast milk can also contribute to the overall antiinflammatory effect of breast milk. Demonstrated antioxidants contained in breast milk include an ascorbate-like compound, uric acid,  $\alpha$ -tocopherol,  $\beta$ -carotene, and L-histidine, all of which scavenge oxygen radicals. Blood levels of  $\alpha$ -tocopherol and  $\beta$ -carotene are higher in breastfed than un-supplemented formula-fed infants. Catalase, glutathione peroxidase, and lactoferrin are functionally antioxidants. Antioxidant activity has been demonstrated in colostrum and, at lower levels, in mature human milk.

Additionally, specific cytokines that can exhibit antiinflammatory effects have been identified in human colostrum and milk: TGF- $\beta_1$  and  $\beta_2$ <sup>239,287,310</sup> and IL-10.<sup>96</sup> A cytokine antagonist, IL-1RA, and soluble receptors for TNF- $\alpha$  are also found in colostrum and milk.<sup>40,305</sup> Palkowetz et al.<sup>253</sup> have reported that IL-1RA can decrease the action of IL-1 $\beta$ .

Both human colostrum and milk cause a diminished influx of PMNs to a local site of inflammation in two different *in vivo* models of inflammation in rats.<sup>49,118,221</sup>

The inflammatory response can be protective for the host at the same time as it can produce the symptoms of clinical illness. Breast milk contains a large variety of antimicrobial factors that exert their protective effect without causing significant inflammation (e.g., sIgA, oligosaccharides, lactoferrin, and nucleotides). Many other cells and factors in breast milk participate in a complex interaction to both protect the infant and limit the potential damaging effects of an uncontrolled inflammatory response. Further study into the dynamic interplay of the many factors in breast milk with developing infants' mucosal barriers and immune systems is needed to fully understand the protective immune response and the antiinflammatory benefits of human milk.

## Allergic Protective Properties (See Chapter 17 on Human Milk as Prophylaxis in Allergy)

In discussing the allergic protective properties of human milk, it is difficult to identify specific protective factors that are proved to protect against

allergy. It is equally difficult to discuss the proposed mechanisms of protection because the exact mechanism of "oral tolerance" remains theoretic, and the relative importance of contributing factors to hypersensitivity must still be adequately defined. Some of the important variables concerning tolerance and sensitization are genetic background of the host, nature and dose of the antigen, frequency of exposure, timing (age) at first and subsequent exposures, immunologic status of the host, and route of exposure.

During the neonatal period, the small intestine has increased permeability to macromolecules. Infants have more serum and secretory antibodies against dietary proteins than children or adults. Production of IgA in the intestinal tract is delayed until 6 weeks to 3 months of age. IgA in colostrum and breast milk prevents the absorption of foreign macromolecules when an infant's immune system is immature. Mucin, oligosaccharides, and other factors within breast milk may affect antigen presentation. Protein of breast milk is species specific and therefore nonallergic for human infants. No antibody response has been demonstrated to occur with human milk in infants. It has also been shown that macromolecules in breast milk are not absorbed.

Indirect evidence can be inferred from a demonstration of an infant's response to cow milk protein. Within 18 days of taking cow milk, the infant will begin to develop antibodies. Since the advent of prepared formulas, in which the protein has been denatured by heating and drying, the incidence of cow milk allergy has been considered to be 1%. The most reliable means of diagnosing cow milk allergy is by challenging with isolated cow milk protein. Although circulating antibodies and coproantibodies have been identified, these are not reliable techniques for a clinician involved in patient care.

The allergic syndromes that have been associated with cow milk allergy include gastroenteropathy, atopic dermatitis, allergic rhinitis, chronic pulmonary disease, asthma, eosinophilia, failure to thrive, and sudden infant death syndrome, or cot death, which has, in some cases, been attributed to anaphylaxis to cow milk.<sup>164,190</sup> GI symptoms have received the greatest attention and include spitting-up, colic, diarrhea, blood in the stools, frank vomiting, weight loss, malabsorption, colitis, and failure to thrive. Cow milk has been associated with GI protein and blood loss. The diagnosis is best made by elimination of cow milk from the diet and, when appropriate, challenge tests. Cutaneous testing is of little help. Cow milk allergy has been described in breastfed infants, and exclusive breastfeeding alone is not sufficient for an infant at high risk to become sensitized to cow milk proteins.<sup>160</sup>

The incidence of cow milk allergy in exclusively breastfed infants has been estimated as 0.4% to 0.5%, compared with the overall incidence, ranging from 1.9% to 7.5% in population-based studies.<sup>129</sup>

Murray<sup>222</sup> showed the association of nasal secretion eosinophilia with infants freely fed cow milk or solid foods, compared with eosinophilia in strictly breastfed infants. In infants receiving cow milk, 32% had high eosinophilic secretions. Only 11% of breastfed infants had eosinophils present in nasal secretions.

Not surprisingly, many different antigenic specificities are recognized when the colostrum or milk of one species is fed to or injected into another species. Cow milk is high on the list of food allergens, particularly in children. Sensitivity to cow milk is responsible for at least 20% of all pediatric allergic conditions, according to Gerrard.<sup>100</sup> Evidence indicates that IgA antibodies play an important role in confining food antigens to the gut. Food antigens given to bottle-fed infants before they can make their own IgA, and when they are deprived of that in human milk and plasma cells, may be expected to be more readily absorbed.

Glaser<sup>102</sup> first made the association between the drop in breastfeeding and the rise in allergy. He pioneered the theory of prophylactic management of allergy. Allergy in infancy is associated with a familial history of atopic disease and elevated cord blood IgE levels. The introduction of "foreign" proteins to an infant's diet, and even to the mother's diet, in the breastfeeding dyad can lead to allergic symptoms in the infant. Exclusive breastfeeding does not protect high-risk children from allergic symptoms unless the mother also adheres closely to a restrictive diet that excludes common allergens.<sup>6,13</sup>

A large body of literature examines whether breastfeeding protects against atopic disease. In 1988, Kramer<sup>180</sup> defined 12 standards for methodology and the study of allergy and breastfeeding. The standards clarified the definitions of breastfeeding, measurable outcomes, and the diagnostic criteria for specific allergic syndromes, defined children at high risk for atopic disease, and addressed methods to decrease bias and control for confounding variables. Several recent large meta-analyses have been performed assessing the protective effect of breastfeeding against allergic rhinitis, atopic dermatitis, and asthma.<sup>98,99,212</sup> Exclusive breastfeeding during the first 3 months of life protected against allergic rhinitis (summary odds ratio 0.74, 95% confidence interval 0.54 to 1.01), with or without a family history of atopy.<sup>212</sup> Exclusive breastfeeding for at least 3 months was associated with lower rates of atopic dermatitis in children with a family history of atopy.<sup>98</sup> Exclusive

breastfeeding in the first months of life was protective against asthma during childhood (odds ratio 0.70, 95% confidence interval 0.60 to 0.81).<sup>99</sup>

**Chapter 17** discusses the prophylactic management of the potentially allergic infant.

## *Protection Against Chronic Disease in Childhood*

The major elements in human milk related to the infant's immune system are direct-acting antimicrobial factors, antiinflammatory factors, and immunomodulating bioactive compounds.<sup>131</sup> Epidemiologic studies have produced compelling information that suggests that breastfeeding for 4 months or longer can provide some immunologic protection against some childhood-onset diseases.<sup>107,113,206</sup>

In 1991, Virtanen et al.<sup>325</sup> reported a prospective long-term study among children in Finland that showed a significantly lower incidence of type 1 diabetes in those at-risk children who had been breastfed for 4 months or longer. Other epidemiologic studies have demonstrated a decreased incidence of type 1 insulin-dependent diabetes mellitus in breastfed children.<sup>27,206,241</sup> These clinical observations have been supported in the laboratory by studies of diet control in diabetic mice. The isolation of a bovine albumin peptide as a possible trigger of type 1 insulin-dependent diabetes mellitus makes further study imperative.<sup>168</sup> Based on limited data, the recent Agency for Healthcare Research and Quality report cautiously concluded that breastfeeding for at least 3 months reduced the risk for type 1 diabetes, compared with breastfeeding for less than 3 months. For type 2 diabetes, the same report concluded that breastfeeding in infancy produced a decreased risk, compared with not breastfeeding.<sup>155</sup>

The review of the national perinatal collaborative study by Davis et al.<sup>67</sup> showed a protective effect against development of childhood cancer by being breastfed for 4 months or longer for children followed for 10 years. The effect was greater for acute leukemia and lymphoma. The role of infant feeding practices showed a similar effect of breastfeeding as protective in postponing or decreasing the occurrence of inflammatory bowel disease in childhood.<sup>177,279</sup> Greco et al.<sup>119</sup> reported a decreased risk for celiac disease in breastfed infants. The AHRQ report concluded that an association exists between breastfeeding for at least 6 months and a decreased risk for developing acute lymphocytic leukemia and acute myelogenous leukemia.<sup>155</sup>

Maternal renal allografts have a better survival rate in individuals who were breastfed in infancy,

compared with those who were not breastfed.<sup>48,175</sup> The mechanism of these apparent long-term immunologic benefits remains unclear, although theories abound.<sup>107</sup> Given the potential for confounding factors and bias in large long-term studies, confirmation of these proposed benefits by additional, carefully controlled trials is required.

## Summary

An increasing amount of accumulated epidemiologic literature, utilizing improved methodology and statistics, demonstrates the protective benefits of human milk for infants. A large number of bioactive factors have been identified and measured in breast milk during the period of lactation. Additional research is needed to clarify the interactions and the mechanisms of action of the many bioactive factors in human milk and then correlate these immunomodulatory actions with specific protective benefits for the infant.

## CHAPTER 6

# *Psychological Impact of Breastfeeding*

---

The mental health of the mother will have a significant impact on her postpartum recovery and a dramatic influence on the infant's well-being. Breastfeeding has a significant impact on the outcome for both mother and infant especially during the first year postpartum.

Although the previous chapters provide more than adequate information to support the preference for breastfeeding in almost every case, the critical impact in the return to breastfeeding in modern cultures rests with the issue of a mother's role and her perception of breastfeeding as a biologic act. The maternal influences include psychophysiological reactions during nursing, long-term psychophysiological effects, maternal behavior, sexual behavior, and attitudes toward men. All professionals providing support care in the perinatal period need to have a clear view, not only of the biologic benefits of breastfeeding, but also of their own psychological attitudes about the breast itself.

"For men, breasts are sexual ornaments—the crown jewels of femininity."<sup>60</sup> This is not true worldwide, however, and other body parts (e.g., small feet, nape of neck, buttocks) are sexually charged, with much of the fascination resulting from full or partial concealment. Until the fourteenth century, the nursing Madonna was the prevailing image, but in truth, the availability of a mother's milk meant life or death for every newborn.

The breast has assumed many roles throughout history, moving from sacred to domestic to political to erotic. The definition of the breast has been provided by moralists, historians, poets, pornographers, lovers, and women themselves. Much of the rhetoric today is about the breast in crisis: "The breast is torn between nurturance, eroticism,

and the fear of cancer."<sup>60</sup> In the eyes of the beholder, babies see food, men see sex, physicians see disease, business sees dollar signs, and religion sees spiritual symbols. Psychoanalysis places breasts in the center of the unconscious. The breast has a privileged place in human thought. Perhaps the love affair with science has turned women from being comfortable with their breasts as a source of infant nurturance to being uncomfortable and ashamed of breastfeeding and yet has them searching through science and medicine for the perfect size or shape.<sup>60</sup>

The breast has been regarded as a sex object in the Western world for more than a century, and its biologic benefits have been downplayed. This is clearly demonstrated by the conflicting mores that permit pornographic pictures in newspapers, movies, and nude theaters but insist on the arrest of a mother for indecent exposure who is discreetly nursing her baby in public.

Proponents of breastfeeding have generally accepted, even before the upsurge of interest and research in attachment, that the major reason to breastfeed is to provide the special relationship and closeness that accompany nursing. Conversely, the major contraindication to breastfeeding was lack of desire to do so. This was evidenced by it being considered more appropriate to present breastfeeding as a matter of personal choice with no compelling reasons to urge a mother to consider nursing. The concern about creating guilt in the mother who chooses not to nurse has been significant, and it often resulted in a passive attitude on the part of the clinician so that the mother received no prenatal counseling about infant feeding.<sup>31</sup> As efforts to educate the public in general and women in particular about the benefits of breastfeeding

have been increased, guilt is being used as a defense for doing nothing. Far more disturbing have been the aggressive attacks on breastfeeding promotion justified by the fear of producing guilt in the mother who chooses not to breastfeed.<sup>47</sup> Other public health campaigns have not been muted or halted for fear of producing guilt in those who are obese, smoke, or abuse drugs.

## Bonding and the Impact of Breastfeeding

The studies performed to understand bonding have largely been done without reference to breastfeeding. A supposedly comprehensive book, *Attachment and loss* by Bowlby,<sup>7</sup> which reviews early mother-infant interactions extensively, never mentions breastfeeding. In addition, suckling is given extensive treatment without making a distinction between bottle and breast or implying that an alternative to the bottle exists. The emphasis in the 1940s was on the effects of disrupting already-formed attachments. Separation in the neonatal period was ignored, and infant socialization was studied from 6 months of age.

Work by Spitz<sup>52</sup> and others has identified the devastating effects on infants deprived of long-term maternal contact. These investigators demonstrated major deficits in both mental and motor development, as well as general failure to thrive. The impact on the mother had not yet been described. Klaus and Kennell<sup>29</sup> provided those data in their many writings on mother-infant interactions, which are summarized in their book *Parent-infant bonding*. Evidence indicates that the maternal-infant bond is the strongest human bond when two major facts are considered: an infant's early growth is within the mother's body and survival after birth depends on her care. Although the process had not been meticulously described yet, Budin<sup>9</sup> noted in 1907 that when a mother was separated from her infant and was unable to provide the early care of her sick child, she lost interest and even abandoned the infant.

The immediate emotional reactions of mothers to their newborns were studied by Robson and Kumar in 193 women (two groups of primiparas,  $n=112$  and  $n=41$ , and one group of multiparas,  $n=40$ ); 40% of the primiparas and 25% of the multiparas recalled that their predominant emotional reaction when holding their babies for the first time was indifference. Maternal affection was more likely to be lacking if the mother had an amniotomy or painful labor or had received more than one dose of meperidine (pethidine) unrelated to cesarean or forceps delivery. The

authors found no difference between mothers who breastfed or bottle fed. The feelings of indifference persisted for a week or longer. This study points out that normal women may be initially indifferent toward their babies, whereas others experience great elation.

The development of positive feelings in primiparous women toward their normal newborns occurred before delivery in a third of women, immediately at birth or on the first day for 42%, and by the second or third day for 19% in a study by Pascoe and French.<sup>45</sup> Mothers who breastfed were more likely to express positive feelings. Labors of less than 9 hours were associated with positive feelings, but no association with social class, infant sex, type of delivery, or duration of initial mother-infant contact was found.

Klaus and Kennell<sup>29</sup> noted that mothers in the United States showed different attachment behavior when permitted early contact with their premature infants compared with mothers who had first contact at 3 weeks of age. Mothers of full-term infants who were allowed contact within the first 2 hours and subsequent extra contact behaved differently at 1 month and 1 year with their babies compared with control subjects. Jackson et al.<sup>25</sup> made similar observations in the Yale Rooming-In Unit from 1945 to 1955 but failed to provide control observations.

In part because of the thought-provoking work of Klaus and Kennell<sup>29</sup> in the 1970s, remarkable changes have taken place in labor, delivery, and postpartum services in hospitals in the United States and around the world. Mothers have been "allowed" to have their infants to hold and cuddle as soon as possible after delivery, and fathers have been "allowed" to participate in the birth experience. The take-charge attitude of health care professionals has relaxed, and gradually hospital perinatal care has been humanized. In the meantime, a number of investigators have challenged the power of bonding. In a critical review of early and extended maternal-infant contact research, Siegel suggests that, although many longitudinal experiences affect parenting behavior in complex ways, reasonable judgment supports early and extended contact whenever possible.

When a normal, healthy infant born to an unmedicated mother is placed on the mother's abdomen immediately after the cord is cut, the infant crawls to the breast, finds the nipple, and latches on, beginning to suckle.<sup>50</sup> This event takes place unassisted by the mother or an attendant. The warmth of the mother maintains the infant's body temperature. This is described as a series of events beginning with the infant resting and occasionally looking at the mother, then moving toward the breast with some lip smacking and mouthing.

Approaching the breast, the infant turns from one to the other breast before finally moving toward one nipple, bobbing over it, and grasping the areola and suckling (Figure 6-1). Experiments that involve washing one breast demonstrate that the infant chooses the unwashed breast. When the mother has been medicated during labor, the "medicated" infant struggles to find the breast and often fails. Infants who are left with their mothers seldom cry during this awake, alert period.<sup>50</sup> If unimpeded, this process takes 40 to 45 minutes, which suggests the original baby-friendly mandate of initiating breastfeeding within a half hour may have been hasty. Physiologically, the stimulus to the mother's nipple and the stimulus to the infant's mouth trigger the release of vital hormones in both mother and infant, beginning the maturation of the intestinal mucosa and enhancing nutrient absorption for both mother and infant.

This awake, alert period immediately after delivery provides an opportunity for receiving the first measure of colostrum, which is not only nourishing but also protective from an immunologic and infectious standpoint.

When a newborn is separated from the mother in the first hours postpartum, crying occurs and stops on reunion.<sup>27</sup> The cry has been studied by sound spectrographic analysis in a group of infants in contact with their mothers for the first 90 minutes compared with those kept in a crib. The separated infants cried 10 times more than the contact infants. On analysis, the cry was characterized as a discomfort cry compared with patterns seen in cries of hunger or pain.

The impact of early mother-infant interaction and breastfeeding on the duration of breastfeeding has been reported; no data appear to be available as to whether mothering is different between mothers who breastfeed and bottle feed in this early period. Sosa et al.<sup>51</sup> reported the effect of early mother-infant contact on breastfeeding, infection, and

growth. Breastfeeding mothers who were permitted early contact but not early breastfeeding were compared with mothers without early contact who also breastfed. The mothers with early contact were observed to nurse 50% longer than the control subjects. The early-contact infants were heavier and had fewer infections. Sosa et al.<sup>51</sup> conducted a similar study in Brazil, in which each mother nursed immediately on delivery and the infant was kept beside the mother's bed until they went home. At home, they had a special nurse make regular visits to help in the breastfeeding. The control subjects had traditional therapy, that is, contact at feeding times after an early glimpse. Infants were housed in a separate nursery. At 2 months, 77% of the early-contact mothers and only 27% of the control mothers were successfully nursing. The early and continued contact may have been accompanied by increased support and assistance from the nursery staff. This added support could facilitate breastfeeding and thus be the cause of the improved outcome.

An additional study of early contact by deChâteau et al. in Sweden investigated a group of 21 mothers with early contact and 19 control mothers, all of whom were breastfeeding in the hospital.<sup>10a</sup> The only difference in management was the first 30 minutes of early contact because 24-hour rooming-in was provided for all mothers after 2 hours postpartum. The length of breastfeeding differed: for the early-contact group, 175 days, and for the control subjects, 105 days. Follow-up observations at 3 months showed different mothering behavior. The study group displayed more attachment behavior, fondling, caressing, and kissing than the control group.

Unless heavy medication or difficult delivery intervenes, an infant experiences a period when the eyes are wide open and the infant can see, has visual preferences, turns to the spoken word, and responds to the environment. Similar periods in the state of consciousness of the infant

**Figure 6-1.** Infant crawling to breast (A), making mouthing and sucking movements (B), then taking breast (C). (From Righard L, Alade MO: Effect of delivery room routines on success of first breast-feed, *Lancet* 336:1105, 1990.)

may last only a few seconds or minutes during the next 1 to 2 days.

Although some mothers begin the attachment process when the decision to have an infant is made, after conception the physiologic changes in the maternal body strengthen the developing bond. During pregnancy, listening to the fetal heart and watching echocardiographic images of fetal movements are confirming factors created by modern medicine. The first picture in an infant's scrapbook may be of the infant as a 12-week fetus. The moment of delivery, the first glimpse, and the first hours are intense opportunities for further "bonding" to occur. For some, however, the process will take a day or a week before the mother feels true love for the infant. Unfortunately, studies investigating this timeline do not distinguish women who breastfeed from those who bottle feed.

As in every area of medicine, new ideas and new theories invite criticism. The best type is neither partisan nor polemical and serves to dispassionately repeat the studies and confirm or disprove.<sup>17</sup> Many investigators have affirmed the "bonding" theory. Other critics,<sup>1</sup> however, have been hostile yet unable to disprove that biologic factors might play a significant role in a mother's response to her infant. A new group has called the theories "a bogus notion," reflecting medicine's need to control women and to enhance market demands and the status of medicine itself.<sup>14</sup> Further, it is argued that bonding is demeaning to women because it rests on the idea of instinct. These critics agree that increased contact between mother and infant in the first few days increases maternal emotional response, that early contact enhances breastfeeding, and that early extended contact decreases the incidence of child abuse, with effects solely on the parents, not the child.

Further study is needed, although randomly assigning a mother to a restricted contact control group would be difficult, if not unethical, today. Skin-to-skin versus clothed contact and hormonal components in relationship to behaviors remain to be explored. The father's and siblings' roles also deserve additional attention. Despite his criticism of bonding research, Lamb<sup>30</sup> has been supportive of the trend toward humanizing childbirth to provide a rich emotional experience for parents.

Sensitive periods in biologic phenomena are times when events alter later behavior. The existence of a sensitive period in human behavior is disputed, although it has been shown to exist in other species. Human bonding occurs in a longer period of time.<sup>30</sup> The power of attachment enables mother and father to make many sacrifices necessary

for their infant.<sup>28</sup> More than 50 years of investigation have confirmed the observations that the human maternal-infant bond can be facilitated, supported, and encouraged by more caring sensitive processes beginning with labor and throughout the perinatal period.

Human relationships are complex. A newborn brings joy, fear, anxiety, frustration, and triumph, reminds Righard. Adaptability and compensation in the developmental processes are part of human existence. The concept of bonding has drawn attention to this period of life and began the process of understanding the mother-infant relationship.

## *Body Contact and Cultural Tradition*

---

If we look at other mammals, lactation behavior, including the duration and frequency of feedings, is species specific and predictable because it is a genetically controlled behavioral characteristic of the species. Only those animals kept in zoos or laboratories reject their young. Among higher primates, learning plays a significant role; monkeys reared without role models have to be taught how to groom and feed their young. In humans, breastfeeding behavior is highly variable from one culture to the next. Different cultures of the world have different sets of "rules" about lactation as they do about many other aspects of life and death. Cultural tradition dictates the initiation, frequency, and termination of breastfeeding. Learning plays a key role in the lactation process, but the learning is focused on the beliefs, attitudes, and values of the culture.

The degree of body contact permitted by the culture is a fundamental difference.<sup>42</sup> Simpson-Herbert describes the degree of mother-infant body contact as the physical and social distance that mothers keep from their babies. The physical distance is viewed as a reflection of the social distance sanctioned by the culture.

Cultures prescribe how often infants will be held or carried and how they will be carried (e.g., in the arms, a pouch, or a sling, or on a cradleboard). How infants are clothed, where they are placed when not held, and where they spend the night are culturally determined and affect breastfeeding. The cultural constraints that control maternal behavior include those on the kinds and amounts of maternal clothing, acceptability of breast exposure, and beliefs on frequency and length of feedings.<sup>3</sup>

The effect of increased carrying of infants was studied by Hunziker and Barr<sup>24</sup> in a group of primiparous breastfeeding women in Montreal.

<sup>1</sup>References 4,14–19.

The crying pattern of normal infants in industrialized societies has been reported to increase until 6 weeks of age, followed by a decline to 4 months, with most crying occurring in the evening. The investigators had the study families increase carrying the infants either in the arms or in a carrier to a minimum of 3 hours per day, whereas control infants were placed in a crib or a seat with a mobile in view. At 6 weeks, significantly less (43%) crying was observed in the "carried" infants, especially in the evening. Similar but smaller differences were noted at 4, 8, and 12 weeks.

When Cunningham et al. randomly provided either soft baby carriers or plastic infant seats to a group of low-income women in a clinic in New York City, they found the infants carried in a soft carrier were more securely attached than those placed in a seat when tested with the Ainsworth Strange-Situation Study. The study and control infant groups had an equal number of mothers who breastfed, and thus the authors found no effect of breastfeeding on study results. They concluded that in low-income groups, mother-infant relationships benefited from early use of soft carriers and "contact comfort."

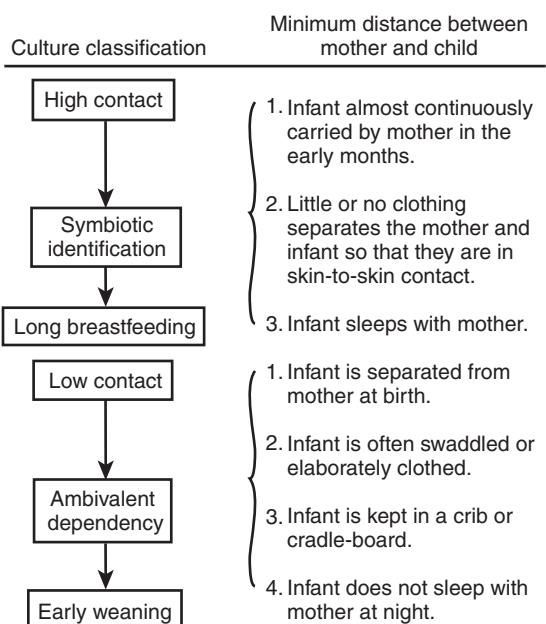

Although the mean length of breastfeeding was similar in both groups, the breastfeeding was not defined, that is, as exclusive, partial, or minimal. Also, time spent holding to breastfeed versus time spent holding to bottle feed was not noted. There were 21 women who breastfed and 28 women who bottle fed. Although it is helpful to use carriers with bottle-fed infants, it should not be done to the abandonment of breastfeeding support programs.

Anthropologic studies of 60 societies by Whiting<sup>59</sup> considered mother-infant body contact. He classified these cultures as high or low in contact as shown in Figure 6-2.

Other factors influence the development of cultural mores, including climate and means of food gathering. Simpson-Herbert points out that when infants are heavily clothed and swaddled, as in cold climates, they are neat packages that can be put down easily. Inuit people are an exception, however, traditionally keeping infants inside mothers' parkas for warmth and frequent feedings. Breastfeeding is almost axiomatic in warm climates where clothing is loose or absent; frequent holding and carrying are common, and the breast is readily accessible.

The diet of hunter-gatherer societies is not conducive to early weaning because meat, roots, nuts, and berries are difficult for infants to chew and digest, whereas the softer foods of the agricultural societies can be prepared for early infant feeding.

Study of specific world societies reveals that North American and European women are concerned with the beliefs that it is indecent to expose

**Figure 6-2.** Anthropologic studies of mother-infant body contact in 60 societies. (From Whiting JWM: Causes and consequences of the amount of body contact between mother and infant. In Munroe RL, Munroe RD, Whiting BB, editors: *Handbook of cross-culture human development*, New York, 1980, Garland.)

the breast, it is possible to spoil an infant with too much handling, and early weaning is a sign of infant development. Western mothers keep their distance from their babies. Mothers in high-body contact societies spend at least 75% of the time in contact with their babies, whereas low-contact societies spend less than 25%.

Since the 1990s, infant care in Western societies has included carrying infants in carriers close to the parent's body. Co-sleeping with the infant for easy access to the breast through the night and the concept of the family bed has emerged as more conducive to good parent-infant attachment. Breastfeeding increases sleep duration for new parents according to a study by Doan et al.<sup>13</sup> They demonstrated that supplementing with formula at night resulted in more sleep loss similar to that of bottle-feeding parents. Exclusive breastfeeding resulted in 40 to 45 minutes more of sleep.

The practice of co-sleeping and bed sharing, although customary in many cultures, is rare in industrialized societies. Careful scientific study of co-sleeping has revealed a number of benefits, but present custom is based on the bottle-feeding philosophy that embraces separation of parent and child. Where the infant sleeps is not just a family issue but a medical one according to McKenna,<sup>40</sup> who has performed the seminal studies on co-sleeping and pointed out the benefits of bed

### **BOX 6-1. Safe Sleeping Environments for Infants**

Families should be given all the information that is known about safe sleeping environments for their infants, including the following:

- Place babies in a supine position for sleep.
- Use a firm, flat surface and avoid waterbeds, couches, sofas, pillows, soft materials, and loose bedding.
- Use only a thin blanket to cover the infant. Assure the head will not be covered. In a cold room the infant could be kept in an infant sleeper to maintain warmth.
- Avoid the use of quilts, duvets, comforters, pillows, and stuffed animals in the infant's sleep environment.
- Never put an infant down to sleep on a pillow or adjacent to a pillow.
- Never leave an infant alone on an adult bed.
- Inform families that adult beds have potential risks and are not designed to meet federal safety standards for infants.
- Ensure that there are no spaces between the mattress and headboard, walls, and other surfaces that may entrap the infant and lead to suffocation.

sharing. As a result of extensive study on the subject, the Academy of Breastfeeding Medicine has developed "A Guideline on Co-Sleeping and Breastfeeding" (Box 6-1).<sup>1</sup>

Breastfeeding is often enhanced by bed sharing, and providing that precautions are taken, bed sharing is safe and healthy. Bed sharing has been singled out by the AAP Committee on SIDS as a major cause of SIDS. This is not true when associated with breastfeeding. It is true when associated with drugs, smoking, and alcohol. The alternative to bed sharing while breastfeeding is the very hazardous sofa, lounge chair, or rocker.

### *Psychological Difference Between Breastfeeding and Bottle-Feeding*

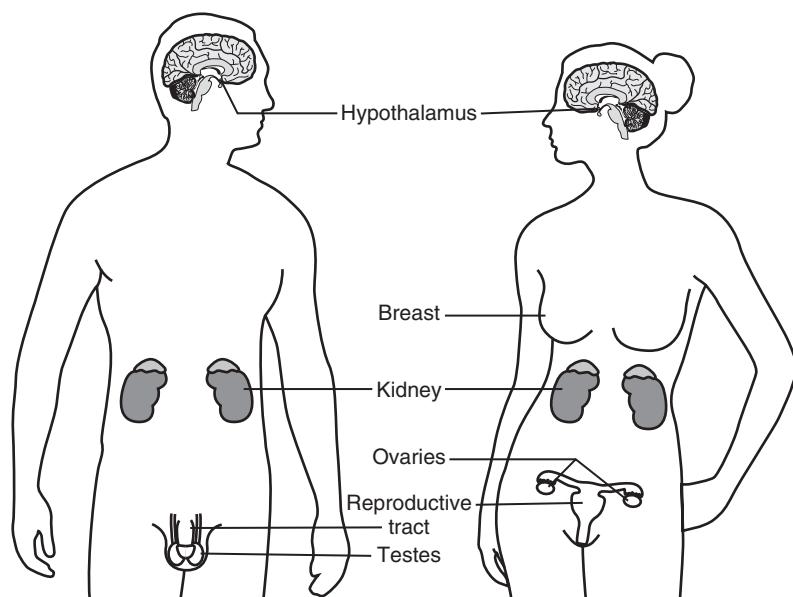

Professionals have spent decades reassuring mothers that they can capture the same emotional and behavioral experience by feeding an infant from a bottle as they can feeding with the breast, with the same warmth and love. Technically speaking, the same warmth is not present because lactating breasts have been shown to be warmer than nonlactating breasts. This warmth can be demonstrated by infrared pictures and thermograms. Responses to stress appear to be muted in lactating women. Using graded treadmill exercises, lactating women had significantly decreased plasma levels of adrenocorticotrophic hormones, or corticotrophin, cortisol, and

epinephrine compared with match-control nonlactating women. Plasma glucose did not rise as it did in nonlactating women.<sup>16</sup>

At 1 to 12 months postpartum Mezzacappa and Katkin examined subjective stress as well as individual differences in both mothers who breastfed and those who bottle fed. They administered the Perceived Stress Scale and the trait component of the State-Trait Personality Inventory. The 10-item Perceived Stress Scale is widely used to index subjective stress, and the State-Trait Personality Inventory is a 30-item questionnaire assessing anxiety, anger, and curiosity. Mothers who breastfed had significantly less perceived stress in the month preceding the test than did the those who bottle fed. No significant differences were seen among groups in anxiety, anger, or curiosity. Maternal age, time postpartum, parity, and work status were controlled for. In a second experiment, the authors examined the acute psychological effects of breastfeeding and bottle-feeding. Positive and negative mood were assessed in the same mother before and after a feeding. They recruited mothers who were both breastfeeding and bottle-feeding, studying them in two sessions a week apart, randomly sequenced. The mothers completed the Positive and Negative Affect Scale, rested 10 minutes, fed the infant, rested 10 minutes, and retook the test. The mood was significantly less positive after bottle-feeding than after breastfeeding. Mood became significantly less negative after breastfeeding than after bottle-feeding. A possible explanation is the surge of oxytocin during let-down.<sup>56</sup> Uvnäs-Moberg<sup>53a,56</sup> has reported mood effects of breastfeeding mediated by oxytocin. She describes oxytocin levels as inversely related to negative moods and emotions. The higher the levels of oxytocin, the more calm the mother (Figure 6-3).

Mezzacappa and Katkin conclude that the results confirm that breastfeeding buffers mood. They attributed this to psychological effects of breastfeeding itself and not to the differences between women who breastfeed and those who bottle feed because the participants did both and were their own controls.

Newton and Newton<sup>43</sup> suggest that special caution should be used in evaluating statistical associative studies that purport to investigate the hypothesis that breastfeeding and bottle-feeding are psychological equivalents. "Because breastfeeding involves a large measure of personal choice and because it is related to attitudinal and personality factors, no groups of breastfeeders and bottle feeders are likely to be equal in other respects. Therefore the relation of breastfeeding to any particular psychosocial measure may not be cause and effect, but simply the differences due to other uncontrolled covariates."<sup>43</sup> A human mother's care

**Figure 6-3.** Sites of oxytocin action in humans. Oxytocin acts on multiple organ systems in men and women to regulate various physiological processes. In women, these include the milk let-down response by the smooth muscle of the breast, and uterine contractions; in men, they include contractions of the smooth muscles of the reproductive tract. Oxytocin is also involved in regulation of water balance by the kidneys and is released by central neurons to influence behavior. (Redrawn from McCarthy MM, Altemus M: Central nervous system actions of oxytocin and modulation of behavior in humans, *Mol Med Today* 3:269, 1997 (Figure 1).)

of her infant is derived from a complex mixture of her genetic endowment, the response of the infant, a long history of interpersonal relationships, her family constellation, this and previous pregnancies, and the community and culture.

The method chosen to feed a baby is but one item in a whole style of maternal-child interaction. It is unlikely that this style is determined by the method of feeding; according to Righard. Breastfeeding is a different activity when it is carried out by a small minority compared with breastfeeding that is commonplace in the community. After many years of promoting artificial feedings, breastfeeding has become the norm as it had been historically for centuries.

In a study of patterns of variation in breastfeeding behaviors, Quandt<sup>48</sup> offers three explanations: cultural, biologic, and bicultural. Predictions of exclusive breastfeeding duration were most accurate for women with a breastfeeding style of infrequent feedings and therefore early weaning, whereas predictions for women with a style of frequent feeding were confounded by cultural factors that independently affected supplementation.

Before reviewing specific psychological attributes relating to breastfeeding, the distinction between styles of nursing in Western societies should be considered. The Interagency Group for Action on Breastfeeding developed a schema for breastfeeding definitions. Newton and Newton,<sup>43</sup> however, have described two distinct styles—unrestricted

breastfeeding and token breastfeeding—that are important to understanding maternal choices.

## Unrestricted Breastfeeding

Unrestricted breastfeeding means the infant is put to the breast whenever he or she cries or fusses. Feeding is ad lib and not by the clock, usually leading to 10 or more feedings per day. The infant receives no bottles, and solids are not introduced until the second half of the first year. Breast milk continues to be a major source of nourishment beyond the first year of life. It is interesting that this was routine practice in the United States in the beginning of the twentieth century, as attested by writings on the subject of child rearing. The present recommendation of WHO and major professional organizations (i.e. American Academy of Pediatrics [AAP], American College of Obstetrics/Gynecology [ACOG], American Academy of Family Practice [AAFP]) is unrestricted exclusive breastfeeding for 6 months.

## Token Breastfeeding

Token breastfeeding means feeding characterized by rules and regulations. Both frequency and duration of feeding are determined by the clock. It is deemed unnecessary to permit unlimited suckling.

Weaning usually occurs by the third month, if not before. Supplementary bottles and solids are not uncommon. As a result, the let-down reflex is never well established. Engorgement may occur. An infant is frequently too frantic from crying or too sleepy to feed well at the appointed times.

New definitions of breastfeeding (i.e., exclusive, partial) have been published to standardize statistical comparisons (see Chapter 1) but do not reflect the psychosocial differences between unrestricted and token breastfeeding. The American Academy of Pediatrics Section on Breastfeeding recommends exclusive breastfeeding for 6 months and the gradual inclusion of solids (never before 4 months), preferably at 6 months or later.<sup>32</sup>

A University of Rochester study<sup>32</sup> of urban physicians revealed that those pediatricians who prescribed solids by 3 months or earlier also suggested supplementary bottles and had been in practice 20 years or longer. Most of the physicians in the family medicine program in the same community, however, provided no supplements and no solids until 6 months and had been in practice less than 20 years. More than 50% of mothers in that community who planned to breastfeed had made contact with some childbirth or breastfeeding program and chose their physician according to practice style.

Definition of breastfeeding in the United States has been undertaken by the Breastfeeding Promotion Consortium convened by the U.S. Department of Agriculture semiannually since 1990.<sup>19</sup> The report points out that many definitions (legal, programmatic [for WIC food allotments], surveillance, and monitoring) were used for policies and guidelines and for research. Descriptively, it includes initiation, duration, and intensity. The Breastfeeding Promotion Consortium is concerned about monitoring for surveillance purposes. The clinician needs to know frequency per day, length of a feeding, and the provision of any other liquids or foods.<sup>31</sup> The CDC has assumed the responsibility of monitoring breastfeeding trends annually.

## *Imprinting, Pacifiers, and Dummies*

Scores of infants are being introduced to pacifiers or dummies shortly after birth, all too often by an impatient perinatal staff member who knows a breastfed infant should not be bottle fed. Free pacifiers are being provided as gifts by some formula companies eager to beat the competition. The UNICEF/WHO's 10 steps to becoming a baby-friendly hospital (see Chapter 1) include the exclusion of pacifiers from the hospital's provisions. Do pacifiers have a long-range impact on infants? For bottle-fed infants, probably not, if possible dental problems are excluded; a pacifier will provide the sucking a bottle-fed infant may not receive during a feeding. For a breastfed infant, the answer may be different.

Human imprinting is little discussed in pediatric textbooks and rarely noted when discussing infant feeding, yet human infants, like any other mammalian newborns, recognize the mother by the oral, tactile, and olfactory modes. "The most sensitive organ and the one over which a newborn mammal has the most control, its mouth, is the organ central to mammalian and human imprinting," states Mobbs. It is thought that the imprinting process, or "stamping" as it was initially termed, takes place for a brief period early in postnatal development when an animal seeks a particular class of stimuli (i.e., objects of a particular shape). Having found such an object or one resembling it, the animal responds with an unlearned pattern of attachment behavior. The process is innate. Comfort sucking and formation of nipple preference are genetically determined behaviors for imprinting to the mother's nipple. The recognition of the mother is at first through the distinctive features of the nipple. Although imprinting is multisensory and varies from species to species, it is oral/tactile for humans and other higher mammals.

Mistakes and mishaps can occur in the process when a newborn fixes on a rubber nipple (bottle), thumb, or pacifier (Table 6-1). In birds,

**TABLE 6-1** Instinctive Fixation on Sucking Objects in the Process of Oral, Tactile, Mother Recognition

Objects of Fixation				
	Human Breast	Filled Nursing Bottle	Thumb/Finger/Knuckles	Empty Bottle/Pacifier (Dummy)/Cloth
Nutritive	Yes	Yes	No	No
Animate	Yes	No	Yes	No
Nonself	Yes	Yes	No	Yes
Infant control	No	No	Yes	No

From Mobbs EJG: Human imprinting and breastfeeding: are the textbooks deficient? In Llewellyn-Jones D, Abraham S, editors: *Proceedings: 16th annual congress*, Pokolbin, South Wales, March 1989, Australian Society for Psychosomatic Aspects of Reproductive Medicine.

innate responses are preferentially selective to supernormal-size stimuli. Nonnutritive sucking on thumbs or pacifiers is displacement activity that would normally be directed at imprinting to mother's nipple and reflects a tendency toward supernormal size. In other species with multiple births or litters, the offspring imprints to one teat throughout the lactation period. The one nipple preference sometimes reflects emotional attachment to the object rather than a preoccupation with a need for sucking. According to Passman and Halonen,<sup>46</sup> who found 42% of the interaction with the dummy to be nonsucking attachment, the preference for one nipple was maintained.

Mothers of thumb-sucking infants are less likely to breastfeed successfully, as was demonstrated in a study of 93 mother-infant pairs. Those who used a dummy or pacifier breastfed a shorter period (mean of 5.5 months compared with 7.5 months). Nonnutritive sucking on objects was added to the list of causes of lactation failure by Lilburne et al. after this study. Margaret Mead stated that in those societies where access to the breast is unlimited and frequent suckling is accepted, no thumb sucking occurs.<sup>49</sup>

A randomized prospective study of 750 mother-infant pairs was performed by Howard et al.<sup>23</sup> The pairs were randomly assigned to early pacifier at 2 weeks or no pacifier. A significant negative impact on duration of breastfeeding was seen in the group given a pacifier early.

Although the term "nipple confusion" has been questioned in the medical literature, strong psychosomatic evidence does show that human imprinting can be altered by introducing a foreign object during the process of imprinting.

## *Personality Differences Between Mothers Who Breastfeed and Mothers Who Bottle Feed*

Clear differences exist between mothers who practice unrestricted breastfeeding and those who bottle feed. Even some distinctions between women who do token breastfeeding and those who bottle feed have been noted. It has been said that maternal personality is more important than either breastfeeding or bottle-feeding per se to the development of the infant's personality.

Experimenters looking at these factors have provided a wealth of somewhat conflicting information. Chamberlain studied the differences between mothers who bottle fed and those who practiced unrestricted breastfeeding with their second child. The groups were similar in age, education, parity, intelligence, and socioeconomic status. The

mothers who breastfed were less defensive about their method of feeding, were more oriented toward home life, and had higher radicalism scores. The mothers who bottle fed confirmed the hypothesis that they had problems with trying to breastfeed their first child because of inadequate lactation, possibly a psychosomatic reaction. They also had a greater incidence of sexual performance problems, as indicated by a higher surgency score. A higher surgency score indicates increased gaiety, enthusiasm, effervescence, and impulsiveness and an increase in conversion reaction symptoms (hysteria) and sexual anomalies. The mothers who breastfed wanted their children to do things typical of children; the mothers who bottle fed preferred their children to be conservative and other-person oriented and urged them to be more adult. A study of stress and mood measured the differences between exclusive breastfeeders and formula feeders.<sup>18</sup> Breastfeeders have more positive moods and perceived less stress. Serum prolactin levels were inversely related to stress and mood. Higher serum cortisol, lower stress, and lower anxiety were seen in breastfeeders compared to formula feeders and controls (undergraduate and graduate nursing students). Breastfeeding appeared to be somewhat protective of negative moods and stress. Breastfeeding was associated with higher prolactin levels (Groer).

Call studied the emotional factors favoring successful breastfeeding and noted that of 104 consecutive mothers delivering at an Air Force hospital, 42.6% of the multiparas and 50% of the primiparas chose bottle-feeding. Of the mothers who breastfed, 48% of the multiparas and 40% of the primiparas were successful beyond 3 weeks. Failure was associated with engorgement, lack of let-down reflex, and psychological conflict. The two conflicts seen in those who did not nurse and those who failed were as follows:

1. They had a conflict in accepting the biologic maternal role in relation to the infant versus other roles society holds for women. The maternal role is considered a general class attitude in middle-class American society.
2. They had a conflict regarding the functioning of the breast itself, that is, as an organ for nourishment of the young versus a sexual organ, affording the breast the same psychological value as the penis in the male. Nursing thus became a "castration" threat.

## *Psychophysiologic Reactions During Nursing*

Newton and Newton<sup>43</sup> have equated psychophysiological reactions during nursing to the degree of

successful lactation. During unrestricted suckling, the gentle stroking of the nipple by undulating motion of the infant tongue occurs 3000 to 4000 times in a single feeding. This should result in an increase in temperature of the mammary skin and rhythmic contraction of the uterus. Failure to experience these signs in early lactation is associated with failure to produce adequate milk.

## Let-Down Reflex

When an unrestricted breastfed infant cries, the mother has the urge to suckle the infant because the cry has triggered her let-down reflex. The breast is turgescent and ready for the infant. Unrestricted crying is rarely seen in these infants. With token breastfeeding, such a response does not occur on schedule, and from feeding to feeding the milk supply may be little or, conversely, gushing. The infant is unable to cope with the unpredictability. Insufficient milk is rarely a problem when infants are carried and fed frequently.

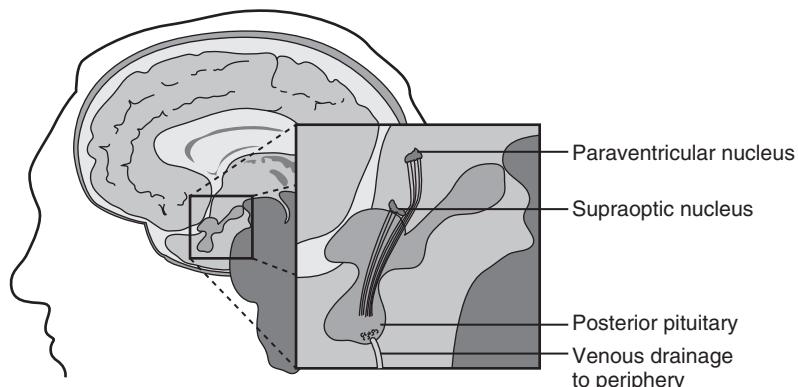

The role of various hormones in inducing maternal behaviors in animals has been extensively studied. Rosenblatt showed that both male and female rats, including virgin females, manifest maternal behavior after 5 to 7 days of contact with foster pups. Manipulation of estrogen, progesterone, and prolactin has demonstrated that estrogen is the most potent inducer of maternal behavior, progesterone usually is inhibitory, and prolactin strangely ineffective.

More recently, evidence indicates that prolactin does have a role in stimulating maternal behaviors in rats, but only when it is primed by placental lactogens that affect the maternal brain (medial

preoptic area) regarding maternal responses at birth. The brain of the maternally behaving rat is altered as a result of the dam's behavior toward her pups. Morphologic changes are seen in the supraoptic nucleus, which contains oxytocinergic neurons important for lactation. The supraoptic nuclei of lactating animals have a higher incidence of dendritic bundling compared with those of non-maternal virgin rats.<sup>39</sup> These experiments support the concept that maternal behavior in lactating animals can have a profound effect on the morphology and physiologic functioning of oxytocinergic neurons in the hypothalamus (Figure 6-4).

When oxytocin was administered intranasally to humans, it played a key role in social attachment thus increasing the benefits from social interactions. It specifically affects a person's willingness to accept social risks and causes a substantial increase in trust among humans. The mother-infant bond depends upon human trust. Studies using animals have confirmed the effects of oxytocin on the regulation of behavior. In pregnancy and postpartum, oxytocin affects bonding and parenting behaviors. The actions of oxytocin on the brain are regulated by gonadal steroid hormones, particularly estrogen. Studies comparing lactating and nonlactating postpartum women's behavior have assumed there were higher oxytocin levels in the lactating women. Results suggest<sup>39</sup> that breastfeeding within 1 hour of birth, when oxytocin levels are high, causes long lasting enhancement of bonding and interactive behavior between mother and infant.

Other studies have also found this when the oxytocin levels were not sampled during breastfeeding; oxytocin levels were thought to be related to bonding behaviors such as gaze, vocalizations, and affectionate touch.<sup>15</sup>

**Figure 6-4.** The source of oxytocin. Oxytocin is supplied to the posterior pituitary from neurons located in the paraventricular and supraoptic nuclei of the hypothalamus. It is then released from the pituitary into the circulation in response to appropriate stimuli. These same neurons, in addition to accessory oxytocinergic neurons located elsewhere in the brain, project broadly throughout the central nervous system. Receptors for oxytocin are discretely distributed in the brain and, in most mammalian species, are found in the hypothalamus and components of the limbic system. (Redrawn from McCarthy MM, Altemus M: Central nervous system actions of oxytocin and modulation of behavior in humans, *Mol Med Today* 3:269, 1997 (Figure 2).)

When levels were measured in 22 puerperal women, the suckling-induced oxytocin during nursing was pulsatile, with discrete, short pulses. When the women were subjected to the stress of loud noise (70 dB) by earphones or to the stress of performing mathematical problems, the frequency of pulsatile release of oxytocin was significantly lower. No difference was seen in prolactin levels or milk yield. These data suggest that psychological relaxation is necessary for a successful let-down response, confirming what Newton and Newton<sup>43</sup> had observed more than 50 years ago.

The induction of maternal behavior after administration of oxytocin experimentally in rats by Pedersen and Prange demonstrated that estrogen priming is necessary for the effect, but oxytocin may be the triggering hormone for maternal behaviors. A strong relationship between the peptide hormones native to the central nervous system and the reproductive hormones results not only in endocrine effects but also in behavioral effects.<sup>22</sup>

## ***Unrestricted Nursing***

---

The long-term psychophysiologic response to unrestricted nursing is a more even mood cycle than the mood swings associated with ovulation and menstruation. Unrestricted nursing is associated with secondary amenorrhea for as long as 16 months. In relating the rate of success in breastfeeding to experiences at birth, Jackson et al.<sup>25</sup> reported that the more difficult the labor, the less successful the breastfeeding. A direct correlation has also been made with the amount of medication and anesthetic given during labor and delivery and subsequently the sleepiness of the infant and, ultimately, the inadequacy of the suckling. Newton and Newton<sup>43</sup> observed that mothers who talked to their babies on the second day nursed their babies longer, that is, beyond the second month.

Modahl and Newton<sup>41</sup> measured mood state differences between mothers who breastfed and those who bottle fed when feeding and not feeding. They used the Curran and Cattell questionnaire, which measures transient mood states rather than personality traits. Bottle feeders showed significantly more anxiety, stress, depression, regression, fatigue, and guilt than breastfeeders. Mothers measured while bottle-feeding reported higher levels of these states and more extroversion than the control group of those who bottle fed tested in a nonfeeding situation. Members of another control group who were lactating but also gave bottles were measured while not feeding and showed less anxiety, stress, depression, regression, fatigue, and guilt than the average population. Measurements were taken at home with no examiner present.

The psychophysiologic responses of mothers who breastfeed and those who bottle feed to their infants' signals were measured by Wiesenfeld et al., using physiologic monitoring, while mothers observed previously prepared videotapes of their own infants while they smiled, were quiescent, and cried. Strikingly different response patterns characterized mothers who breastfed and those who bottle fed across all response measures. Mothers who breastfed were physiologically more relaxed but were more apt to want to interact with their child and expressed greater satisfaction with the feeding experience. The authors interpreted these patterns as suggesting a physiologic influence of breastfeeding rather than maternal personality factors influencing the choice of feeding mode.

When 60 primiparous mothers' maternal role adjustments were analyzed by measuring mother-infant mutuality and maternal anxiety scores, the infant-feeding method (breast, bottle, or both) was found to account for considerable variation by Virden. Women who breastfed had scores indicating less anxiety and more mutuality, a central factor in maternal adjustment, than women who bottle fed. The Maternal Attitude Scale was used. The findings are compatible with other studies showing breastfeeding to be emotionally gratifying and that breastfeeding stimulates a sense of emotional union between mother and infant.<sup>49</sup>

Oxytocin, known to be an important activator in the let-down reflex, has been shown to be important throughout the life cycle in both sexes. Oxytocin has been shown to enhance human trust (Kosfeld). Oxytocin has modulatory effects on neural functioning that are important in the regulation of behavior including parenting. The action of oxytocin in the brain is regulated by gonadal steroid hormones particularly estrogen.<sup>39</sup> Oxytocin has an essential role in prosocial approach behavior as well as other social behaviors. Oxytocin may well be essential in the difference between women who breastfed and those that do not.

## ***Impact of Society, Medical Profession, and Family***

---

### **SOCIETY**

Newton<sup>44</sup> has pointed out that a woman's joy in, and acceptance of, the female biologic role in life may be an important factor in her psychosexual behavior, which includes lactation. She found that women who wished to bottle feed also often believed that the male role was the more satisfying role. Nulliparous women who planned to breastfeed their children more often stated their satisfaction with the female role, according to Adams.<sup>2</sup>

Breastfeeding behavior has been related to a woman's role in life as influenced by her cultural locale, education, social class, and work. Breastfeeding rates and weaning times vary in the United States by geographic area. The smaller the community, the longer is the duration of breastfeeding. Cross-cultural studies in large cities show variation in rates of nursing. These rates are influenced by education, and in the current generation, the higher the education, the higher the incidence of breastfeeding.

## MEDICAL PROFESSION

An enthusiastic physician in the practice can influence the number of mothers who breastfeed; this has been demonstrated. If the physician provides knowledgeable medical and psychological support, the success rate of the patients who intended to breastfeed will increase. Some patients who had not formed an opinion or given it any thought in their preparation for motherhood will be persuaded to try. In addition, this physician will attract patients to the practice who are already successfully breastfeeding but find their own physician unable or unwilling to support their efforts.

A study was done at the University of Rochester in a small community where more than 50 pediatricians practiced.<sup>33</sup> The pediatricians described their own practices according to the number of mothers who breastfeed (high, 75%; moderate, 50%; low, 25%). They were also asked when the mothers started solid foods, general practice "regulations," and finally, how their own children were fed. The physicians with a high incidence of breastfeeding in their practices recommended starting solids after 4 months and had few rules and regulations about the practice, and usually their own children had been breastfed. Physicians with a high number of women who bottle fed recommended starting solids by 6 weeks and had many rules and regulations about the practice, and their own children had been bottle fed. When asked about using lay groups to help their patients breastfeed, female physicians were more apt than male physicians to discredit what these lay mothers could do to help other mothers.

A national survey conducted among a representative sample of obstetricians, pediatricians, and family physicians by mailed questionnaire reinforced the observation that a physician's attitude and personal beliefs about breastfeeding influence the advice given.<sup>46</sup> It further confirmed that not all physicians were informed about current knowledge on human lactation, not all physicians discussed lactation with their pregnant patients, and not all believed it was worth counseling time when problems arose. Despite national efforts to increase

physicians' knowledge base regarding breastfeeding,<sup>47</sup> there remains a residual cluster of physicians who do not support breastfeeding. The correlation to the feeding mode of their own children is clear. When trained in a program that supports breastfeeding, this trend is muted.

## THE FAMILY

### Impact on Infants

For infants, differences exist between breastfeeding and bottle-feeding in the alleviation of hunger, the mother-infant interaction, oral gratification, activity, development, personality, and adaptation to the environment. Often mother and baby are alone together during breastfeeding, and the mother gives her full attention to the baby with stroking and fondling. Social interaction with the baby is less frequent during bottle-feeding, and the mother is often in a distracting social situation or someone else feeds the infant. The breastfed infant has control of what is happening, or at least shares control, whereas the mother controls the bottle and the bouts of sucking.

In a study of newborns at 6 to 7 days of age, the effects of breastfeeding, giving breast milk by bottle, and just holding the infant were measured.<sup>37</sup> Results suggest that the total mother-infant interaction during breastfeeding has a positive influence on neonatal behavior. It induces a more stable state for an infant compared with that generated by giving the same human milk in a bottle and increases some sucking and holding times.

The attitudes of the husband, close family, and friends influence a mother's attitude toward breastfeeding. More important, these attitudes influence the rate of success and the age at weaning more negatively than positively. One study showed that a grandmother's interest did not influence the mother's decision to nurse as frequently as did a friend's (peer's) decision to bottle feed. A woman whose husband is not supportive of breastfeeding weans early or does not start at all.<sup>26</sup>

## DEVELOPMENT

Early assessment of newborns in the first and second weeks of life shows more body activity with breastfed than bottle-fed infants. They are more alert and have stronger arousal reaction. Statistics reported by Douglas on age of learning to walk in Great Britain showed a distinct difference, with breastfed infants starting 2 months earlier than bottle-fed infants. The longer the infant was nursed, the more striking the differences. Thus prolonged breastfeeding does not impede development as has been implied by advocates of early

weaning. A study in Illinois compared children exclusively breastfed for 4 months, 9 months, and more than a year with bottle-fed infants.<sup>21</sup> The children who were exclusively breastfed for 4 and 9 months scored significantly higher on achievement tests, but the difference was reversed beyond a year. Exclusive breastfeeding beyond a year increased morbidity as well, which is in keeping with the concept that solids should be added in the second half of the first year as promoted by WHO, the AAP, and others.

A cross-cultural study of 50 3-year-old children in Hawaii, reflecting the cultural diversity of the islands, provided periodic behavioral assessments as part of the heptachlor toxicity exposure study. The study, which used the McCarthy scales, showed that the duration of breastfeeding was correlated with general cognition, verbal and quantitative scores, and memory, regardless of socioeconomic status, sex, or pesticide exposure. No associations to motor skills at 3 years of age were seen in this study.<sup>4</sup>

An extensive study by Morrow-Tlucak et al. investigated differences between breastfed and bottle-fed infants. Batteries of infant assessment measures and maternal interviews were conducted by trained examiners blind to the risk factors during home visits when the infant was 6, 12, and 24 months of age. The 350 children were born to women at the Cleveland Metropolitan General Hospital who were part of a study of child development and psychosocial risk factors. The Bayley scales and the Home Observation Measurement of Environment were done. A significant difference among bottle-fed children, children breastfed 4 months or less, and those breastfed 4 months or more was found at all points, with extended breastfeeding showing a positive effect.

Animal research has also shown a relationship of weaning time to learning skills. Because it has become evident that species-specific proteins and amino acids exist, it is possible that the brain develops more physiologically with the precise basic nutrients. Comparisons with animal species show that the more intelligent and skillful groups within a species are nursed longer.

## PERSONALITY

The personality and adjustment of infants as related to their early feeding experiences has been the subject of much discussion. The personality of the mother and the temperament of the child need to be considered. Some conflicting information is reported in studies retrospectively analyzing the effects of breastfeeding on outcome in terms of security and behavior. The emphasis has been on

the duration of the breastfeeding rather than on the quality of the relationship.

In a prospective study of a birth cohort of New Zealand children followed to the age of 8 years, both maternal and teacher assessments of conduct disorder showed a statistically significant tendency for conduct disorder scores to decline with increasing duration of breastfeeding.<sup>16</sup> Overall, however, the authors suggest that no real evidence indicates that breastfeeding is protective against conduct disorders.

When abrupt weaning takes place, it may be psychologically traumatic for infant and mother. In animals, when the mother is stressed while lactating, the nursing's plasma cortisone levels are elevated. The psychologically depressed mother may not experience postpartum depression until the infant is weaned from the breast. It has been accepted that early experience, including feeding experience, does influence later behavior in the long run. The performance in young college women on an anxiety scale questionnaire Institute for Personality and Ability Testing (IPAT) and a personality inventory Eysenck Personality Inventory (EPI) showed that women who had been bottle fed had higher anxiety scores and greater neuroticism than women who had been breastfed, irrespective of duration of breastfeeding. Study continues to be done measuring the impact of nursing at the breast and the complexity of life's events.

## Impact on the Father

Since the birthing process moved into the hospital setting, fathers have been moved farther from the nucleus of the new family. In recent years, this trend has been reversed. Research on interaction with infants focused on the mother until Parke et al. observed all three together. In the triadic situation, a father tends to hold the baby twice as much and touches the baby slightly more but smiles significantly less than the mother. The father plays the more active role when both are present. The study was conducted with middle-class participants who had been to childbirth classes, but the same results were obtained among low-income families without preparation or the presence of the father in the labor and delivery room. The infant had to be relatively active and responsive to capture the father's attention. The investigators believed that fathers were far more involved in, and responsive toward, their infants than our culture had acknowledged. Other studies have shown that when fathers were asked to undress their babies and establish eye contact with them in the first few days of life, they showed more caregiving behavior 3 months later than did control subjects.

Newton and Newton<sup>43</sup> describe the early attachments of the new family as follows:

Father interacts with baby: Engrossment  
 Mother interacts with baby: Bonding  
 Baby interacts with mother: Attachment

Fathers have been brought back into the child-birth scene as coaches. The coach role has been described as the father's role in shared childbirth. The idea of coaching can have negative connotations because a coach is one who presses the players to work and try harder but always to win. Ideally, the father should be a partner and supporter in labor, delivery, and breastfeeding. Raphael<sup>49</sup> has suggested that the father may well play the role of a doula. A doula is one who provides psychological encouragement and physical assistance to the newly delivered mother. Raphael further indicates that the lack of a doula to support the mother predisposes her to failure with breastfeeding.<sup>49</sup>

The stress placed on sharing responsibilities of parenthood implies an across-the-board division of labor. This implies that parenting is equal for women and men. Fathers and mothers have complementary activities. Parents are not equally able to do all things. Nurturing an infant is more than just feeding. Therefore, the father should play a significant role with the infant. For instance, when an infant is fussy and does not need to be fed, comforting is often best done by the father; nonnutritive cuddling is best done by a father. "Nonnutritive Cuddler" is an important role for the father and equally as important in the balance of parenting roles.

According to Waletzky,<sup>58</sup> a father's most common negative reaction to breastfeeding is jealousy of the physical and emotional closeness of the nursing mother and child. The degree of jealousy may reflect how much and how happily the mother breastfeeds. Actually, fathers may express distress because they have no similar way to bring food and contentment to their baby. Male envy of female sex characteristics and reproductive capacity has been identified by Lerner<sup>34</sup> as "a widespread and conspicuously ignored dynamic." Improving the birth experience for fathers is a significant means of helping them feel closer to their babies and better about themselves as fathers, according to Waletzky.<sup>58</sup>

Fathers who object to their wives' breastfeeding may do so because they do not want to share this part of their lover with an infant. Some fathers express concern that the breast will leak and destroy any sexual mystique. On the other hand, many men take great pride in the knowledge that their infants will be breastfed and support their wives in this effort. The decision to breastfeed should be made with full involvement of the father.

## Impact on Siblings

Although some information is available about siblings and breastfeeding with regard to behavior patterns, no known studies compare siblings of bottle-fed and breastfed infants. Just as siblings frequently want to try the infant's bottle, they may want to nurse at the breast. The child will reflect the mother's attitude toward breasts and nursing. If the mother nurses secretly or in private and isolates herself from the family, it may cause concern in the sibling and produce feelings of shame or guilt toward breasts.

## Breastfeeding and Feminism

"Breastfeeding empowers women and contributes to gender equality [and therefore] is an important feminist, human rights and women's issue," states Van Esterik.<sup>57</sup> Despite Eyer's statement that the results of mother-infant research "will be shaped to address social and political agendas ... and women inspired by feminism helped to precipitate a reform movement that actively embraces bonding."<sup>14</sup> Van Esterik points out that writers on feminist theory almost always ignore the breasts and motherhood as well. Breastfeeding advocates have been criticized as wanting to tie women down.

Policy makers have consulted with women's groups before breastfeeding legislation was drafted, and new legislation has improved the work environment for nursing women and public opinion about the breastfeeding dyad. Progress has been made to make breastfeeding the medical and social norm. Breastfeeding is an emotional issue for many women, and strategies should be developed for framing the issue in nonjudgmental ways.

Possible negative effects, such as employers threatening to fire women rather than provide maternity entitlements, have been anticipated and dealt with. Breastfeeding campaigns have stressed the welfare of both mother and child.

## Intimacy and Breastfeeding

Breastfeeding is an intimate activity for some women, but most health professionals tend to present it in the context of the biopsychosocial model.<sup>12</sup> The closeness of the mother-infant dyad is a feminine image.

According to McAdams,<sup>38</sup> the definition of intimacy includes 10 characteristics in the exchange between people: joy and mutual delight, reciprocal dialog, openness, contact, union, receptivity, perceived harmony, concern for the other's well-being, surrender of manipulative control and the desire to master, and being in an encounter.

The theoretical definition for intimacy, states Timmerman,<sup>55</sup> is "a quality of a relationship in which the individuals must have reciprocal feelings of trust and emotional closeness toward each other and are able to openly communicate thoughts and feelings with each other. The conditions that must be met for intimacy to occur include reciprocity of trust, emotional closeness and self-disclosure."

Breastfeeding provides body contact with another and is the source of comfort, security, warmth, and nourishment for the infant and reciprocity for the mother. A mother's perception of breastfeeding as intimate describes her concept of the mother-infant relationship. The spouse's perception, however, may have the greatest effect on the success and duration of breastfeeding. Jordan and Wall<sup>26</sup> suggest that "supporting the father during breastfeeding may help improve the mother's satisfaction with breastfeeding, the duration of breastfeeding and adaptation of both parents to parenting."

## Abuse and Neglect

A 15-year prospective cohort study of 7223 Australian mother-infant dyads (full term) examined the incidence of child maltreatment including neglect, physical abuse, and emotional abuse. As substantiated by child protective reports, potential confounders included socioeconomic status, pregnancy "wantedness," substance abuse, employment, and anxiety and depression; 512 children (4.3%) had been maltreated (i.e., maternal abuse or neglect). As breastfeeding decreased, the risk for abuse increased. Non-breastfed children were 4.8 times more likely to be abused, and, when adjusted for confounding factors, the risk was still 2.6 times higher. Infants who were breastfed were nonneglected.<sup>54</sup>

When a woman has been abused, this may affect her ability to breastfeed and her fear of further abuse. Studies of women in Brazilian ghettos have correlated low rates of breastfeeding with experiences with abuse, especially spousal abuse.<sup>10</sup> Chin<sup>10</sup> also reported on a community-based participatory research project that emphasizes the life experiences and perspectives of its low-income population with respect to the cultural logic that forms infant-feeding choices.

## Psychosocial Risk Factors and Early Weaning

Support from clinicians and maternal depressive symptoms have been associated with breastfeeding duration.<sup>54</sup> In a prospective cohort study of

low-risk mothers enrolled at a health maintenance organization (HMO), the dyads were randomized to home visits or not. Of the original group of 1163, 1007 (87%) were breastfeeding at birth, 872 (75%) were breastfeeding at 2 weeks postpartum, and 646 (55%) were breastfeeding at the 12-week interview. Mothers who were breastfeeding at 12 weeks had received encouragement from their clinician. Breastfeeding discontinuation was associated with clinical depression and, for some, returning to work. The authors associated stress with depression and the discontinuance of breastfeeding.

Psychosocial well-being was also investigated by Li et al.<sup>35</sup> in relation to breastfeeding duration. Experience of stressful life events during pregnancy increased the odds for early cessation of breastfeeding independent of maternal sociodemographic parameters. They reported that separation, divorce, financial problems, and residential moves were important predictors for shorter duration of breastfeeding. Posttraumatic stress syndrome symptoms have been described by mothers in the national survey "New Mothers Speak Out." Using a 17-point scale to measure posttraumatic stress disorder, the survey identified 18% of mothers with some symptoms, and 9% appeared to meet all the criteria for the diagnosis. Black non-Hispanic mothers had the highest score (26%), compared with non-Hispanic whites (17%) and Hispanic mothers (14%) ( $p < 0.01$ ). The higher scores were associated with unplanned pregnancy, low education, and low income, but not traumatic birth.<sup>11</sup>

In this same survey mothers were also asked to answer the seven-question short version of the Postpartum Depression Screening Scale. The questions involved feelings in the 2 weeks before the survey. A score of 14 or higher was found in 63% of the women (i.e., two out of three) (Table 6-2); 5% of mothers reported suicidal thoughts, a troubling proportion. Among mothers who had cesarean delivery, 8 of 10 had pain in the first two months. Among women with a vaginal birth, almost half (48%) had perineal pain, with 15% complaining that it was a major problem, which usually involved an episiotomy. Pain associated with an episiotomy was more likely to interfere with activity.<sup>22</sup>

When this group of mothers who took the survey were asked to report words that came to mind about the first 2 months postpartum, *tired*, *messy*, *unsure*, and *isolated* were mentioned frequently. Only 19% of first-time mothers were confident (and only 23% of multiparas). Breastfeeding intentions were high before birth (61% planned to exclusively breastfeed and only 20% to feed formula). After birth 23% dropped breastfeeding if they had cesarean delivery, and 7% of mothers who delivered vaginally discontinued. All mothers commented

**TABLE 6-2** Mothers' Experience of Dimensions of Depression in 2 Weeks Before Survey\*

Base: All Mothers <i>n</i> =1573	Strongly Disagree (%)	Disagree (%)	Neither Agree nor Disagree (%)	Agree (%)	Strongly Agree (%)
Had shifting emotions	26	15	10	27	21
Experienced sleep disturbance	32	19	6	25	17

Available at [www.childbirthconnection.org/newmothersspeakout](http://www.childbirthconnection.org/newmothersspeakout) (Accessed 01.08.09.); LTMI = Listening to Mothers I.

on the hospital environment where free formula and pacifiers were distributed regardless of mother's wishes. They also noted a lack of support for breastfeeding and that it was too difficult to get breastfeeding established; 14% tried breastfeeding and did not like it. Success at breastfeeding and at breastfeeding for as long as a mother had planned appeared to be clearly related to having a partner and education and somewhat to income.<sup>22</sup>

The most poignant commentaries were those volunteered by mothers indicating that childbirth can be scary, disruptive, and exhausting. Other thoughts included that the mothers felt they were not in control even when they had carefully planned ahead.<sup>11</sup>

When Borra et al.<sup>6</sup> examined whether breastfeeding influenced the risks of postnatal depression, they found the beneficial effects were strongest at 8 weeks postpartum and weaker after 8 months. For mothers who had no symptoms before birth, the risk of postpartum depression was greatest among women who had not intended to breastfeed. The effect of breastfeeding on maternal depression was highly heterogeneous and very dependent upon intentions during pregnancy. Mothers not depressed during pregnancy that planned to breastfeed and did had the lowest risk of depression. Those that planned to breastfeed but were unable to for various reasons were at an increased risk. They also found that providing specialized support to new mothers who were unable to breastfeed was essential to diminishing the risk of depression postpartum.<sup>6</sup>

some women do not breastfeed. It cannot be blamed on society or the medical profession when a woman cannot accept this as part of the biologic role of a mother. A physician who does not understand the complexities of rejecting breastfeeding cannot hope to assist a mother to succeed in breastfeeding.

Exploring the question of whether body satisfaction and maternal attachment affect breastfeeding, 38 women at approximately 35 weeks' gestation were given the maternal-fetal attachment scale, the eating disorders examination, and the body satisfaction scale; 30 women who intended to breastfeed were more satisfied with their gravid shape and had higher levels of maternal-fetal attachment. The mother's age and body mass index did not differ between those who breastfed and those who bottle fed. Mothers with high-body dissatisfaction did not breastfeed. Not surprisingly, five mothers with a history of bulimia had difficulty breastfeeding, and three thought it was distasteful and adversely affected their appearance.<sup>52</sup> In a report of six women with bulimia nervosa who had bilateral reduction mammoplasty, the surgeons report that postoperatively the women were relieved of their physical symptoms and had improvement in their psychological well-being.<sup>53</sup> Previously, women with eating disorders had been disqualified for plastic surgery. Macromastia can cause a distortion of the body image and in such cases can be the root cause of the bulimia.<sup>36</sup>

Our society has assumed that no valid intellectual stimulation can occur in the company of young children. Mothers are made to feel intellectually stagnant and uncreative while breastfeeding. Indeed, they are also made to feel asexual at the peak of their sexual cycle. In response, new mothers struggle in panic to maintain their social and professional ties. They feel they must produce tangible works to be productive. Bloom poignantly points

## Why Some Women Do Not Breastfeed

Before the trend toward bottle-feeding can be permanently reversed, one has to understand why

out that one of the greatest intellectual voyages of our time was undertaken when Jean Piaget sat at his son's crib and observed the child's successive attempts to grasp a rattle. A nursing mother learns about her child through many internal, subjective, and kinesthetic modes that were not open to Piaget. When a mother wrote of her observations in this setting, her writing was ignored as unscientific and trivial.

Bentovim<sup>5</sup> has taken a systems approach to successful breastfeeding, pointing out that a range of physical, psychological, and sociologic factors are involved. "Breastfeeding is a systemic product of many interacting factors rather than a product of individual behavior only,"<sup>5</sup> according to Bentovim. A good experience with breastfeeding can ensure an intense interaction and synchronous response of giving and taking. According to Brazelton,<sup>8</sup> this is the essence of the infant's beginning to create a secure world for the self.

Beliefs and attitudes toward breastfeeding influence the choice and the success of breastfeeding. Bentovim<sup>5</sup> points out that it may be possible to restore breastfeeding as the natural choice. Society has begun to accept breasts not only as good for the infant and development, but also as the object of less ambivalent and secret pleasure. The role of the health professional in this area is important. Hendrickse<sup>20</sup> states that the biggest block in the minds of women relates to feelings of shame associated with breastfeeding. More than half the women in the Newcastle survey were prevented from choosing breastfeeding because of a sense of shame. The shame is a result of relating the breast to concepts of sexuality.

## *Failure at Breastfeeding: Grief, Shame, Guilt, or Anger*

When a mother who had planned to breastfeed is unable because of illness in herself or her baby, or when a mother begins to breastfeed and must stop, a grief reaction often occurs. A mother experiences a great loss. Prolonged mourning and depression may occur. Some women report feeling more distant from this child than from her other children if the others had been successfully breastfed. The stronger the commitment had been to breastfeed, the stronger is the grief reaction. Few mothers found help, according to Righard in this study, from either professionals or lay support groups. Professionals failed to understand the feeling of failure or loss. The support groups tended to magnify the guilt and sense of failure.

The emotions are complex surrounding this intimate activity. Physicians who must recommend discontinuing breastfeeding for medical reasons should be aware of the impact and provide for

appropriate support for mothers. A woman's choice of feeding method does not make her a good or bad mother, and her inability to produce adequate milk for her infant does not make her a bad mother. Lactation failure is often a reflection on the system and the culture rather than the person.

A random sampling of educated middle-class women in a university neighborhood revealed that a number of women had difficulty breastfeeding. The study did not describe methodology or how it was randomized, but the report reflected much shame, guilt, and finally anger. Failure of breastfeeding by a woman or her friends can be a powerful influence against deciding to breastfeed a future child.

Fear, shame, and guilt were regarded by Freud as different forms of anxiety. Objective anxiety is fear (fear of failure) and arises from external dangers; social anxiety is shame resulting from the criticisms of others; and conscience anxiety is guilt. Real external dangers produce normal anxiety, but when one overreacts, this is neurotic anxiety. Defenses against guilt feelings include repression, rationalization, and projection. Any guilt can be borne more easily if someone else has had a similar experience. Thus knowing other women have failed to breastfeed successfully relieves guilt.

Lasting anger after lactation failure has become more visible. The woman who writes an angry tirade against breastfeeding in a letter-to-the-editor after a news story supporting breastfeeding deserves understanding and support. She is likely a victim of poor medical management and inadequate social support to breastfeed. Letter writing can be therapeutic, but it is never a cure for the underlying hurt.

In our clinical experience, well-educated women who have difficulty producing enough milk or who have an infant who fails to thrive are driven to find out why. The Lactation Study Center has received many calls from women who may even have had trouble feeding one or more other infants and wants to be "tested" to find the cause. Testing resources are limited and reveal little more than can be identified with a good history of breast response in pregnancy and postpartum. The mother's need usually involves a desire to know that the situation is out of her control. The best management beyond ruling out simple remediable causes (positioning, timing, or reduction of fatigue) may be the therapy of a good listener and the reassurance that one is still a good mother.<sup>54</sup> Confirming that the prolactin levels are low can be a great source of comfort for the mother that it was not her fault (*Table 6-3*).

## **Avoiding Guilt as a Reason Not to Promote Breastfeeding**

In many interactions physicians, especially obstetricians, are encouraged to provide enough information about breastfeeding to a woman prenatally to allow

**TABLE 6-3**

Reasons for Breastfeeding Discontinuation Vary by Weeks

Main Reason for Discontinuation	Week of Breastfeeding Discontinuation				
	0-1 (n = 105) (%)	2-3 (n = 74)* (%)	4-6 (n = 112) (%)	7-9 (n = 53) (%)	10-12 (n = 19) (%)†
Infant still hungry/not enough milk	27	18	38	28	11
Problems sucking/latching on	23	12	1	1	5
Breast pain/soreness	14	14	4	0	0
Mother returned to work or school	4	14	29	34	58
Mother sick or on medication	2	12	6	11	11
Bottle-feeding easier or more convenient	8	9	7	13	0
Lack of energy/desire to discontinue	4	8	7	2	4
Other‡	18	13	8	11	11

\*Mothers were asked, during the 2- and 12-week interviews, to report when they discontinued and the reason for breastfeeding discontinuation. Of the 135 women who discontinued breastfeeding at 2 weeks, 132 (98%) women responded to this question.

†Of the 321 additional women who discontinued breastfeeding after 2 weeks, 231 (72%) responded to this question.

‡Other reported reasons for discontinuation included infant not gaining weight or sick, breast milk intolerance, and infant spitting up.

From Taveras EM, Capra AM, Braverman PA, et al: Clinical support and psychosocial risk factors associated with breastfeeding discontinuation, *Pediatrics* 112:108–115, 2003.

her to make an informed choice. The response often is, "No, I don't want to make a mother feel guilty, so I say nothing."

No studies in the literature support this position. In the dozens of reports on efforts to increase breastfeeding among many cultures, no report on producing guilt feelings is available. Women interviewed with open-ended questionnaires have not mentioned guilt feelings in response to the questioning. The only individuals who ever mention guilt are those in the older generation whose daughters are now choosing breastfeeding. The grandmother feels guilty because no one ever told her; no one ever encouraged her to breastfeed; "If only she had known ... if only her doctor had told her..." In the interest of good health, physicians counsel their patients about good nutrition, weight gain, smoking, drinking, and a number of detrimental personal behaviors without any concern for the guilt they might produce because of the importance of the issue. The feeding choice has an equally important impact for both mother and infant.

In a study at the University of Rochester prenatal clinic, women were randomly assigned to the group attending the Best Start program to encourage breastfeeding or to the control group spending the same time in "counseling" about pregnancy and delivery but nothing about breastfeeding.<sup>33</sup> After delivery, interviewed mothers in both groups were comfortable about their own infant-feeding decision. Those who received breastfeeding encouragement and chose to bottle feed said it was right for them and denied any guilt feelings.

## Summary

Decades of research have shown that the breast plays an important role in the growth, development, identity, and psychological well-being of women. Not all women have the same level of comfort with their breasts or see them in the same way with respect to their primary purpose, nourishment of the newborn offspring. The infant, on the other hand, when given the opportunity, will find the breast, seek out and latch on, and suckle. Infants at birth are programmed to breastfeed. Their innate reflexes of rooting and suckling are designed for breastfeeding. Infants also can be taught other mechanisms for feeding. The intricacies of how women choose infant-feeding methods remain to be identified. This choice is influenced by culture, community, personal experiences, education, and the opinions of those close to the mother. The greatest external influence is the primary health care provider, the obstetrician or midwife.

Physicians can make a difference. Women indicate that they rely heavily on the messages they hear from their physicians. The issue of guilt is no more important in choosing to breastfeed than it is in choosing to smoke, drink, abuse drugs, or give in to problems of overeating. The physician's role in the latter situations has always been clear: take a firm stand and provide guidelines for the patient. In addition to providing information and support regarding infant-feeding choices, the physician is in a critical position to facilitate breastfeeding

in its early hours and to be supportive and constructive in ensuring its success with appropriate monitoring of progress, not only in the hospital but in the first weeks and months of the infant's life. Midwives do this intuitively.

The impact of breastfeeding on the mother herself is more difficult to identify. Mothers who breastfeed are not different at the onset but do change in their relationship with their infant. Breastfeeding does have an impact psychologically on both mother and infant.

## CHAPTER 7

# *Benefits of Breastfeeding for Infants/Making an Informed Decision*

Breastfeeding is not a matter of choice, it is a public health matter, strongly stated the section on Breastfeeding of the American Academy of Pediatrics in its policy statement in 2012. The American College of Obstetrics and Gynecology (ACOG) has also signed on to this statement as has the American Academy of Family Practice (AAFP). "The discussion is over, human milk is for human infants" proclaimed Myers at the twenty-fifth Surgeon General's Workshop in 2009. The evidence is overwhelming. The Old Testament states firmly that women should breastfeed their children. The Koran also indisputably commanded mothers to breastfeed their infants until they were 2 years old. Christians had been conspicuously silent until 1995 when Pope John Paul II spoke out and proclaimed that the women of the world should breastfeed their children.

So why are we still discussing it? The evidence of the value of breastfeeding for both mother and child continues to mount. Along with the dozens of studies confirming what we already knew, there have been published challenging papers where the evidence is carefully culled to present a different picture. Studies analyzing the benefits have compared the "ever breastfed" to the formula-fed child. Ever breastfed includes any infant who went to breast only once. The most challenging problem is setting up a controlled study randomly assigning women to breastfeed or including controls that were not to breastfeed; such a study is neither ethical nor possible. Formula feeding has been called the largest experiment in life with no science to

prove it is safe or efficacious. Formula is a necessary commodity only because not all women can or will breastfeed.

The evidence of the benefits of breastfeeding presented here is selected from the best of medical research. There has never been a study done that proves formula is better nor, in fact, even equal. Formula is adequate when human milk is not available.

## *Compelling Reasons to Breastfeed*

### **SPECIES SPECIFICITY**

Species specificity encompasses all the benefits of being breastfed for human infants because breast milk is more than just good nutrition. Human breast milk is specific for the needs of human infants, just as the milk of thousands of other mammalian species is specifically designed for their offspring. For optimal growth of brain and body, as well as protection against infection and development of immunity, human milk is specifically designed for all the needs of human infants.

### **NUTRITIONAL BENEFITS**

Many benefits of breastfeeding are related to how children eat rather than what they eat as they get older. Breastfeeding eating is different from bottle-feeding, which depends on the maternal feeding style and her control of the process. The more frequently the infant bottle feeds (regardless of bottle

content) the more likely the mother focuses on giving the infant enough. Mother encourages finishing every drop. This continues with later feeding habits to clean the plate and take more. This behavior is often the basic problem with obesity. In breastfeeding, the infant takes what he wants, no more. Feeding at the breast is a satisfying experience so that additional suckling is rarely needed.

The unique composition of breast milk provides the ideal nutrients for human brain growth, especially in the first year of life. Cholesterol, docosahexaenoic acid (DHA), and taurine are particularly important. Cholesterol is part of the fat globule membrane and is present in approximately equal amounts in both cow milk and breast milk. Maternal dietary intake of cholesterol has no impact on breast milk's cholesterol content. Formula naturally lacks human DHA and taurine. The cholesterol in cow milk, however, has been removed in infant formulas, which are cholesterol-free. These elements—cholesterol, DHA, and taurine—are readily available from breast milk and are essential nutrients for human infants, especially for growth of the brain. Regardless of what additives are manufactured and added to bovine formula, they all have their origin from some other species and have been chemically extracted and subjected to extensive heat.

The maximum bioavailability of essential nutrients, including micro minerals, means that digestion and absorption are highly efficient. Comparison of the biochemical percentages of constituents of breast milk and infant formula fails to reflect the highly efficient bioavailability and utilization of constituents in breast milk compared with modified cow milk, from which only a small fraction of some nutrients is absorbed.

Nourishment with breast milk is a combination event, in which nutrient-to-nutrient interaction is significant. The process of mixing isolated single nutrients in formula does not guarantee the nutrient or nonnutrient benefits that result from breastfeeding. The composition of human milk is a delicate balance of macronutrients and micronutrients, each in the proper proportion to enhance absorption. Ligands bind to some micronutrients to enhance their absorption. Enzymes also contribute to the digestion and absorption of all nutrients. All enzymes and hormones have been destroyed by processing in infant formulas.

An excellent example of balance is the action of lactoferrin, which binds iron to make it unavailable for *Escherichia coli*, which depends on iron for growth. When the iron is bound, *E. coli* cannot flourish and the normal flora of the newborn gut, *Lactobacillus bifidus* (*Bifidobacterium bifidum*), can thrive. In addition, the small amount of iron in human milk is almost totally absorbed, whereas only about 10%

of the iron in formula is absorbed by the infant. Nutrients such as proteins are examples of constituents in human milk with multiple functions, which include preventing infection and inflammation, promoting growth, transporting micro minerals, catalyzing reactions, and synthesizing nutrients.<sup>93</sup>

## IMPACT ON CARDIOVASCULAR HEALTH

A study asking the question of whether perinatal supplementation of long-chain polyunsaturated fatty acids prevents hypertension in later life concluded that long-chain polyunsaturated fatty acids depended upon other nutrients as well. Thus it was concluded that breastfeeding the infant can protect against insulin resistance and hypertension in later life.<sup>18</sup> A meta-analysis by Martin et al.<sup>58</sup> involving 15 studies and 17,503 subjects revealed that a small reduction in diastolic blood pressure was associated with breastfeeding, which confers long-term benefits on cardiovascular health. Another study by Martin et al.<sup>59</sup> reported a reduced risk for atherosclerosis by breastfeeding as recorded in the 65-year follow-up of the Boyd Orr Cohort. The Boyd Orr Cohort is an historical cohort based on the Carnegie Survey diet and health in prewar Britain 1937 to 1939. This cohort involves 4999 participants of 1343 families in 16 centers in England and Scotland who participated in a 1-week diet survey when 0 to 19 years old between 1937 and 1939. The trace rate was 88 when they were sent follow-up surveys. In 2002, 2563 of the original cohort were alive and living in Britain. Controlling for numerous variables, socioeconomic status, smoking, and alcohol made little difference.<sup>57</sup> A prospective cohort study of 2512 men between 45 and 59 years of age were studied according to their infant feeding history. There was a positive association between breastfeeding and coronary heart disease mortality and incidence. There was no evidence of a duration-response effect. Breastfeeding was not associated with stature, blood pressure, insulin resistance, total cholesterol (TC), or fibrinogen. These data, however, only compared ever breastfed and bottle fed. Small studies of exclusively breastfed infants have shown breastfeeding impacts blood pressure. Large studies use all subjects if ever breastfed and the significance is muted. Studies of TC and low-density lipoprotein (LDL) cholesterol showed that levels were higher in infants while consuming breast milk which contains cholesterol. (Formula contains no cholesterol.) Levels in adult life are lower in breastfed infants suggesting that breastfeeding has long-term benefits for cardiovascular health.<sup>74</sup> Adult glucose tolerance tests showed lower 120 minute glucose levels in individuals who had been breastfed.<sup>79</sup>

In this same Boyd Orr Cohort, Martin et al.<sup>59</sup> studied the impact of breastfeeding and social mobility after 60 years. Prevalence of breastfeeding varied from 45% to 86% by district but not with household income, number of siblings, birth order, or social class in childhood. Breastfeeding was associated with upward social mobility; the longer the duration, the greater the probability, an effect that was not explained by other factors. Childhood obesity and infant feeding has also been evaluated by systematic review of published studies on Medline since 1966.<sup>74,35,36</sup> In 28 studies involving 298,900 subjects providing odds ratios, breastfeeding was associated with a reduced risk for obesity compared to formula-fed infants. Even in six studies adjusted for parental obesity, maternal smoking, and social class the effect was reduced but present.

For decades, growth in infancy had been measured according to data collected on infants who were exclusively formula fed, until the publication of data in the 1990s on the growth curves of infants who were exclusively breastfed.<sup>25</sup> The physiologic growth curves of breastfed infants show a pattern similar to that of formula-fed infants at the 50th percentile, with significantly fewer breastfed infants in the 90th percentile. This is most evident in the examination of the Z-scores, which indicate that formula-fed infants are heavier compared with breastfed infants, meaning that more are obese.<sup>25,24</sup> The World Health Organization (WHO) constructed an international study involving seven countries, rich and poor, to record how children should grow.<sup>101</sup> All participants were exclusively breastfed and had good health. The growth curves from these observations are available worldwide and should replace old curves that demonstrate how children grow, the tall and the short, the fat and the thin, the sick and well. These old curves which included all children are mathematical averages of the good and bad. These growth issues are discussed more completely in Chapter 11.

A study of adolescents, assessing body composition including height, weight, skinfolds, and waist circumferences, showed an effect of being breastfed if "never breastfed" was compared to breastfed over 4 months in a European multicentered study. Breastfeeding for at least 1 year or more had a profound effect on the development of obesity in Hispanic toddlers. Breastfeeding in this group was associated with a reduced intake of sugar-sweetened beverages.<sup>20,83</sup>

## INFECTION PROTECTION

Leukocytes, specific antibodies, and other antimicrobial factors protect breastfed infants against many common infections. Protection against

gastrointestinal infections is well documented.<sup>36</sup> Protection against infections of the upper and lower respiratory system and the urinary tract is less recognized but equally well documented. These infections lead to more emergency room visits, hospitalizations, treatments with antibiotics, and health care costs for the infant who is not breastfed.<sup>2</sup>

The incidence of acute lower respiratory infections in infants has been evaluated in a number of studies examining the relationship between respiratory infections and breastfeeding or formula feeding in these infants.<sup>77</sup> These studies confirm that breastfed infants are less likely to be hospitalized for respiratory infection and, if hospitalized, are less seriously ill.<sup>11</sup> In a study of infant deaths from infectious disease in Brazil, the risk for death from diarrhea was 14 times more frequent in formula-fed infants, and the risk for death from respiratory illness was 4 times more frequent.

According to the report from the Agency for Health Research Quality (AHRQ) in 2007,<sup>36</sup> breastfeeding for 4 or more months is associated with a reduction in the risk for hospitalization secondary to lower respiratory tract disease.

The association of wheezing and allergy with infant feeding patterns has also shown a significant advantage to breastfeeding. In a report from a 7-year prospective study in South Wales, the advantage of breastfeeding persisted to age 7 years in nonatopic infants, and in at-risk infants who were breastfed the risk for wheezing was 50% lower (after accounting for employment status, passive smoking, and overcrowding).<sup>10</sup> Breastfeeding is thought to confer long-term protection against respiratory infection as well.

Upper and lower respiratory tract infections have been evaluated in case-control studies, cohort-based studies, and mortality studies in both clinic attended and hospitalized children in many countries of the developed world.<sup>20,15,52</sup> The results show clearly that breastfeeding has a protective effect, especially in the first 6 months of life. Acute respiratory infections (ARIs) were studied by Vereen et al. because they are a major cause of infant morbidity. Ever breastfed were compared with never breastfed in a cross-sectional analysis of viral severity in 629 mother-infant dyads. When the infant had ARI, breastfeeding was associated with a decreased risk of having lower versus upper respiratory tract infection. A randomized, controlled trial indicated that withholding cow milk and giving soy milk provided no such protective effect.<sup>12</sup> The incidence of acute otitis media in formula-fed infants is dramatically higher than in breastfed infants,<sup>1,3</sup> not only because of the protective constituents of human milk but also because of the process of suckling at the breast, which protects the inner ear. When an infant

feeds by bottle, the eustachian tube does not close, and formula and secretions are regurgitated in the tubes. Child care exposure increases the risk for otitis media, and bottle-feeding amplifies this risk.<sup>15,52</sup> The longer the breastfeeding, the more prolonged the protection.<sup>36</sup>

## IMMUNOLOGIC PROTECTION

In addition to the protection provided by breastfeeding against acute infections, epidemiologic studies have revealed a reduced incidence of childhood lymphoma,<sup>21</sup> both acute lymphocytic and acute myelogenous leukemia,<sup>36,5,48</sup> and type 1 insulin-dependent diabetes,<sup>96</sup> as well as type 2 diabetes and Crohn disease,<sup>45</sup> in infants who have been exclusively breastfed for at least 4 months, compared with formula-fed infants. In a systematic review and meta-analysis of breastfeeding and childhood cancer published in 49 references between 1966 and 2004, the authors report lower risks such as decreased incidence of acute lymphoblastic leukemia, Hodgkin's disease, and neuroblastoma. These findings were based on "ever breastfed," not inclusive breastfeeding for 6 months.<sup>60</sup> Within this cohort, a meta-analysis by Kwan et al.<sup>49</sup> strongly supported the impact of breastfeeding on limiting the risk of childhood leukemia. It demonstrated that longer breastfeeding reduced the risk.

## ALLERGY PROPHYLAXIS

Breastfed infants at high risk for developing allergic symptoms such as eczema and asthma by 2 years of age show a reduced incidence and severity of symptoms in early life.<sup>10</sup> Some studies suggest the protective effect continues through childhood.<sup>9,43</sup> A significant reduction in risk for childhood asthma at age 6 years was reported by Oddy et al.<sup>72</sup> if exclusive breastfeeding is continued for at least 4 months. Available evidence regarding full-term infants in developed countries suggests that exclusive breastfeeding for at least 3 months is associated with a reduced risk for atopic dermatitis in children with a family history of atopy.<sup>30</sup>

Prolonged breastfeeding may improve subsequent lung function at 10 years old. Forced vital capacity, forced expiratory volume, and peak expiratory flow were measured in 1456 children who were part of the Isle of Wight Study; 196 were not breastfed, 243 were breastfed less than 2 months, 142 were breastfed more than 2 months but less than 4 months, and 374 were breastfed at least 4 months. Lung volume was enhanced in the breastfed children. The authors<sup>4</sup> speculate that the effect on airflow was mediated by lung volume changes, which could be the result of prolonged

suckling at the breast, providing a mechanical stimulus to improve the mechanics of ventilation.<sup>4</sup>

## PSYCHOLOGICAL AND COGNITIVE BENEFITS

The prevailing impression from large epidemiological studies is that being breastfed results in higher cognitive function and higher performance intellectually. Does breastfeeding alter early brain development? Morphometric brain imaging has supported this premise.<sup>23</sup> Increased white matter and subcortical gray matter volume and parietal lobe cortical thickness have been observed. When quiet magnetic resonance imaging (MRI) scans were used to compare measurements of white matter microstructure in 133 healthy children aged 10 months through 4 years who were exclusively breastfed a minimum of 3 months with those formula fed or fed a mixture, the breastfed children had increased white matter in frontal and associated brain regions. Other regions were anatomically consistent with improvements in cognitive and behavior performance measures. The developmental advantages associated with breastfeeding are supported by the hypothesis that breastfeeding promotes healthy neural growth and white matter development, according to investigators.<sup>23</sup>

Nielsen and O'Hara<sup>71</sup> noted that children who had been breastfed were more mature, secure, and assertive, and they progressed farther on the developmental scale than nonbreastfed children. More recently, studies by Lucas et al.<sup>56</sup> and other investigators<sup>38</sup> found that premature infants who received breast milk provided by tube feeding were more advanced developmentally at 18 months and at 7 to 8 years of age than those of comparable gestational age and birth weight children who had received formula by tube. Such observations suggest that breast milk has a significant impact on the growth of the central nervous system. This suggestion is further supported by studies of visual activity in premature infants who were fed breast milk compared with those who were fed infant formula. When similar studies were performed in full-term infants, visual acuity developed more rapidly in the breastfed infants.<sup>40</sup> Even when DHA was added to formula, the performance by breastfed infants was still better.<sup>39</sup>

An 18-year longitudinal study reported by Horwood and Fergusson<sup>33</sup> demonstrates a small but detectable increase in childhood cognitive and educational achievement in infants who were breastfed. The effects were confirmed in a range of measures, including standardized tests, teacher ratings, and academic outcomes in high school

and young adulthood. More than 1000 children in New Zealand participated. Children who were breastfed for 8 months or longer had a mean test score at age 18 that was 0.11 to 0.30 standard deviation units higher than those not breastfed.

To examine the association between duration of infant breastfeeding and intelligence in young adult life, Mortensen et al.<sup>68</sup> conducted a prospective longitudinal cohort study of more than 3000 individuals in Denmark born between 1959 and 1961. They concluded that, independent of a wide range of possible confounding factors, a significant positive association between duration of breastfeeding and intelligence test results existed, using two separate intelligence tests.

In an effort to examine the minimum duration of exclusive breastfeeding for optimal neurologic outcome, Bouwstra et al.<sup>6</sup> assessed the quality of general movements at 3 months of 147 breastfeeding, healthy term infants. General movement quality is considered a sensitive marker of neurologic status according to the authors. They demonstrated a positive effect between breastfeeding duration and general movement quality with a saturation effect at about 6 weeks. They concluded that exclusive breastfeeding for at least 6 weeks might improve neurologic outcome.

## Evidence-Based Systematic Reviews

In 2007, two careful, comprehensive assessments of the value of human milk and breastfeeding were published: one from the AHRQ,<sup>36</sup> the other from the Department of Child and Adolescent Health and Development of WHO. The AHRQ reviewed the evidence on the effects of short- and long-term breastfeeding on infants and maternal health outcomes in developed countries. More than 9000 abstracts were screened and 400 individual studies reviewed. The data supported a long list of advantages (Tables 7-1 and 7-2) but did not support the increase in cognitive performance. The relationship between breastfeeding and cardiovascular disease was unclear. Maternal risk reduction is noted in Table 7-3, and only weight loss and osteoporosis reduction was unclear from the studies. The authors did comment that breastfeeding did not mean exclusive breastfeeding.<sup>36</sup> The Irish Nursing Homes Organization (INHO) analysis also reflected a lack of clarity in terms of impact on intellectual performance, cardiovascular disease, and obesity.<sup>61</sup> When the analysis was complete, however, they were able to confirm that long-term subjects who were breastfeeding experienced lower mean blood pressure and TC and higher performance on intelligence tests. The prevalence of overweight and obesity and type 2 diabetes was lower among breastfeeding infants. Although all

**TABLE 7-1** Advantages of Breastfeeding as Determined by AHRQ

Full-Term Infant Outcomes	Reduction in Relative Risk
Acute otitis media	50% reduction
Atopic dermatitis	Equivocal
Gastrointestinal infections	64% reduction
Lower respiratory tract disease	72% reduction
Asthma	27% reduction
Cognitive development	Equivocal because of confounding factors
Obesity	24%, 7%, 4% for each month of breastfeeding
Risk for cardiovascular disease	Blood pressure: up to 1.5 monthly reduction; LDL cholesterol: 7.0–7.7 mg/dL reduction; all-cause CV mortality: needs further investigation
Type 2 diabetes	39% reduction (confounders not well controlled)
Childhood leukemias	19% reduction (all); 15% (AML)
SIDS	36% reduction

AHRQ, Agency for Health Research Quality; *AML*, acute myelogenous leukemia; *CV*, cardiovascular; *LDL*, low-density lipoprotein; *SIDS*, sudden infant death syndrome.

Summarized from AHRQ report no. 153<sup>35,36</sup>.

**TABLE 7-2** Maternal Advantages of Breastfeeding as Determined by AHRQ

Mother Outcomes	Reduction in Relative Risk
Return to prepregnancy weight	Unclear
Maternal type 2 diabetes	2%-12%
Osteoporosis	Unclear
Postpartum depression	Too few studies
Breast cancer	28% for 12 or more months (4.3% for each year of breastfeeding)
Ovarian cancer	21%

Intensity and duration of breastfeeding were not defined in most studies, thus diluting the magnitude of the effects.<sup>44</sup>

AHRQ, Agency for Health Research Quality.

were statistically significant some differences were modest. The definition of breastfeeding, exclusive or partial, and length of breastfeeding remain significant factors in measuring outcome.

Since these two meta-analyses were performed, several new studies have been published that further support advancement in intellectual skills.<sup>51</sup>

TABLE 7-3 Reduction of Risk for Disease		
Infant	Risk for acute otitis media	No evidence
	Nonspecific gastroenteritis	Cognitive performance
	Severe lower respiratory tract infection	Cardiovascular disease
	Atopic dermatitis	Infant mortality is developed
	Asthma	
	Obesity	
	Type 1 and 2 diabetes	
	Childhood leukemia	
	SIDS	
	Necrotizing enterocolitis	
Maternal	Risk for type 2 diabetes	No relationship
	Breast cancer	Osteoporosis
	Ovarian cancer	Return to prepregnancy weight
	Postpartum depression	Weight loss?

Breastfeeding for 3 months or longer was found to enhance language skills and motor skills in a cross-sectional study of 22,399 children with concerns about language decreasing the longer they were breastfeeding.<sup>22</sup>

Evidence from a large randomized trial examining breastfeeding and cognitive development in 17,046 healthy breastfeeding infants, 81.5% of whom were followed for 6.5 years, showed exclusive breastfeeding at 3 months of 43.3% in the experimental group and only 6.4% in the control group and a higher rate of breastfeeding at all ages through 12 months. This was part of the Promotion of Breastfeeding Intervention Trial (PROBIT) study group in Belarus.<sup>46</sup> The experimental group had higher mean scores in the Wechsler Abbreviated Scales of Intelligence, which measures both verbal and performance intelligence quotient (IQ). Teachers' academic ratings were significantly higher.

The authors considered it strong evidence that prolonged and exclusive breastfeeding improves children's cognitive development.<sup>46</sup>

Using the data from the National Longitudinal Study of Adolescent Health (26,000 schools in the United States) on sibling pairs, it was estimated that the effect of having been breastfed on high school graduation, high school GPA, and college attendance was significant. Cognitive ability and adolescent health seemed interrelated to breastfeeding.<sup>82</sup> A novel approach utilized in 2011 to improve the causal inference in observational studies compared high, middle, and low income cohorts. Breastfeeding was thought by

these authors to have a causal relationship to intelligence. The causal effects of breastfeeding on IQ were determined in a systematic review that looked at the role of confounders. Walfisch concluded that the apparent effect on intelligence was due to confounding. Confounding was based on failure to control for parental IQ.

Although data on cognitive ability was impressive, it did not meet AHRQ scrutiny. Nevertheless, evidence continues to mount. The original studies<sup>56,31</sup> actually were done on premature infants, measuring visual activity and auditory acuity, both of which are electroencephalographic responses to standard stimuli. The reactions are unrelated to demographics such as intellectual scores or socio-economic status of the parents. The value of receiving human milk was clearly demonstrated. A more accurate assumption is that breastfeeding allows a child to reach his/her full potential. It is clear that no study has ever suggested that artificial feedings contribute to good brain growth.

### Does Breastfeeding Reduce the Risk for Sudden Infant Death Syndrome?

The policy statement for the American Academy of Pediatrics on Sudden Infant Death Syndrome (SIDS) released in 2011 again affirmed the value of supine sleeping for infants and recommends a pacifier for sleep time along with the list of cautions against soft surfaces, soft covers, and toys.<sup>94</sup> It is stated that co-sleeping is a major cause of SIDS. Concern has arisen about co-sleeping deaths occurring in hospitals in the first few days of life. Fifteen deaths and three near deaths were reported occurring between 1999 and 2013 as reported by members of the National Association of Medical Examiners. The problem is believed to be underreported. Associated circumstances were falling asleep while breastfeeding in eight cases, obesity, and swaddling, but all were bed sharing.<sup>95</sup> The committee states that breastfeeding infants are more easily aroused than formula-fed infants, a safety factor. They also state that some epidemiological studies have proven a relationship between breastfeeding and reduction of SIDS, but others have not. The committee acknowledged<sup>16</sup> the value of breastfeeding but did not recommend breastfeeding as a strategy to reduce SIDS.

The recommendation for pacifier use included a delay in beginning a pacifier in a breastfeeding infant until 1 month of age. It is also stated that if the pacifier falls out of the mouth during sleep that it not be reinserted. There is an increased incidence of plagiocephaly from positioning, and the increase in malocclusion and otitis media from pacifier use was acknowledged. A paper published in 2009 by Vennemann et al.<sup>96</sup> reported that the

population-based, case-control study of 333 cases of SIDS and 998 matched controls from Germany showed breastfeeding reduced the risk for SIDS by 50% at all ages; 73% of infants died before 6 months of age.

In a letter to the editor in 2014, the Taskforce<sup>94</sup> states that the Taskforce supports the value of breastfeeding in preventing SIDS.

## *Benefits of Breastfeeding for Mother*

Breastfeeding may provide a mother with a number of benefits, which should be included during discussions about making an informed decision regarding how to feed one's infant.

### **EMPOWERMENT**

In addition to clinically proven medical benefits, breastfeeding empowers a woman to do something special for her infant. The relationship of a mother with her suckling infant is considered the strongest of human bonds. Holding an infant to the mother's breast to provide total nutrition and nurturing creates an even more profound and psychological experience than carrying the fetus in utero. These observations have been tested in animal experiments in which oxytocin and prolactin have triggered parenting behavior with non-pregnant subjects.

In studies of young women enrolled in the Women, Infants, and Children (WIC) program in Kentucky who were randomly assigned to breastfeed or not to breastfeed and who were provided with a counselor/support person throughout the first year postpartum, the women who breastfed changed their behavior.<sup>32</sup> They developed self-esteem and assertiveness, became more outgoing, and interacted more maturely with their infants than did the women assigned to artificial feeding. The women who breastfed turned their lives around by completing school, obtaining employment, and providing for their infants.

### **POSTPARTUM RECOVERY**

Women who breastfeed return to a prepregnancy state more promptly than women who do not, and they have a lower incidence of obesity in later life (Box 7-1).<sup>93,87</sup> The presence of oxytocin stimulates the uterus to contract and involute with each feeding so that the uterus returns to the prepregnant state within 6 weeks. The extra pregnancy tissue storage is utilized in the production of milk, and the return to prepregnancy weight is thus facilitated.

### **BOX 7-1. Benefits of Breastfeeding**

#### **INFANT**

- Species specificity
- Nutritional advantages
- Infection protection
- Immunologic protection
- Allergy prophylaxis
- Psychological benefits

#### **MOTHER**

- Postpartum recovery
- Psychological benefits, empowerment
- Improved health risks

## **DECREASED RISK FOR OSTEOPOROSIS**

The risk for osteoporosis in later life is greatest for women who have never borne an infant, somewhat less for those who have borne infants, and measurably less for those who have borne and breastfed infants.<sup>41-89</sup> The bone mineral loss experienced during pregnancy and lactation is temporary. Bone mineral density returns to normal after pregnancy and even after extended lactation when mineral density may exceed the original baseline. Serum calcium and phosphorus concentrations are greater in lactating than in nonlactating women. Lactation stimulates the greatest increases in fractional calcium absorption and serum calcitriol after weaning.<sup>42</sup> Postweaning concentrations of parathyroid hormone are significantly higher than in other stages, and urinary calcium loss is significantly lower.<sup>17</sup> Studies reporting the history of fractures in postmenopausal women do not address exclusivity or duration of breastfeeding nor do they account for body mass index (BMI) or hormone replacement therapy.<sup>36</sup>

## **MATERNAL RISK FOR CARDIOVASCULAR DISEASE, HYPERLIPIDEMIA, AND DIABETES**

The occurrence of cardiovascular disease in women has become an urgent consideration since heart attack and stroke have become more common in women. The correlation with breastfeeding and reduction of risk for cardiovascular disease has been reported for more than two decades.<sup>86</sup> The influence of initial infant feeding on cardiorespiratory risk factors in adults in 9377 persons born during 1 week in 1958 in England has been reported by Rudnicka et al.<sup>85</sup> Breastfeeding was described as never breastfeeding, partially or wholly for less than a month, or breastfeeding more than a month. Little impact was found except for reduced waist circumference, waist/hip ratio, and lower odds of obesity.<sup>81</sup> One month of some breastfeeding would hardly be expected to have a long-range impact.

On the other hand, a study from the Women's Health Initiative of over 139,000 women more than 63 years of age with at least one live birth concluded that increased duration of lactation was associated with a lower prevalence of hypertension, diabetes, hyperlipidemia, and cardiovascular disease in women who reported 12<sup>44,91</sup> or more months of lactation in their lifetime. In a study of 1262 women, it was demonstrated that for every 6 months of breastfeeding the risk of developing type II diabetes, was reduced further. It has been suggested that the role of body weight may reduce the effect.

## **PROTECTION AGAINST OVARIAN CANCER**

A woman's increasing number of pregnancies, increasing length of oral contraceptive use, and increasing duration of lactation are generally agreed to be protective against ovarian cancer.<sup>99</sup> When the relationship between lactation and epithelial ovarian cancer was studied from a multinational database, short-term lactation was as effective as long-term lactation in decreasing the incidence of ovarian cancer in developed countries where ovulation suppression may be less prolonged in relation to lactation.<sup>83</sup> In a study of black women, who are known to have a lower incidence of ovarian cancer, breastfeeding for 6 months or longer, as well as four or more pregnancies and oral contraceptive use, further reduced the incidence of ovarian cancer.<sup>37</sup>

Siskind et al.<sup>88</sup> studied the modifying effect of menopausal status on the association between lactation and risk for ovarian cancer in 824 cancer patients and 855 community control subjects. No association was noted in women whose cancer occurred postmenopausally; however, breastfeeding was somewhat protective against ovarian cancer before menopause in this study. Breastfeeding of more than 12 months cumulative duration was associated with a reduction of the risk for ovarian cancer compared with never breastfeeding. Ovarian cancer was reported in the subgroups of pre- and postmenopausal women but had less robust evidence according to the AHRQ report.<sup>36</sup>

## **REDUCED INCIDENCE OF BREAST CANCER**

A mother with a new diagnosis of breast cancer should not nurse her infant in the interest of having definitive treatment immediately because prolactin levels remain high during lactation, and the role of prolactin in the advancement of mammary cancer is still in dispute. Although endogenous prolactin by itself may not be a risk factor, it could, along with

sex steroids, contribute to the acceleration of malignant growth.<sup>92</sup> All lumps in the lactating breast are not cancer and are not even benign tumors. The lactating breast is lumpy, and the "lumps" shift day by day. If a mass is located and the physician thinks it should be biopsied, this can be done under local anesthesia without weaning the infant.

Surgeons have performed many such procedures after referrals in the past 40 years without postoperative complications. The diagnosis of a benign mass was made in most cases. Immediate surgery relieved tremendous anxiety without unnecessarily sacrificing breastfeeding. With noninvasive mammary imaging techniques such as ultrasound, computed tomography (CT) scanning, and MRI, careful diagnosis can be made without interfering with lactation and without delaying diagnosis.

## **Relationship to Breastfeeding**

Is cancer more or less common in women who breastfeed? The answer is not easy to find, but in countries where breastfeeding is common, breast cancer is uncommon. In the United States, the incidence of breast cancer has steadily risen while the frequency of breastfeeding has declined. It has been suggested that nursing protects a woman against breast cancer. This concept has been investigated in many international studies.<sup>26</sup> Breastfeeding does not predispose a woman to cancer and may protect her.<sup>29</sup> How breastfeeding-induced mammary differentiation confers protective effects against breast cancer is not understood. Accessing the normal cellular hierarchy of the fully differentiated gland has been compared to the cellular hierarchy of breast cancer subtypes. Shared transcription factors of normal breast stem cells and certain aggressive breast tumors suggest that it is an imbalance of certain gene regulatory networks that causes this disease.

A case-controlled study of 453 white women with breast cancer and 1365 white women without breast cancer from upstate New York showed an inverse relationship between length of breastfeeding and incidence of breast cancer in premenopausal women that has not been seen in postmenopausal women.<sup>10</sup> The authors found this apparent protective effect persisted throughout the childbearing years, with statistical control for age, parity, age at first pregnancy, age of menarche, and education. The women with cancer had had a higher incidence of lactation failure caused by "insufficient milk." The authors<sup>10</sup> suggest that the significance of this study may be that women who are unsuccessful at lactation are at increased risk for cancer rather than that breastfeeding is protective.

The combination of low parity and late age at first birth was associated with a sevenfold increase in risk for breast cancer at ages 66 to 80 in a study by Lubin et al.<sup>55</sup> of more than 1400 women in Canada. At all ages, the authors found an increased cancer risk associated with relative infertility, benign breast disease, and not breastfeeding.

Marriage has been established as a negative risk factor for breast cancer. Mortality rates for most causes of death are higher among single women than among ever-married women.

The statistics associating pregnancy and breast cancer influence the picture. In an epidemiologic study, the risk for breast cancer had a linear relationship to the time interval between puberty and childbirth.<sup>67,70</sup> The risk was reduced by one third for women who bore their first child before 18 years of age compared with those women who had their first infant when they were older. The risk for breast cancer for women who become pregnant before 20 years old was about half that of those who first became pregnant after 25 years of age. Births after the first full-term pregnancy did not influence the statistics. Women whose first pregnancy appeared after 30 to 35 years of age had a risk for breast cancer four times that of nulliparous women in the same age group.<sup>68,70</sup>

The incidence of breast cancer is low among groups who nursed their infants, including lower economic groups, foreign-born groups, and those in sparsely populated areas.<sup>68,70</sup> The frequency of breast cancer in mothers and sisters of a woman with breast cancer is two to three times that expected by chance. This influence could be genetic or environmental. Since the isolation of the "breast cancer gene," women who are at risk are being identified. Cancer actually is equally common on both sides of the family of an affected woman. If breast milk were the cause, it should be transmitted from mother to daughter.<sup>103</sup> When mother-daughter incidence of cancer was studied, no relationship was found to breastfeeding. The association between breastfeeding and the incidence of breast cancer among 89,887 women in the U.S. Nurses Healthy Study was sought through an additional questionnaire. The authors<sup>65</sup> suggest that no important association exists between breastfeeding and the occurrence of breast cancer. Data gathered since 1996 have changed the conclusions about breastfeeding being protective.<sup>36</sup>

Unilateral breastfeeding (limited to the right breast) is a custom of Tanka women of the fishing villages of Hong Kong. Ing et al.<sup>34</sup> investigated the question, "Does the unsuckled breast have an altered risk for cancer?" They studied breast cancer data from 1958 to 1975. Breast cancer occurred equally in the left and the right breasts. Comparison of patients who had nursed unilaterally with

nulliparous patients and patients who had borne children but had not breastfed indicated a highly significant increase in risk for cancer in the unsuckled breast. The authors conclude that in postmenopausal women who have breastfed unilaterally, the risk for cancer is significantly higher in the unsuckled breast.<sup>63</sup> They think that breastfeeding may help protect the suckled breast against cancer.<sup>34</sup>

Other authors<sup>47</sup> have suggested that Tanka women are ethnically a separate people and that it is possible that left-sided breast cancer is related to their genetic pool and not to their breastfeeding habits. No mention has been made of other possible influences; for instance, the impact of their role as "fishermen" or any inherent trauma to the left breast.

As early as 1926, Lane-Claypon<sup>50</sup> stated that breasts that never lactated were more liable to become cancerous. Nulliparity and absence of breastfeeding had been considered important risk factors for breast cancer.

In a collective review of the etiologic factors in cancer of the breast in humans, Papaioannou concludes, "Genetic factors, viruses, hormones, psychogenic stress, diet and other possible factors, probably in that order of importance, contribute to some extent to the development of cancer of the breast."

Gradually, studies have appeared challenging the dogma. Brinton et al.,<sup>8</sup> McTiernan and Thomas,<sup>64</sup> and Layde et al.<sup>54</sup> showed the clearly protective effects of breastfeeding. Another example is a study conducted to clarify whether lactation has a protective role against breast cancer in Asian people, regardless of confounding effects of age at first pregnancy, parity, and closely related factors.<sup>102</sup> Similar results were reported by Zheng et al.<sup>104</sup> in a study in Shandong Province, China, in both pre- and postmenopausal women who had a reduced risk for breast cancer. The more months of breastfeeding, the lower the risk. In a hospital-based, case-control study of 521 women with breast cancer and 521 women without breast cancer, statistical adjustment for potential confounders and a likelihood ratio test for linear trend were done by unconditional logistic regression. Total months of lactation, regardless of parity, was the discriminator. Regardless of age at first pregnancy and parity, lactation had an independent protective effect against breast cancer in Japanese women.<sup>102</sup> Breastfeeding over 6 months, regardless of a family history of breast cancer, was protective in a large group of Spanish women whose records were reviewed retrospectively. The authors suggested that the recent increase in breast cancer paralleled the absence of breastfeeding. Although breast cancer incidence is influenced by genetics,

stress, hormones, and pregnancy, in most reports, clearly breastfeeding has a protective effect.<sup>69</sup> A systematic review and meta-analysis do not support the theory that BRCA<sub>1</sub> and BRCA<sub>2</sub> mutation carriers are protected from cancer by breastfeeding.

Two large prospective studies<sup>65,47</sup> did not report a protective effect of breastfeeding. Populations of 50,274 and 89,887 identified 2130 and 459 patients with breast cancer. The odds ratios indicate 1.01 (0.98 to 1.05) and 0.95 (0.86 to 1.06), respectively. As with most studies of this nature, the cancers are well defined but not the breastfeeding. No attempt was made to note exclusivity and associated amenorrhea. The studies obtained breastfeeding histories when the women were older than 45 years old and included all those who ever breastfed. Insufficient milk supply has not been associated with increased risk of breast cancer when a large number of reports were reviewed by Cohen et al.<sup>14</sup>

The concern for exposure to estrogen early in life has been part of breast cancer assessment.<sup>73</sup> In utero exposure to estrogen is greater in twin pregnancies and when the mother is older. Estrogen levels in smokers, however, are lower. Weiss et al.<sup>98</sup> analyzed cancer risk in a population-based, case-control study in the United States (2202 with breast cancer and 2009 control subjects under 55 years of age). Twins were at greater risk than singletons, but no association with maternal age at delivery was found. A reduced breast cancer risk was seen among women who had themselves been breastfed as infants. Following Cochrane guidelines in performing a Medline search of papers from 1990 to 2002, a reduction of women's relative risk for breast cancer and a protective effect against ovarian cancer in women who breastfed their children was demonstrated. Results from meta-analyses in the AHRQ report concluded that there was a reduction in the risk for breast cancer in women who breastfeed their infants.<sup>36</sup> A lifetime breastfeeding history of more than 12 months was especially protective.

In an effort to understand the relationship between breastfeeding and breast cancer, Newton<sup>70</sup> points out that over the past two centuries, women have changed from being pregnant or lactating 60% of the time between menarche and menopause to fewer pregnancies and shorter lactation periods. Thus the amount of time a woman lives with unopposed estrogen (the proliferative phase of the menstrual cycle) was 15% in 1800 and 45% in 1996. Case-control epidemiologic studies consistently show a protective effect (Table 7-4). The most important predictors may be duration of the amenorrheal/hypoestrogenic state and the exposure to breast milk as an infant, according to Newton.<sup>70</sup> Breast cancer mortality is disproportionately high in black women of all ages. African-American women who do not breastfeed are at higher risk for aggressive breast cancer according to Palmer.<sup>75</sup> Women with children who never breastfed were more likely to develop estrogen receptor-negative breast tumors compared to those who never had children. Data from 3700 black breast cancer patients revealed the risk of not breastfeeding. A black mother who had four or more children but never breastfed was more likely to develop estrogen receptor-negative breast cancer compared to a woman with only one child whom she breastfed. According to Palmer,<sup>75</sup> breastfeeding represents a modifiable factor that could reduce the number of cases of estrogen-receptor negative breast cancer and reduce the number of African-American women dying from this disease.

## Radiation Therapy to Breast

Ionizing radiation is carcinogenic to female mammary tissue. Women in Hiroshima and Nagasaki and those subjected to therapeutic radiation for mastitis were followed for many years.<sup>87</sup> The risk for cancer is 3.2 times greater in irradiated breasts, increasing with time after the irradiation. A linear relationship to radiation dose also exists.

**TABLE 7-4** Breast Cancer and Lactation

Study	Population	Odds Ratio	95% Confidence Interval
<b>Likelihood of Breast Cancer</b>			
Pillay et al. <sup>76</sup>	All	0.93	0.83-1.03

BF, Breastfed.

From Newton ER Jr: Does breastfeeding protect women from breast cancer? *ABM News Views* 2:1, 1996.

In the late 1940s and early 1950s, radiation of the breast was performed as a treatment for mastitis. Although this approach seems irrational today, no antibiotics were readily available at that time, and women were hospitalized for mastitis. Sulfa drugs were not identified until the 1940s and penicillin shortly thereafter. The compounds were used only for life-threatening diseases. The effect of radiation on the infected breast was to clear the mastitis dramatically, stop lactation overnight, and seemingly solve the problem. The mother would continue to nurse on the other breast. The long-term follow-up of these women reveals a high incidence of cancer in the radiated breast.<sup>87</sup>

Radiation usually causes destruction to lobules, condensation of the cytoplasm in cells lining the ducts, and fibrosis. Successful lactation after radiation for carcinoma, however, has been reported in a 36-year-old woman with one previous pregnancy and lactation experience 6 years earlier.<sup>19</sup>

## **PROTECTIVE EFFECT OF BEING BREASTFED**

Davis<sup>20</sup> first reported the reduction of childhood-onset cancers in children who have been exclusively breastfed for at least 4 months. The fear of cancer in the breastfed female offspring of a woman with breast cancer does not justify avoiding breastfeeding. Breastfed women have the same breast cancer experience as nonbreastfed women, and no increase occurs in benign tumors.<sup>62</sup> Daughters of women with breast cancer have an increased risk for developing benign and malignant tumors by merit of their heredity, not their breastfeeding history.<sup>68,66</sup> This is confirmed with the identification of a breast cancer gene.

The critical question remains: does being breastfed increase any child's risk for developing breast cancer, especially female offspring? This haunting question, first posed by an experimental scientist, created tremendous publicity and genuine concern among physicians queried by patients. The available data need to be explored.

No documented evidence indicates that women with breast cancer have ribonucleic acid (RNA) of a tumor virus in their milk. No correlation between cancer and RNA-directed deoxyribonucleic acid (DNA) polymerase activity has been found in women with a family history of breast cancer. RNA-directed DNA polymerase activity, a reverse transcriptase, is a normal feature of the lactating breast.<sup>13-84</sup>

## **PROTECTION AGAINST CHILD ABUSE AND NEGLECT**

Many professionals in the field have commented that they had never seen a child who had been

abused or neglected that had been breastfed by the mother. There were no studies and no evidence.

A cohort of 7223 Australian mother-infant pairs have been monitored prospectively for more than 15 years by Strathearn et al.<sup>90</sup> They analyzed the duration of breastfeeding with respect to child neglect, physical abuse, and emotional abuse in 6621 cases (91.7%) based on substantiated child protection agency records. The odds ratio for maternal maltreatment increased as breastfeeding duration decreased. The odds of maternal maltreatment in bottle-fed infants were 4.8 times greater than for children breastfeeding for 4 months or longer. With adjustment for possible confounding, the odds were still 2.6 times greater in mothers who bottle fed. Maternal neglect was especially common among nonbreastfeeding women. Biologically, considering the impact of oxytocin on the brain, the authors found the results understandable.

## ***Contraindications to Breastfeeding***

In reviewing the contraindications to breastfeeding, it is important to look at the entities that put the mother or infant at significant risk and are not remediable. Contraindications are medical; the disadvantages tend to be social. The physician needs to have a clear understanding of the benefits of breastfeeding to measure the risks for a particular mother-infant dyad. The risk/benefit ratio can be determined only by the clinician in a position to weigh all the data, usually the pediatrician for the infant or the obstetrician for the mother or the family physician.

## **INFECTIOUS DISEASES**

In general, acute infectious diseases in the mother are not a contraindication to breastfeeding, if such diseases can be readily controlled and treated.<sup>15</sup> In most cases the mother develops the infection during breastfeeding. By the time the diagnosis has been made, the infant has already been exposed, and the best management is to continue breastfeeding so that the infant will receive the mother's antibodies and other host resistance factors in breast milk.<sup>53</sup> This is true for respiratory infections such as the common cold. Infections of the urinary tract or other specific closed systems, such as the reproductive tract or gastrointestinal tract, do not pose a risk for excreting the virus or bacteria in the breast milk unless generalized septicemia occurs. In certain situations, given the relative virulence and infectivity of the organism, such as with  $\beta$ -hemolytic streptococcus group A, both mother and infant should be treated, but breastfeeding is not contraindicated (Table 7-5).<sup>15,52</sup> When the offending organism is especially virulent

**TABLE 7-5**

## Possible Medical Contraindications to Breastfeeding\*

Problem	Breastfeeding acceptable	Conditions
<b>Infectious diseases</b>		
Acute infectious disease	Yes	Respiratory, reproductive, gastrointestinal infections
HIV	No	HIV positive in developed countries
Active tuberculosis	Yes	After mother has received 2 or more weeks of treatment
Hepatitis		
A	Yes	As soon as mother receives gamma globulin
B	Yes	After infant receives HBIG, first dose of hepatitis B vaccine should be given before hospital discharge
C	Yes	If no coinfections (e.g., HIV)
Venereal warts	Yes	
<b>Herpesviruses</b>		
Cytomegalovirus	Yes	
Herpes simplex	Yes	Except if lesion on breast
Varicella-zoster (chickenpox)	Yes	As soon as mother becomes noninfectious
Epstein-Barr	Yes	
Toxoplasmosis	Yes	
Mastitis	Yes	
Lyme disease	Yes	As soon as mother initiates treatment
HTLV-I	No	
<b>Over-the-counter/prescription drugs and street drugs (see Chapter 12)</b>		
Antimetabolites	Variable	Temporarily pump and discard
<b>Radiopharmaceuticals</b>		
Diagnostic dose	Yes	After radioactive compound has cleared mother's plasma
Therapeutic dose	No	
Drugs of abuse	No	Exceptions: cigarettes, alcohol
Other medications	Yes	Drug-by-drug assessment
<b>Environmental contaminants</b>		
Herbicides	Usually	Exposure unlikely (except workers heavily exposed to dioxins)
Pesticides		
DDT, DDE	Usually	Exposure unlikely
PCBs, PBBs	Usually	Levels in milk very low
Cyclodiene pesticides	Usually	Exposure unlikely
Heavy metals		
Lead	Yes	Unless maternal level $\geq 40$ mcg/dL
Mercury	Yes	Unless mother symptomatic and levels measurable in breast milk
Cadmium	Usually	Exposure unlikely
Radionuclides	Yes	Risk greater to bottle-fed infants

DDE, Dichlorodiphenyldichloroethane; DDT, dichlorodiphenyltrichloroethane; HBIG, hepatitis B immune globulin; HIV, human immunodeficiency virus; HTLV-1, human T-cell leukemia virus type 1; PBBs, polybrominated biphenyls; PCBs, polychlorinated biphenyls.

\*This table provides a brief summary. Each situation must be decided individually. Contraindications are rare.

Modified from Lawrence RA: A review of the medical benefits and contraindications to breastfeeding in the United States. In *Maternal and child health technical information bulletin*, Arlington, Va., 1997, National Center for Education in Maternal and Child Health.

or infection occurs through direct contact or respiratory droplets, separation of the infant and mother is indicated regardless of the mode of feeding (formula or breast milk). Examples of such infections include smallpox and tuberculosis. In these situations, giving the infant expressed breast milk

without maternal contact is appropriate. A mother who bottle feeds also exposes her child by contact but provides no protective properties because they are not present in formula. See Chapter 13 for discussion of management of infectious diseases during lactation.

Many agents in breast milk protect against infection, and their presence is not affected by nutritional status. Protection against infection is important in the United States, especially among infants exposed to multiple caregivers, child care outside the home, compromised environments, and less attention to the spread of organisms.<sup>32</sup> One of the most important and thoroughly studied agents in breast milk is secretory immunoglobulin (sIg, specifically, sIgA), which is present in high concentrations in colostrum and early breast milk and in lower concentrations throughout lactation, when the volume of milk is increased.<sup>32</sup> sIgA antibodies may neutralize viruses, bacteria, or their toxins and are capable of activating the alternate complement pathway.<sup>15</sup> The normal flora of the intestinal tract of the breastfed infant, as well as the offspring of all other mammalian species studied until weaning, is bifidobacteria or lactobacilli.<sup>32</sup> These bacteria further inhibit the growth of bacterial pathogens by producing organic acids. This is in striking contrast to formula-fed infants, who have comparatively few bifidobacteria and many coliform bacteria and enterococci. In addition, although the attack rates of certain infections are similar in breastfed and formula-fed infants in the same community, the manifestations of the infections are much less evident in the infants who are breastfed. This appears to result from antiinflammatory agents in breast milk.<sup>52</sup>

For a few specific infectious diseases, the possible infectious risk for breastfeeding outweighs the benefits.<sup>15,53,80</sup> See the following section and refer to Chapter 13.

## LIFE-THREATENING ILLNESSES

Life-threatening or debilitating illness in the mother may necessitate avoiding lactation. This clinical judgment should be made with the mother and father with all facts presented. Although one woman may be able to overcome all obstacles and prove she can nurse her baby, it does not necessarily mean that another patient with the same diagnosis can.<sup>8,7</sup> If a mother wants some lay reading on the subject, the clinician should be familiar with available material so any apparent inconsistencies of opinion can be discussed. (See management of specific maternal illnesses in Chapter 16.)

## OVER-THE-COUNTER/PRESCRIPTION DRUGS AND STREET DRUGS

### Medications

Much concern and anxiety have been expressed regarding the question of medications taken by lactating women and the risk to the suckling infant. In

reality, very few drugs are contraindicated during breastfeeding.<sup>53</sup> Each situation should be evaluated on a case-by-case basis by the physician. The important factors include the pharmacokinetics of the drug in the maternal system and the absorption, metabolism, distribution, storage, and excretion in the recipient infant. Variables to consider in the decision include gestational age, chronologic age, body weight, breastfeeding pattern, and other dietary practices. Ultimately, the decision is made by assessing the risk/benefit ratio (i.e., the risk for a small amount of the drug compared with the tremendous benefit of being breastfed).

See Chapter 12 for a full discussion of drugs, medications, and environmental toxins. The contraindications are few but include radioactive medications, antimetabolites, and street drugs (see Table 7-5).

## Drug Abuse

Breastfeeding is contraindicated in women who are IV drug abusers.<sup>93</sup> The possibility of the infant receiving substantial amounts of drug through the milk is real; deaths have been reported in the recipient neonate. IV drug abusers have high incidences of hepatitis, HTLV-I/II, or HIV, which may be transmitted to the breastfed infant from the infected mother (see Chapter 12).

## *Disadvantages of Breastfeeding*

Because no known disadvantages exist for normal infants, the disadvantages of breastfeeding are those factors perceived by the mother as an inconvenience to her. (In the rare circumstance of galactosemia in the neonate, which involves an inability to tolerate lactose, breastfeeding is contraindicated; see Chapter 14.) In cultures in which nursing in public is commonplace, nursing is not considered inconvenient because the infant and the feeding are always available.

The mother's commitment to the infant for 6 to 12 feedings per day for months may be overwhelming to a woman who has been free and independent. Motherhood itself changes a woman's lifestyle.<sup>12</sup>

Guilt from failure, shame, and other anxieties are of considerable concern. Surveys evaluating the decline of breastfeeding have revealed that mothers describe feelings of shame, immodesty, embarrassment, and distaste. These feelings are more common in lower economic groups. Research on wider sociologic and psychological factors regarding the feelings and attitudes toward breastfeeding can have considerable influence on the choice to breastfeed and will be helpful in dealing with these issues.

Professionals and lay persons, under the banner of "supporting breastfeeding," occasionally get caught up in a rush to "convert" all mothers and parents to breastfeeding. Sometimes the push is to change many hospital routines and regulations to facilitate without assessing the full impact of those changes on all mothers and infants. A sense of balance should be maintained. It is important to appreciate that some normal women cannot or will not nurse their babies. Their babies will survive and grow normally. Each woman, infant, and family should be supported in their choice of infant feeding; it is their choice to make. The education and support should be specific for the particular needs of each mother-infant dyad.

The sharp letter by Fisher<sup>28</sup> brings this to focus when she describes the frustrations and disappointments of others and dispels what she calls the myths about breastfeeding. She expresses anger over her failure to successfully breastfeed her child. Her anger is an outward sign of inner guilt about this perceived failure.

The popular press has drawn attention to parenting trends that divide responsibility for the infant equally between mother and father after the birth. This, of course, necessitates some bottle feeding. The justification is division of labor and equal opportunity for both parents to serve the needs of the baby. This is probably another way of expressing breast envy and jealousy. Some husbands are jealous because they have no similar way to provide food and contentment to their infants, according to Waletzky.<sup>97</sup> "A certain manliness was required to foster breastfeeding in one's family when society as a whole was hostile to it," according to Pittenger and Pittenger.<sup>78</sup> They point out that the perinatal period is a breeding ground for marital and parental maladjustment. Shared responsibility does not mean that the father must feed his baby half the time. The father can take primary responsibility for another of the numerous needs, such as bathing or dressing the infant or nourishing the mother while she breastfeeds. Fathers can become "nonnutritive cuddlers" for infants, a very important role.

Many writers, however, have described participation in childbirth as a potentially beneficial experience for men. The father's feelings are useful during labor and delivery. These experiences contribute to heightened self-concepts and better adjustments to roles as husband and father. The quality of the birth experience has been cited as the major determinant of paternal attachment. Paternal attachment has led to greater pride in breastfeeding and a more secure, self-confident support person for the mother who is breastfeeding.

Perinatal counseling of prospective new parents may anticipate these reactions, and the professional will have an opportunity to facilitate the best experience possible.<sup>12</sup>

## CHAPTER 8

# *Practical Management of the Mother-Infant Nursing Couple*

---

Management of lactation begins with understanding the physiologic process of suckling and the physiologic process involved in latching on to the breast. For thousands of years, women fed their young by breastfeeding. They learned the art from senior women in the family. It was not a medical issue. The social structure of the family has changed, and the natural learning pathways are gone. The physician now has a critical role in the management of human lactation.

Successful nursing depends on the successful interaction of mother and infant, with appropriate support from the father, the family, and available health care resources. Because mothers and infants vary, no simple set of rules in hospitals can be outlined to guarantee success. In fact, one of the difficulties has been that rigid systems were established for initiating lactation in hospitals that did not fit all mother-infant couples. Many physicians have not received formal education about breastfeeding; thus they resort to gaining information from a variety of sources, including personal experiences, and may assume that this is the correct way to approach the situation.

Nowhere in medicine do one's personal interests or prejudices become more evident than in the area of counseling about childbirth and breastfeeding. Having a child does not make one an expert on the subject. Conversely, not having a child does not preclude the development of exceptional knowledge. Some of the world's most revered experts in human lactation have neither had a child nor nursed an infant, but they have brought to the situation the eye of a skilled observer and the experience of a broadly trained clinician, unencumbered by emotional bias and personal prejudices.

Historically, rigid dogmas have directed management of lactation. In the effort to replace these with what was perceived as more rational management, new dogmas have arisen. Once there was a paucity of literature; now there is a deluge from all sources, some valid, others questionable. The careful art and science of breastfeeding are being lost in the rage of righteousness. No rules exist for breastfeeding. As in all other areas of medicine, a clinician adapts the recommendations to individual patients and their circumstances.<sup>151</sup>

It is not ordinarily a physician's role to teach a mother how to breastfeed. Instead, nursing staff who interact in the perinatal period, including obstetric office nursing, labor/delivery, nursery, postpartum, birth center, pediatric office personnel, and midwives, have job descriptions that include hands-on assistance for a mother in the process of breastfeeding. A physician does, however, need to understand the anatomy and physiology and the basics of breastfeeding to recognize problems and determine their solutions (Table 8-1). This chapter addresses the basic breastfeeding process. It is not a "how-to" manual for mothers, but the physician should be familiar with one or two good sources of information to suggest for patients, such as K. Huggins' *The Nursing Mother's Companion*, now in its 6th edition after 25 years of inspiring mothers to breastfeed. *The Womanly Art of Breastfeeding* from La Leche League International is also available.

The references for this chapter are not an exhaustive list of all material written on the topic; rather, they are intended to assist a reader in locating research that supports the evidence-based concepts described here.<sup>108,126</sup>

**TABLE 8-1** Common Breastfeeding Conditions and Symptoms and Their Connection with Breast Anatomy

Clinical Condition	Symptoms	Anatomic Relationship
<b>Glandular anomaly</b>		
Hypoplasia	Low milk production	Possible deficiency of glandular tissue
Hyperplasia	Excessive breast growth, lymphedema, possible necrosis	Excess glandular tissue
<b>Breast surgery</b>		
Reduction mammoplasty	Low milk production	Large volume of glandular tissue removed, severing milk ducts (fewer in number than previously thought); possible nerve damage inhibiting milk ejection reflex
Breast augmentation	Low milk production	Possible compression of milk ducts by implant; possible deficiency in volume of glandular tissue
<b>Palpable mass</b>		
Blocked duct	Mass (small or large) with or without pain; possible reduction in milk production	Compression of ducts: possible cause of blocked duct; if large lobe affected a significant reduction in milk production may occur; identification of the level of duct obstruction by ultrasound ensures treatment of entire affected area
Galactocele	Mass (generally small)	Possible ductal abnormality
Benign mass (cyst, fibroadenoma)	Mass	Possible compression of ducts causing blocked duct; possible obstruction of milk flow in the area of attachment of the infant to the breast
Malignant mass	Palpable nonresolving mass	Irregularly shaped mass that may be mistaken for a blocked duct or galactocele; ultrasound with or without mammography needed for diagnosis
Infant sucking mechanism	Ineffective suck	Lack of milk sinuses and evidence that vacuum plays a major role in milk removal may alter intervention
Milk expression	Differences in efficiency of pumping Differences in effectiveness of pumping	Theorized that women with large milk ducts or duct dilations at milk ejection express milk quickly Poor shield fit may result in compression of superficial ducts and inhibit milk flow
Milk ejection	Time of increased milk availability	Small ducts lacking lactiferous sinuses do not store a large amount of milk; optimization of milk removal during milk ejection will improve milk removal from the breast

From Geddes DT: Inside the lactating breast: the latest anatomy research, *J Midwifery Women's Health* 52(6), November/December 2007.

Infant feeding and care practices were assessed by the Department of Health and Human Services and published as a supplement to *Pediatrics* in 2008. It documents various aspects of infant feeding, as reported by more than 2000 women nationally for 1 year postpartum in 2004 and compares results with a similar study in 1993. This report serves as a reality check for many routines held dear.<sup>36</sup>

The home access to e-technologies was evaluated by Laborde et al.<sup>69</sup> in France. They noted that women with available technologies were more apt to be employed, did not use pacifiers, and did not smoke. Duration of breastfeeding was not different overall, suggesting that technology has not replaced good health resources and support systems yet.<sup>28</sup>

The key to the management of the mother-infant nursing couple is establishing a sense of

confidence in the mother and supporting her with simple answers to her questions when they arise. Good counseling also depends on understanding the science of lactation. Then, when a problem arises, a mechanism already is in place for a mother to receive help from her physician's office before the problem creates a serious medical complication.

## Peripartum Breastfeeding Management

All pregnant women should receive education about the benefits and management of breastfeeding to provide an opportunity to make an informed decision. The obstetrician with prenatal consultation should make an assessment of the potential

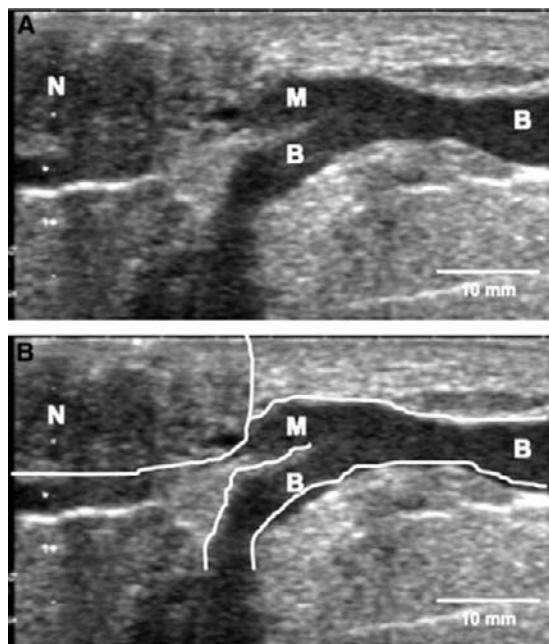

for successful breastfeeding if a problem is identified. Labor and delivery with the presence of a doula has been shown to enhance breastfeeding. Mode of delivery and use of anesthesia and medications also impact breastfeeding. Provision for breastfeeding within the first hour of life and the availability of rooming-in are also essential. The Academy of Breastfeeding Medicine (ABM) provides a helpful protocol for successful peripartum management.

A model of breastfeeding policy is also provided by the ABM, which is designed so that hospitals can incorporate it into their own policies.<sup>101</sup> It meets requirements for the Baby Friendly Hospital Initiative.

## The Science of Suckling

The ability to lactate is characteristic of all mammals, from the most primitive to the most advanced. The divergence of suckling patterns, however, makes it urgent that human patterns be studied specifically. Some aquatic mammals, such as whales, nurse under water; others, such as the seal and sea lion, nurse on land. A variety of erect or recumbent postures are assumed by different terrestrial mammals.<sup>24</sup> Nursing may be continuous, as in the joey attached to a marsupial teat, or at widely different intervals characteristic of the species and parallel to the nutrient concentrations of the milk. The intervals may be a half hour for dolphins, an hour for pigs, a day for rabbits, 2 days for tree shrews, or a week for northern fur seals.

New anatomy research gathered for the first time in 160 years since the brilliant work of Sir Ashley Cooper has been generated in the laboratory of Peter Hartmann in Australia and his eclectic team of scientists. They have had access to the latest digital technology. They have shown that the milk ducts of the breast are small (Figure 8-1), compressible, superficial, and closely intertwined.<sup>40</sup> There are no "dilated sinuses" that store large amounts of milk. The amount of adipose tissue in the breast is very variable and not a measure of the amount of glandular tissue; there is twice as much glandular tissue as fat.<sup>32</sup> Magnetic resonance imaging has identified some central ducts in the breasts of lactating women. The anatomy of the lactating breast was redefined with ultrasound imaging in Hartmann's laboratory.<sup>103</sup> Ducts were found to number four to eight, and branches drain glandular tissue directly beneath the nipple and merge into a collecting duct very close to the nipple. They do increase in diameter during milk ejection. Milk production is not dependent on neural stimulation but is hormonal. Milk ejection is critical to successful lactation. Failure to remove milk results in

**Figure 8-1A and B.** Ultrasound image of a main milk duct (Toshiba, Aplio). The nipple is the round hypoechoic (dark) structure in the left of the image (N). The main duct (M) branches into two ducts (B) approximately 5 mm from the nipple. Note the small diameter of the ducts (approximately 3 mm). (From Geddes DT: Inside the lactating breast: the latest anatomy research. *J Midwifery Women's Health* 52(6), November/December 2007, Figure 3.)

decreased milk production. Multiple milk ejections occur during breastfeeding, even though a woman usually only senses the first milk ejection.

Although many anatomic distinctions exist as well, the principal mechanism of milk removal common to all mammals is the contractile response of the mammary myoepithelium under the hormonal influence of oxytocin released from the neurohypophysis.<sup>145</sup>

The key function in all species is effective control of milk delivery to the young in the right amount and at the appropriate intervals, which requires a production system, exit channels, a prehensile appendage, an expulsion mechanism, and a retention mechanism. The primary, secondary, and tertiary ducts form an uninterrupted channel for the passage of milk from the milk-producing alveoli to the prehensile appendage. A process of erection of the areolar region facilitates prehension by the young during suckling. The principal object of the suction produced by the facial musculature of the young is to draw the nipple into the mouth and retain it there. Positive pressure is used to expel milk from the gland by the contractile changes in the mammary gland provided by the myoepithelial cells (see Figure 3-15). The sympathetic nervous stimuli can oppose milk ejection by increasing

vasoconstrictor tone, thereby reducing access of circulating oxytocin to the mammary myoepithelium. Sympathetic activity also can occur during conditions of apprehension or muscular exertion. The milk-ejection reflex can be blocked by emotional disturbance or reflex excitation of the neurohypophysis. The central nervous system control of milk ejection indeed suggests that restraining mechanisms exist to ensure that milk ejection can only occur under circumstances wholly conducive to the effective removal of milk by the suckling young.

In all species that have been studied, a rise in intramammary pressure and flow of milk occurs as a reflex event in suckling. The excitation of the neurohypophysis results in the release of oxytocin, which is conveyed via the bloodstream to mammary capillaries, where it evokes contraction of the myoepithelium. The successive ejection pressure peaks, demonstrated in lactating women, can be duplicated more accurately by a series of separate oxytocin injections than by the same total dose as a single injection or by a continuous infusion of the hormone. This strongly suggests that oxytocin is released from the neurohypophysis in spurts. The study of suckling patterns in all species shows a high degree of ritualization, which in turn suggests a close neural connection between cognitive or behavioral and hormonal responses.

Attention has focused on the mechanisms that control suckling behavior, on its incidence, on events that precipitate and terminate it, on the effects of stress, and on how development modifies it. Suckling is characteristic of each species and is vital for survival. *Suckling* means to take nourishment at the breast and specifically refers to "breastfeeding" in all species. *Sucking*, however, means to draw into the mouth by means of a partial vacuum, which is the process employed when bottle feeding. *Sucking* also means to consume by licking.

Although suckling has been studied in young and mothers in other species, a large portion of human data have been collected using a rubber nipple and bottle. Other mammals suckle only in the nutritive mode, whether receiving milk from the nipple or not. Human infants were noted to have two distinct patterns with rubber nipples: a nutritive mode and a nonnutritive mode.<sup>145,146</sup> When this work was repeated using the breastfeeding model, no difference between nutritive and nonnutritive suckling rates, but rather a continuous variation of suckling rate in response to milk-flow rate, has been seen.<sup>15</sup> Suckling rates in other species correlate with milk composition and species-specific feeding schedules (one suck per second in great apes and four to five sucks per second in sheep and goats).

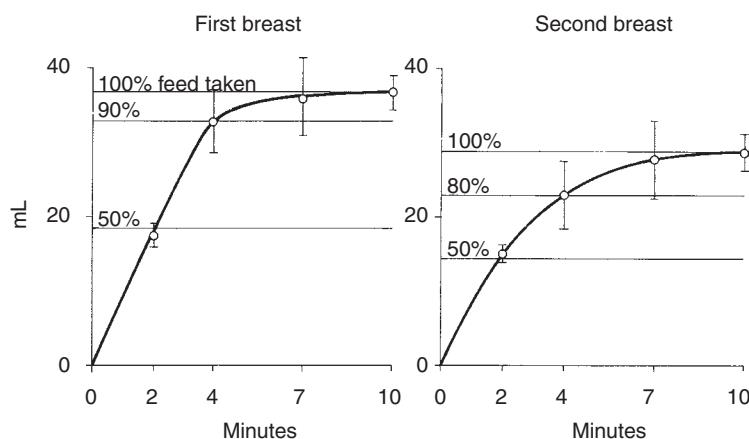

In further experiments, an inverse linear relationship was found between milk flow and suckling rate. Thus the higher the milk flow, the lower the suckling rate. In human infants younger than 12 weeks of age, suckling will terminate with sleep and be reinstated on awakening, a pattern that is well described in other species. In infants older than 12 weeks, suckling is not always terminated by sleep. At 12 to 24 weeks, infants will play with the nipple, explore the mother, and not always elicit nipple attachment. Continuous measurement of milk intake during a given feeding from one breast showed a progressive reduction in intake volume per suck and an increase in the proportion of time spent pausing between bursts of sucking.

Using the miniature Doppler<sup>147</sup> ultrasound flow transducer, Woolridge and Baum<sup>148</sup> studied 32 normal mother-baby pairs from 5 to 9 days postpartum. Intakes during trials averaged 34.2 g ( $\pm 3.7$  g) on the first breast and 26.2 g ( $\pm 3.5$  g) on the second breast. At the start of feeds, the average suck volume was about 0.14 mL/suck, which decreased to about 0.10 mL/suck or less. The mean latency for release of milk was 2.2 minutes after the infant began to suckle. The researchers also noted that on the first breast the flow increased and stabilized after 2 minutes, with concomitant slowing and stabilizing of sucking pattern during the remainder of the feed. On the second breast the suck volume fell off dramatically toward the end of the feed (50% reduction from peak to end of feed) (Figure 8-2).

These observations support the theory that infants become satiated at the breast, and milk remains unconsumed in the breast. During the first month of life, infants consume a given amount of fluid with decreasing investment of time.<sup>148</sup> The amount of fluid per suck increases over time. The control of intake appears to come under intrinsic control of the infant during the first month of life.<sup>98</sup>

A cineradiographic study of breastfeeding was done by Ardran et al.<sup>7</sup> in 1957 and compared with a similar study of bottle feeding.<sup>8</sup> The nipples and areolae of 41 breastfeeding mothers were coated with a paste of barium sulfate in lanolin, and cineradiographic films were taken with the infant at breast. These were then reviewed meticulously. Box 8-1 lists the authors' conclusions in their original description. These observations are of historic interest, but newer techniques in imagery have more accurately described the understanding of human suckling.

The development of real-time ultrasound improved the definition of images. Several studies have been published using this noninvasive technique to observe the action of the infant's tongue and buccal mucosa and the maternal nipple areola. Using a video recorder in the 1980s that allowed frame-by-frame analysis and recorded simultaneous respiration, the pattern of suck, swallow, and

**Figure 8-2.** Mother-infant pattern of milk flow. (From Lucas A, Lucas PJ, Baum JD: Pattern of milk flow in breast-fed infants, *Lancet* 2:57, 1979.)

breathing was documented during a period of active suckling at the breast. A suck was defined by Weber et al.<sup>137</sup> as the beginning of one indentation of the nipple by the tongue to the beginning of the next. Weber et al. had examined six breastfed and six bottle-fed infants between 1 and 6 days of life. Not all sucks were associated with a swallow. Box 8-2 summarizes the process.

Observations of suckling using improved techniques from 2 to 26 weeks showed that suckling starts with a series of fast sucking movements and then stabilizes. In a 2-week-old breastfeeding infant, sucking and breathing pattern proportions alternated smoothly at about two sucks to one breath, with swallowing occurring with every suck. Bottle feeding patterns were variable and sometimes asynchronous with sucking and breathing.

#### BOX 8-1. Radiographic Interpretation of Suckling at Breasts

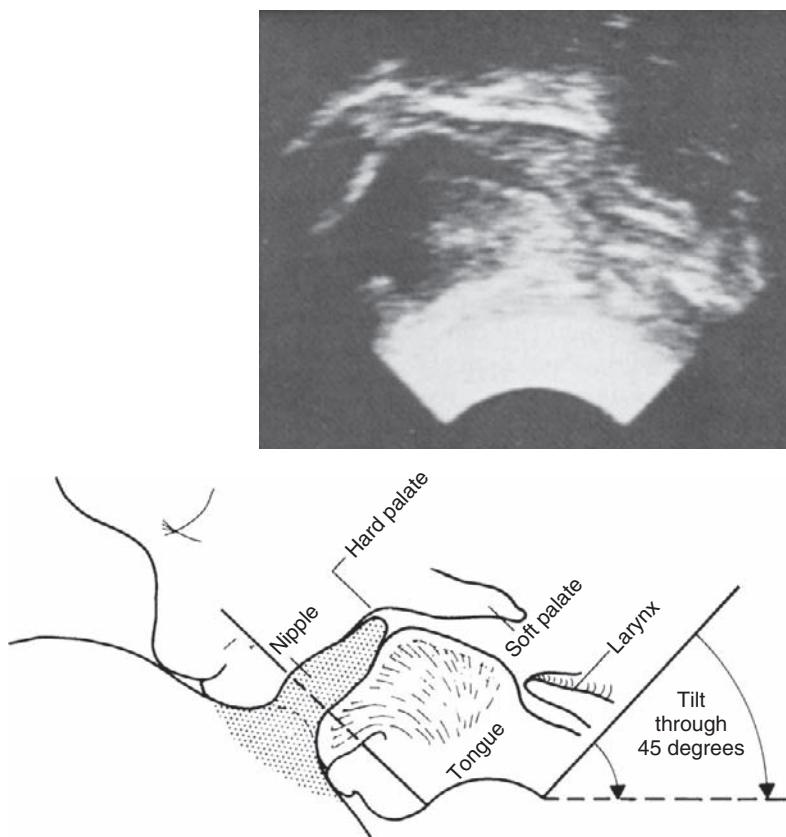

1. The nipple is sucked to the back of the baby's mouth, and a teat is formed from the nipple and the adjacent areola and underlying tissues.
2. When the jaw is raised, this teat is compressed between the upper gum and the tip of the tongue resting on the lower gum. The tongue is applied to the lower surface of the teat from the front backward, pressing it against the hard palate; the teat is reduced to approximately half its former width. As the tongue moves toward the posterior edge of the hard palate, the teat shortens and becomes thicker.
3. When the jaw is lowered, the teat is again sucked to the back of the mouth and restored to its previous size.
4. Each cycle of jaw and tongue movement takes place in approximately 1.5 seconds. The pharyngeal cavity becomes airless and the larynx closes every time the upward movement of the tongue against the teat and hard palate is completed.

#### BOX 8-2. Ultrasound Interpretation of Suckling at Breasts

1. The lateral margins of the tongue cup around the nipple, creating a central trough.
2. The suck is initiated by the tip of the tongue against the nipple followed by pressure from the lower gum.
3. There is peristaltic action of the tongue toward the back of the mouth.
4. The tongue elevation continues to move the bolus of milk into the pharynx.

The process of suckling has been described as a pulsating process similar to peristalsis along the rest of the gastrointestinal (GI) tract. This undulating motion, as described by cineradiography, did not involve stroking or friction, as was clearly pointed out by Woolridge.<sup>147</sup> The nipple should not move in and out of the infant's mouth if the breast is positioned correctly. The tip of the tongue does not move along the nipple. The positive pressure of the tongue against the teat (areola and nipple), coupled with ejection of the milk from increased intraductal pressure, evacuates the milk, not suction. The negative pressure created in the mouth holds the nipple and breast in place and reduces the "work" to refill the ducts. Visual observations and videotapes made in our laboratory to study suckling show the undulating motion of the external buccal surfaces even in newborns. Ultrasound confirms the molding of buccal mucosa and tongue around the teat, leaving no space.

In breastfeeding the tongue action is a "rolling," or peristaltic, action from the tip of the tongue to the base, not side to side. In bottle feeding the tongue action is more piston like or squeezing. When the infant rests between sucks, the human nipple is indented by the tongue, and the latex teat is expanded in bottle feeding (Figures 8-3 and 8-4).

**Figure 8-3.** Ultrasound of infant at breast. Still picture of ultrasound scan frame from video recording. Scanner head is at bottom, with a sector view of 90 degrees. Below is an artist's impression of image showing key features. Image is seen best when tilted through 45 degrees so that the infant's head is vertical. Picture corresponds to point in sucking cycle when maximum point of compression of nipple by tongue has almost reached tip of nipple. Once nipple has become fully expanded, fresh cycle of compression will be initiated at base of nipple and will then move back. (From Weber F, Woolridge MW, Baum JD: An ultrasonographic study of the organization of sucking and swallowing by newborn infants, *Dev Med Child Neurol* 28:19, 1986.)

**Figure 8-4.** Infant sucking on rubber nipple, which fills mouth and thus prevents tongue action and provides flow without tongue movement. Flow occurs even if lips are not tight around rubber hub.

The change in nipple dimensions during sucking is detailed by Smith et al.,<sup>123</sup> who also used ultrasound and examined 16 term infants ages 60 to 120 days and their mothers. They demonstrated that human nipples are highly elastic and elongate during active feeding, including approximately 2 cm of areola, to form a teat approximately twice its resting length. They also showed that infants' cheeks (buccal membranes), with their thick layer of fatty tissue, known as sucking fat pads, act to make a passive seal to create a vacuum (as opposed to the concept that the cheeks are sucked in by the negative pressure). Milk ejection was noted to occur after maximal compression of the nipple.

## COORDINATION OF SUCK AND SWALLOW

The ability to swallow is developed in utero during the second trimester and has been well demonstrated by fetal ultrasound. Fetal swallowing of

amniotic fluid is an important part of the complex regulation of amniotic fluid. The suck is actually part of the oral phase of the swallow. Little was done to examine the role of swallowing on the suckling rate until Burke<sup>17</sup> studied the role of swallowing in the organization of suckling behavior, although with a bottle and solutions of 5% and 10% sucrose solution. The author reported two major observations: "First, the frequency of swallowing in newborns increased significantly as a function of increasing concentration and amount of sucrose solution given per criterion suck. Second, there was a significant difference in the duration of the sucking interresponse times that immediately followed the onset of swallowing and the duration of interresponse times not associated with swallowing." These observations explain those of previous investigators regarding nutritive and nonnutritive sucking.

The coordination of sucking and swallowing was observed by ultrasound by Weber et al.<sup>137</sup> as a movement of the larynx. By 4 days of age, both breastfed and bottle-fed infants were swallowing with every suck. Later in the feeding the ratio of sucks to swallows changed to 2:1 or more until sucking stopped. Swallowing occurred in the end-expiratory pause between expiration and inspiration (see Figure 8-3). The change in suck/swallow ratio seemed to be a function of the availability of milk.

## FACTORS THAT INFLUENCE SUCKLING

As one manages infants with difficulty feeding, a number of rituals are often initiated to enhance infant behavior. Only a few of these have been evaluated for their effect.<sup>95</sup> The effect of the infant's position, that is, supine or supported upright to a 90-degree angle, was found to have no influence on the sucking pattern or pressure. The effect of temperature, however, was found to be significant. Sucking pressure decreased as environmental temperature increased from 80°F to 90°F (26.6°C to 32.2°C), which may have application in encouraging an infant to nurse. This effect was shown to increase from the third to the fifth day of life. Higher sucking pressures have been recorded in the morning than in the afternoon.

When the size of latex nipples was studied, the large nipple elicited fewer sucks and a slower sucking rate than smaller nipples, although the volume of milk delivered was the same, in this study, with all nipple sizes. Although human nipple size cannot be altered, this knowledge may help in assessing the response of a newborn in specific situations. Increasing nipple size and decreasing sucking rate may be significant in considering using an adult finger for finger feeding.

The volume of each swallow was calculated during breastfeeding in 1905 by Süsswein,<sup>127</sup> who counted swallows and made test weighings. His observations were later confirmed with elaborate electronic equipment.<sup>148</sup> The average swallow of a newborn is 0.6 mL, which is also the exact amount drawn from a bottle equipped with an electromagnetic flowmeter transducer and a valve that responds to negative pressure at each suck in modern studies, even though the sucking mechanism between breast and bottle is different.<sup>118</sup> The size of the hole in the nipple influences the volume of the suck only in the valved bottle. When breastfed infants were compared with a group fed by cup from birth and a group fed by bottle, the breastfed infants had a stronger suck than either of the other two groups, who did not differ from each other in sucking skill.<sup>24,26</sup>

Patterns of milk intake using electronic weighings in interrupted feeds were studied. Fifty percent of a feed from each breast was consumed in 2 minutes and 80% to 90% by 4 minutes, with minimal feeding from each breast in the last 5 minutes. Bottle-fed infants, evaluated with the same technique of test weighings, took 84% of the feeding in the first 4 minutes. Bottle feeding patterns were linear, whereas the breastfed infant had a biphasic pattern when nursed on both breasts. The total intake of the two types of feeds was similar in volume in the same 25 minutes of total time.

## FAT CONTENT AND SUCKLING

The high concentration of fat in breast milk toward the end of a feed was hypothesized as a satiety signal to terminate the feeding. When this was studied using high- and low-fat formulas, it was found that high-fat milk did not act to cue babies to slow or stop feeding.<sup>92</sup> In fact, babies appeared to feed more actively on high-fat milk, sucking in longer bursts with less resting. When human milk of low- and high-fat content was fed from bottles, switching the baby from low-fat breast milk to high-fat breast milk, the babies did not alter either milk intake rate or sucking patterns.

To test the hypothesis fully, a study carefully observed infants switching from the first to the second breast and back to the first breast. Infants were 2 months old and well established at exclusive breastfeeding. No significant difference was seen in the time taken to attach to the new breast and the time taken to reattach to the previously suckled breast. Mean milk intake from the first breast was 91.7 g (range 58 to 208 g), higher than that from the second breast (mean 52.5 g, range 8 to 75 g). The mean fat contents before and after nursing on the first breast were 23 and 52 g/L, whereas

on the second breast they were 24 and 48 g/L. This shows that infants will nurse when fat content is higher, contrary to the theory that increasing fat causes satiation.<sup>92</sup>

Studies of 3-day-old bottle-fed infants fed sucrose and glucose solutions show that they manifest tongue movements of greater amplitude when fed stronger concentrations of carbohydrate, even though they do not respond to fat content in formula. Sensory apparatus responsible for assessing sweetness is apparently competent in the newborn.

## BREATHING AND SUCKING DURING FEEDING

Breathing and sucking during feeding were studied in normal full-term infants from 1 to 10 days of age, measuring breathing, sucking, and flow of fluid from a feeding bottle with a flow meter. No infant aspirated water, but 8 of 18 infants inhaled saline. Even from a bottle, breast milk was associated with more regular breathing than was formula feeding. It has been demonstrated in other species that newborns will become apneic when fed milk from species other than their own. The coordination of breathing and swallowing improves with an increase in milk availability and with the maturity of the infant.<sup>137</sup>

## SUCKLING PATTERNS AS INDICATORS OF PROBLEMS OR PATHOLOGY

The behavior of an infant at birth is the first opportunity to observe the infant's adeptness at suckling. In a careful analysis of videotapes of newborns in the first 90 minutes of life, Widström and Thingström-Paulsson<sup>141</sup> observed a consistent pattern. Licking movements preceded and followed the rooting reflex in alert infants. The tongue was placed in the bottom of the mouth cavity during distinct rooting. The authors suggest that forcing the infant to the breast might disturb reflex action and tongue position. They further observed that a healthy infant should be given the opportunity to show hunger and optimal reflexes and attach to the mother's nipple by itself.<sup>141</sup>

Righard and Alade<sup>110</sup> observed that an infant placed on the mother's abdomen will self-attach to the breast and suckle correctly in less than 50 minutes. They further reported that when the infants were separated from their mothers for delivery room procedures, the initial suckling attempts were disturbed, and many infants were too drowsy to suckle at all.<sup>110</sup>

Righard and Alade<sup>111</sup> also investigated the prognostic value of suckling technique (faulty vs. correct) during the first week after birth in relation

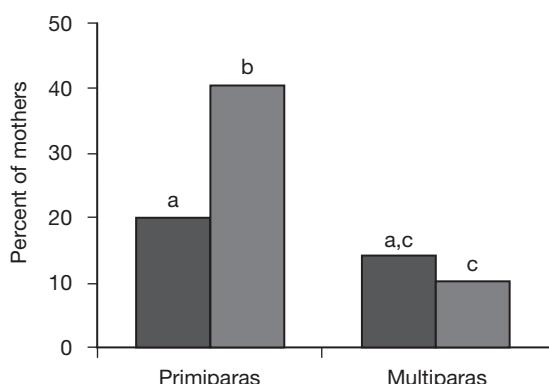

to the long-term success of breastfeeding. For assessment of breastfeeding technique, 82 healthy mother-infant pairs were observed before discharge. The authors defined correct sucking as the infant's mouth being wide open, the tongue under the areola, and the milk expressed in slow, deep sucks. Incorrect sucking was defined as the infant positioned as if bottle feeding, using the nipple as a teat. The oral searching reflex was defined as the infant opening the mouth wide in response to proximity of the nipple to the lips and thrusting the tongue forward in preparation to taking the breast. This reflex is a part of the normal response to circumoral stimulus, resulting in rooting by the infant, who comes forward, opens the mouth wide, and extends the tongue when stimulated centrally on the lower lip and even the upper lip. Stimulus on the side of the mouth or cheeks elicits turning to that side.

It was first noted by Barnes et al.<sup>12</sup> that mothers with difficult labors and deliveries had more problems breastfeeding. The influence of mode of delivery on the initiation of breastfeeding has been reported. For infants delivered by vacuum extraction or cesarean delivery, suckling was delayed and they received more supplements, C-section patients also received postdelivery narcotics, which changed suckling patterns.<sup>117</sup> Parity increases chances of success in lactation, according to Dewey et al.<sup>30</sup> They confirmed the influence of mode of delivery, duration of labor, labor medications, and the use of artificial feedings and pacifiers as well.<sup>2</sup> When these factors are present, extra care should be made to support the mother's efforts to breastfeed (Figure 8-5),<sup>30</sup> particularly monitoring at day 3 and the day of discharge.

C-section rates have risen and fewer women who deliver by C-section breastfeed. Initiation rates require more support and monitoring for C-section patients.<sup>67</sup> At 6 months the long-term success, however, is the same for both vaginal and operative patients who breastfeed.

## Medications During Labor and Epidural Anesthesia

Because of repeated concerns about the possible effect of intrapartum epidural anesthesia on a newborn infant's ability to suckle and the rising incidence of epidurals in some hospitals (more than 50% of vaginal deliveries), Rosen and Lawrence<sup>114</sup> investigated 83 mother-infant dyads who either exclusively breastfed or bottle-fed. An infant's ability to nurse at the breast or take a bottle was scored from multiple observations. Weight loss in the first few days was also evaluated. Epidural anesthesia

**Figure 8-5.** Percentage of mothers with delayed onset of milk production, by parity and infant birth weight, adjusted for mode of delivery, duration of stage II labor, maternal body mass index, and flat or inverted nipples (bars with different letters are significantly different,  $p<0.05$ ). Vertical bars, birth weight  $\leq 3600$  g; horizontal bars, birth weight  $> 3600$  g. N=69 primiparas with infants  $\leq 3600$  g, 61 primiparas with infants  $> 3600$  g, 40 multiparas with infants  $\leq 3600$  g, and 71 multiparas with infants  $> 3600$  g. (From Dewey KG, Nommsen-Rivers LA, Heinig MJ, Cohen RJ: Risk factors for suboptimal infant breastfeeding behavior, delayed onset lactation, and excess neonatal weight loss, *Pediatrics* 112:607, 2003.)

had no apparent effect (although analgesics showed a relationship) on ability to feed or initial weight loss. However, prolonged epidural use (beyond 4 hours or repeated dosing) may well have an effect because the drug has time to be absorbed into the systemic circulation.

The question of duration of epidural anesthesia was investigated by Bader et al.,<sup>11</sup> who found that maternal venous and umbilical venous levels of fentanyl and bupivacaine were relatively constant whether the epidural lasted 1 hour or up to 15 hours. Total doses varied between 27 and 200 mg for bupivacaine and 22 to 300 mg for fentanyl. Significantly, however, bupivacaine was measurable in the umbilical venous sample of the infants ( $0.15 \pm 0.06$  mg/mL). The significance of fetal tissue uptake is unclear. Umbilical artery blood gases and neurobehavioral scores were normal. Neonatal urine in another study<sup>16</sup> had small, but measurable, bupivacaine metabolites 36 hours after delivery when spinal anesthesia was used for cesarean delivery. It is noteworthy that usually the infant is delivered within 15 minutes of medication administration for cesarean delivery, so fetal exposure is minimal when used for C-sections.

The effect on infants of different doses of meperidine given to mothers in labor has been clearly demonstrated. Most hospitals no longer use meperidine.

The sucking rhythms of infants with a normal perinatal course were compared with those of infants with perinatal distress. The analysis showed

that rhythms of nonnutritive sucking were significantly different from rhythms of normal control subjects even when no gross neurologic signs were present.<sup>63</sup> Subtle difficulties with feeding are sometimes the only perinatal evidence of the impact of hypoxia, as noted by low Apgar scores.

Infants whose mothers received bupivacaine epidural anesthesia were described to be less alert and have less ability to orient over the first month of life. Bupivacaine and its metabolites are found in the circulation of infants for the first 3 days of life whose mothers had epidural anesthesia. More recent studies report use of lower doses of bupivacaine and either fentanyl or sufentanyl.<sup>74</sup> Less sufentanyl appeared in the cord blood. Only the Rosen and Lawrence study<sup>114</sup> reported the effects of epidural anesthesia on feeding ability of the neonates.

## Cesarean Delivery

The effect of cesarean delivery on breastfeeding has long been thought to be significant. With the rise in rates of cesarean delivery, the question becomes imperative. A study of 97 women who had infants by cesarean delivery and 88 who delivered vaginally was designed to determine milk production rates at each feed in the first week of life.<sup>33</sup> The volume of milk transferred to the infants born by cesarean delivery was significantly less than that received by the infants born vaginally from days 2 to 5, but volumes were comparable by day 6. Birth weight was regained on day 6 by 40% of the vaginally delivered infants but only 20% of the infants born by cesarean delivery.

A comparison of early sucking dynamics during breastfeeding after C-section showed minor differences in suckling itself; duration and milk intake were similar in both section and vaginally delivered women. Successful initiation, however, required additional lactation support and monitoring in women who were delivered by C-section.<sup>117</sup>

## Sucking Stimulus and Prolactin

When lactating postpartum women nurse their infants, the prolactin level increases from a high baseline level to levels several times over the mean baseline.<sup>5</sup> When nursing women played with but did not feed their infants, prolactin did not rise, despite the initiation of milk dripping. Substitution of a breast pump at regular intervals caused prolactin elevations similar in timing and magnitude to those induced by sucking. When normal, menstruating, nonlactating adult women were stimulated

with a breast pump for 30 minutes, significant prolactin increases occurred in 7 of the 18 women. No response was obtained in normal men.

When the prolactin response was used as a measure of "success" in establishing lactation in the first week postpartum, no difference in prolactin levels was seen between women who had been considered good producers and those who were considered poor producers.<sup>54</sup> Mothers whose infants were in the special care unit, and who were using a breast pump to establish lactation, had minimal prolactin response to pumping but produced a mean of 86 g of milk per pumping. When prolactin levels were measured after use of the breast pump at uniform settings, all three groups were similar. This and the work of others<sup>84</sup> demonstrates that infant suckling plays a significant role in adequate milk production.

Knowledge about infant suckling has been accumulating rapidly, but only recently has it involved study of suckling at the breast. It has been established that the patterns are different mechanically. At the breast, nutritive and nonnutritive suckling varies only in rate, not in pattern. Infants can suckle immediately at birth and tolerate mother's milk (colostrum) best as the pattern of respirations remains physiologic. Inadequate suckling can influence maternal production, but inadequate suckling can be improved.

Management of breastfeeding is best discussed in terms of the three stages: (1) prenatal period, (2) immediate postpartum, or hospital, period, and (3) postnatal, or posthospital, period.

## Prenatal Period

It is most effective to prepare for breastfeeding well in advance of delivery. Prospective parents should consider feeding plans for an infant during the prenatal period, after the pregnancy is well established. Once quickening (awareness of fetal movement) has occurred, an infant becomes more of a reality for the mother and she can relate to planning. Except in sophisticated cultures, the parents generally will not initiate this decision-making discussion, and it is appropriately introduced by the obstetrician, family physician, or midwife in the second trimester. Use of ultrasound and the presentation of an ultrasound picture of the fetus to the parents confirms the reality of a baby. Particularly with first children, it is appropriate to suggest to the parents that they select a pediatrician early. They should request a prenatal conference with the pediatrician to discuss not only feeding but also points of management and child rearing about which they might have questions. If the mother is receiving

prenatal care from a family practice physician, then this step is automatic.

Many mothers decide long before the pregnancy about feeding the infant, but those who choose bottle feeding admit they could have been persuaded, if only someone had cared enough to tell them how important breastfeeding is to the infant. All women know mother's milk is best. Clearly, health care providers have made breastfeeding too complicated and burdened mothers with so many rules and regulations that they cannot cope and default to bottle feeding. When health care workers try to persuade a woman to breastfeed, they perpetuate the image of a difficult chore by saying, "Why not give it a try? It's not that bad," or "You'll be surprised. It isn't that hard," instead of conveying opportunity and good experience with, "It is a marvelous opportunity for you and your baby," or "It will be a special joy." Employment is often cited as the cause of early weaning, but it is actually unemployed women who are at home bottle feeding (see Chapter 18). Any time spent breastfeeding is worthwhile for a working mother and her infant.

The medical profession has been hesitant to take anything but a neutral position in discussions of breastfeeding for fear of pressuring mothers. The evidence is stronger than ever that breastfeeding has distinct advantages for infants and mothers. Parents have the right to hear the data. They can make their own choices. Fear of instilling guilt is a poor reason to deprive a mother of an informed choice, especially because women generally do not feel guilty about their own informed decision. After interviews with hundreds of mothers, half of whom chose to bottle feed, not one felt guilty, but some were disappointed that their physician did not discuss infant feeding.<sup>114</sup>

The prenatal discussion should also include any questions the parents may have about the lactation process and a mother's ability to provide adequately for the infant. An examination of the breasts is part of good prenatal care and an excellent opportunity to discuss breastfeeding. If any anatomic abnormalities exist, then they should be discussed. The breast tissue should be checked for lumps and cysts that might need treatment. The amount of mammary tissue is not correlated with the ability to produce milk. The more generous gland usually results from a more generous fat pad. During pregnancy the fat is replaced by proliferating acini. A woman with small breasts should not be discouraged from nursing.

Breast texture should be assessed by palpation. An inelastic breast gives the impression it is firmly knit together, and the overlying skin is taut and firm so it cannot be picked up. The elastic breast is

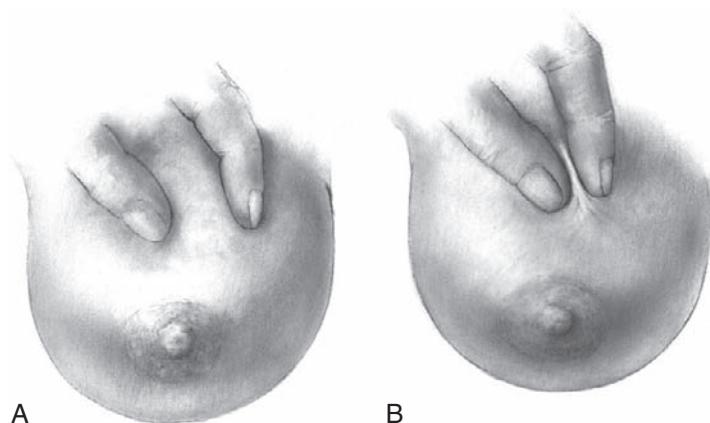

looser, the overlying skin is free, and the tissue is more easily picked up. Inelastic breasts are more prone to engorgement and seem improved by prepartum massaging and close attention to prevention of engorgement (*Figure 8-6*).

Examination of the areola and nipple is equally important to identify any anatomic problems that may need attention before delivery. Gross malformations and inversion of the nipple can be easily detected, but lesser problems may go unnoticed. One must test for freedom of protrusion. When the areola is compressed and the nipple retracts instead of protrudes, it indicates a "tied nipple," or inverted nipple, caused by the persistence of fibers from the original embryologic invagination of the mammary dimple (*Figure 8-7*).

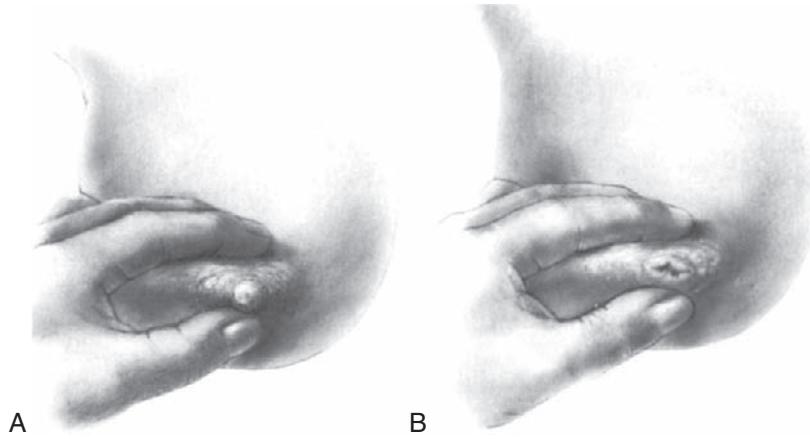

Although a physician may provide literature on breastfeeding or suggest reading sources for the patient, one should avoid dismissing the parents' questions by merely suggesting appropriate readings, because their decision making will be enhanced by open discussion with a knowledgeable professional. Although parents may have access to

childbirth preparation programs in the community, they should not be dismissed to get all their information from such sources. When parents have no opportunity to discuss with their care provider issues such as early infant contact, nursing the infant in the delivery room, and family-centered maternity care, they often experience tremendous disappointment and misunderstanding.

The concerns most frequently expressed by mothers considering breastfeeding are related to themselves, not the infant. Mothers who are more concerned about their own well-being have more trouble adjusting to motherhood and should be provided with more support in adapting to the role. They may be helped by selecting a doula to support them, because our modern culture tends to isolate young couples. Raphael describes a doula as one of "those individuals who surround, interact with, and aid the mother at any time within the perinatal period, which includes pregnancy, birth and lactation."<sup>104</sup> Doulas have been further studied by Klaus and Kennell,<sup>64</sup> who found a clear relationship between the presence of a doula in labor and the outcome of delivery, the

**Figure 8-6.** Texture of breast tissue can be assessed by picking up skin of breast. **A**, Inelastic breast tissue. **B**, Elastic breast tissue.

**Figure 8-7.** **A**, Normal nipple averts with gentle pressure. **B**, Inverted or tied nipple inverts with gentle pressure.

mother's personal experience, and her recovery period (including breastfeeding).

Concerns most frequently expressed prenatally by mothers include the following:

1. What is the effect on the mother's figure? Data indicate that breasts are affected by heredity, age, and pregnancy in that order and only minimally by lactation. Women who have never borne children may "lose their figures" long before a multipara who nurses her infants. Pregnancy enlarges breasts temporarily, as does early lactation, but the effect is temporary. Poor diet and lack of exercise will destroy a figure in both men and women long before any other influence.
2. What is the effect on the mother's freedom? Obviously, only a mother can breastfeed an infant; however, ample data support that it is possible to maintain a career, keep a job, or just get away from the house and still nurse in today's world. Mothers in primitive cultures have returned to the fields, or some form of productivity outside the home, out of sheer necessity for generations. Mothers concerned about this often are best reassured by their peers—that is, mothers who are nursing. In communities with nursing mother groups, it is a simple referral. Employment statistics have revealed that women do successfully return to the work force and continue breastfeeding. Employment is rarely a reason for not breastfeeding, but it may influence duration ([Chapter 18](#)).
3. Many women are concerned about exposing their breasts. Despite the constant barrage of publicity about breasts in the modern press, many women are embarrassed to consider baring their breasts. As pointed out in [Chapter 6](#), shame and embarrassment are important considerations when helping a mother accept breastfeeding. Shame and anxieties arise from the influence of one's life history and previous events; thus intervention is necessary at many levels. Clothes that make discreet breastfeeding possible are readily available and fashionable. Considerable body exposure is not necessary for breastfeeding. In a public survey performed in the Midwest, few people, male or female, in any age group considered breastfeeding embarrassing, and 82% would want their child breastfed. Universal publicity about breastfeeding in public places has created a more accepting attitude in most people, so that a nursing mother no longer needs to hide to feed her infant.

## *Preparation of the Breasts*

---

The prenatal period is a time for a couple to prepare for their new role as parents and to learn as much as

possible about breastfeeding. Most mothers do no special preparation and are successful. Carefully controlled studies do not support the contention that fair-skinned women, especially redheads, are more prone to developing cracked, sore nipples than are others. Mothers who have had trouble with tender, cracked nipples when nursing a previous infant will need extra assistance in putting the infant to breast properly in the first few days, but elaborate rituals prenatally may actually cause problems. Nipple preparation has a negative effect on some women who are not ready to handle their breasts for these preparations during pregnancy and has not proved to make a difference. Proper positioning is highly important.

Bathing should be as usual, with minimal or no soap directly on the nipples and thorough rinsing. Some recommend patting the nipple dry with a soft towel, but this should not be done except after a shower or bath. Persistent removal of natural oils of the nipple and areola actually predisposes the skin to irritation. Montgomery glands in the areola secrete a sebaceous material for the cleansing and lubrication of the areola and nipple. This should not be removed by soaps or chemicals. Tincture of benzoin, alcohol, and other drying agents are contraindicated because they predispose the nipples to cracking during early lactation.<sup>84</sup> Wearing protective brassieres, modern women do not experience the friction to the nipples that looser clothing causes, which may be why cracked nipples are a common problem in modern society but almost unheard of in developing countries and among other mammals. In Scandinavia, it is suggested that pregnant women get as much air and sunshine as possible directly on the breasts before delivery. Wearing a nursing brassiere with the flaps down to expose the nipples under loose clothing serves the same purpose. However, aggressive and abrasive treatment of the nipples does not prevent nipple pain postpartum and may aggravate it. Gentle love making involving the breasts is usually safe and is the most effective preparation.

The use of lanolin, which is miscible with water and thus allows normal evaporation from the skin, does no apparent harm but in controlled studies also made no difference prenatally. Women allergic to wool will also be allergic to lanolin. The use of vitamin A and D ointment prophylactically also makes no difference, having an effect only in the treatment of fissures later. In climates with average to high humidity, ointments are not routinely recommended for breasts and may interfere with Montgomery gland secretion. In extremely dry climates, using ointments sparingly is often necessary.

Some believe gentle traction to the point of discomfort, but not pain, reduces perception of pain in the first week of lactation. A study, carefully

controlled to eliminate subjective discrepancies of interpretation, revealed no significant difference in nipple sensitivity or trauma in those who practiced prenatal nipple rolling, application of breast cream, or expression of colostrum compared with those who had untreated breasts.<sup>58</sup> No increased pain or trauma was reported among fair-skinned participants in the study, treated or untreated. Because many women are not inclined to manipulate their breasts before delivery and might be discouraged from breastfeeding if it is implied that this must be done, physicians should prescribe treatment only when an indication exists.<sup>146</sup>

## *Preparation of the Nipples*

Flat nipples or inverted nipples do not preclude breastfeeding. Flat nipples respond to the same passive treatment with a breast shell that works for inverted nipples. The shells can be worn during the last trimester by women who choose to do so (Figure 8-8). They should be recommended only after careful examination and discussion about advantages and disadvantages by the physician. Follow-up at subsequent prenatal visits is also appropriate.

Alexander et al.<sup>3</sup> estimated that 10% of pregnant women have inverted or nonprotractile nipples, which are thought to contribute to breastfeeding problems.<sup>3</sup> Breast shells (plastic disks with holes in the center and a domed cover) (see Figure 8-8) and Hoffman exercises<sup>52</sup> (stretching and pulling of the nipple and areola, vertically and horizontally) are the most common treatments suggested. Alexander et al.<sup>3</sup> compared use of shells with no treatment and found more sustained improvement in the untreated group. The difference in use of

shells/no shells was 52% and 60%, which is not significant. A large multicenter trial of shells, Hoffman exercises, and no prenatal treatment showed "no treatment" to be most effective.<sup>107</sup> Nipple stretching has had no significant impact and is contraindicated because of its tendency to initiate uterine contractions. The most significant finding was that more women who were instructed to wear shells or do nipple exercises than control subjects who had no prenatal preparation failed to initiate breastfeeding at delivery. More study women also discontinued breastfeeding by 6 weeks compared with control subjects. The women complained that shells caused discomfort, embarrassment, sweating, rash, or milk leakage or were conspicuous.

Such studies illustrate some of the risks of using untried methods to solve problems, although some women probably benefit by using shells. The question deserves further study. The process of assessing anatomic problems and initiating management should not be a deterrent to breastfeeding.

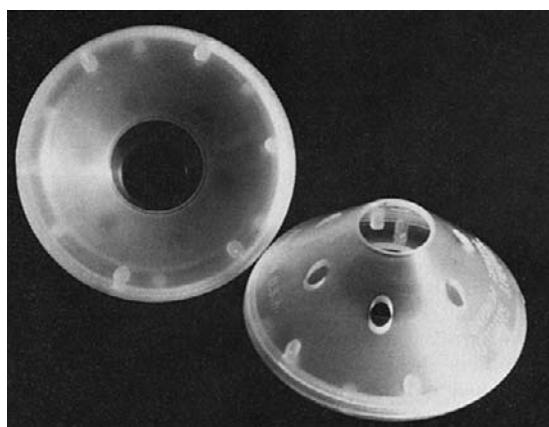

Inverted nipples (see Figure 8-7) can be diagnosed by pressing the areola between the thumb and the forefinger. A flat or normal nipple will protrude; a truly inverted nipple will retract. True inverted nipples are actually rare. Mildly retracting nipples can be improved with gentle stretching to evert them, preferably done before delivery.

One or both nipples may be pierced and may have jewelry inserted. The jewelry should be removed during pregnancy, or as soon as observed, to allow the nipple to recover and avoid any infection. Usually nursing proceeds without a problem. Sometimes milk will leak from the piercings. It can be absorbed by keeping a washcloth handy. The jewelry should not be worn while breastfeeding. The major risk to the mother is infection, which can be avoided by good hygiene and not wearing the jewelry. The risk of the infant swallowing the jewelry if left in place is monumental.

## *Nipple Stimulation to Induce Labor*

The obstetric literature abounds with articles about the use of nipple stimulation in place of the traditional oxytocin challenge test to induce uterine contraction; only a few are cited here.<sup>20,21,79</sup> Using a breast pump or manual expression to produce colostrum is reported to induce labor or increase the strength of contractions in desultory labor.

Taylor and Green<sup>128</sup> reported a case of severe abruptio placentae after nipple stimulation. A series of patients induced labor with self-manipulation of the breasts with a 45% success rate. All patients in the series showed some ripening of the cervix with dilatation and effacement in 3 days of breast stimulation. Lipitz et al.,<sup>73</sup> Amatayakul et al.,<sup>5</sup>

**Figure 8-8.** Breast shells: vented domes worn over ring that allows nipple to evert. Shell is slipped into cup of well-fitting brassiere. Available in several styles and designs.

and Taylor and Green<sup>128</sup> reported a relatively high incidence (45.5%) of exaggerated uterine activity in response to a breast-stimulation stress test, usually within 7 minutes of initiation of stimulation. Although all the cases and series cannot be reported here, it is clear that nipple stimulation in the third trimester can initiate uterine contractions and, in some, labor. Under the direction of an obstetrician, breast stimulation can be effective therapeutically, but it should not be attempted without obstetric evaluation and guidance.

Suggesting stretching (Hoffman) exercises is not advised, especially in women with a tendency to early labor. No study since Hoffman's initial report of two cases<sup>52</sup> has shown the process to be effective in the nipples. Stretching the areola forcefully can damage the delicate Montgomery glands. Prepartum mastitis has also occurred with prenatal expression of colostrum. Whether manipulating the breast prenatally provides the mother with greater comfort in breastfeeding has not been demonstrated. Mothers who choose to bottle feed have told us that having to "exercise" their breasts is one of the "rules" that kept them from breastfeeding.

Pumping with a pulsatile electric pump with a soft Silastic flange has been shown to facilitate latch-on with flat or inverted nipples after delivery. The breast is gently pumped on low settings until the teat is drawn out, and then the infant is offered the breast. Similar pumping is done on the second breast, when that nipple is also inverted, before placing the infant on that breast. Usually the pumping can be discontinued after a few days, or a hand pump is adequate if preferred. Pumping needs to be continued at home to evert the nipples.

These approaches avoid the risk for never initiating breastfeeding. They also provide one-on-one support from the nursing staff, which is very different from sending the mother home to use a strange plastic device.

An infant breastfeeds. An infant does not nipple-feed. If the nipples are flat or inverted, extra care is needed to provide enough areolar tissue in the infant's mouth to allow latch-on. Experienced postpartum nurses can facilitate the breastfeeding experience by assisting with the initial latch to the breast.

## *Surgical Correction*

Inverted nipples have been known to medicine for centuries. Treatment has included various exercises, use of older vigorous infants to suckle, and the use of adults who are hired for this purpose in difficult cases. The first surgical procedure was described in 1873. Other techniques have since been advanced.<sup>46,105</sup> A primary indication for

surgical repair of the inverted nipple is the chronic occurrence of central pockets of inflammation of the nipple, leading to the spread of infection and infectious mastitis. A simple method for correction without division of the lactiferous ducts involves using a purse-string suture and traction of holding sutures. The procedure can be done in the office under local anesthesia, according to Hauben and Mahler.<sup>46</sup> A truly inverted nipple may have fewer ducts. The microscopic pathologic examination of severely inverted nipples indicates the ducts are abnormal.

## *Hand Expression Prenatally*

Some breastfeeding instructions suggest hand expressing the breast to produce a few drops of colostrum every day for the last few weeks of pregnancy. Fortunately, the instructions usually suggest the patient consult her physician first. Manual or any kind of pumping of the breasts may stimulate the uterus to contract. Hand expression has no particular benefit and means that the early-sequestered cells are expressed away in the drops of colostrum before delivery and are lost to the infant. Occasionally, prepartum mastitis has developed from this treatment. The risks far outweigh any seeming benefit.

## *Summary*

1. During the first trimester, make the initial breast examination. Initiate the discussion about how the infant is to be fed and the benefits of breastfeeding. If anatomic variations may interfere with lactation, mention them and discuss possible remedies.
2. At each prenatal visit, offer information about breastfeeding.
3. Investigate the mother's knowledge of breastfeeding, and document her information base to fill in the gaps and correct misinformation. Also inquire about any treatments or routines she has initiated on her own, so that the total management is appropriate.
4. Once quickening has been experienced, the parents are ready to plan more concretely about the baby. Suggest a visit with the pediatrician.
5. As delivery approaches, initiate discussion about feeding the infant immediately after birth, feeding protocols, and the mother's special needs or requests.
6. Be familiar with community resources so that patients can be wisely referred for peer support or assistance unavailable from one's office staff.

7. As more women are electing to breastfeed, consider adding a board certified lactation consultant to your staff.

## **Immediate Postpartum Period**

Immediately after the placenta has separated, the establishment of lactation begins. This is a critical period because many mothers who do not receive the proper support in the hospital are driven to failure at breastfeeding by inept management.

### **NURSING AT DELIVERY**

Every birthing center, certified as "Baby Friendly" or not, should provide the basic minimal management recommended by the ten steps of the Innocenti Declaration.

A mother should be assisted to nurse the infant promptly after delivery and certainly within 30 to 60 minutes. Even if she does not ask, the obstetrician and delivery room staff should suggest and facilitate it.<sup>110,142</sup> It is step 4 of the 10 steps. Data confirm the view that delivery room or birthing center protocols that intercept interaction and suckling between mother and infant also have a negative impact on long-term lactation success.

Oxytocin levels at 15, 30, and 45 minutes after delivery are significantly elevated, coinciding with the expulsion of the placenta. Oxytocin has been associated with positive maternal feelings and with maternal bonding; thus it is appropriate to optimize mother-infant interaction at this point of high oxytocin levels by facilitating suckling.<sup>86</sup>

Disease-oriented physicians, who have been trained to give trials of water first, hours after delivery, are always concerned that the infant may aspirate. Clinical signs of potential for aspiration include low Apgar score, increased secretions, and polyhydramnios. Actually, most infants in the world go straight to the breast on delivery, which has a physiologic effect on the uterus, causing it to contract. Because sugar water and cow milk formulas are irritating to the lungs if aspirated, delay in feeding has been the rule in the United States, where most infants are bottle-fed. Colostrum is not irritating, however, and is readily absorbed by the respiratory tree if aspirated, providing IgA as well in the pulmonary tree. Putting the infant to the breast within the first hour is optimal and compatible with Baby Friendly hospital guidelines.

A few possible obstacles exist to immediate nursing: (1) a heavily medicated mother, (2) an infant with a 5-minute Apgar score less than 6, and (3) a premature infant less than 35 weeks of gestation. The concern for an infant with a

tracheoesophageal fistula is important, but a few precautions should suffice. If hydramnios or excess secretions are present at birth, a tube should be passed to the stomach to make sure the esophagus is patent. If all is well, the infant may nurse. If a tracheoesophageal fistula is found, it is a surgical emergency. Choanal atresia is another anomaly that would be of concern, but infants cannot suck on the breast, or on anything, if they cannot breathe through the nose. Usually an infant with choanal atresia has a low Apgar score or needs some assistance in establishing respirations. Infants are obligate nose breathers.

As noted earlier, healthy newborns placed on the mother's abdomen will find their way to the breast and latch on if unimpeded.<sup>110</sup> For this first breastfeeding, it may be best to have the mother on a bed wide enough to have the infant lie beside her. Newer delivery tables are wide enough. An infant should not be dangled in midair over the breast. If an infant has not been allowed to crawl up to the breast, then the mother should be assisted to turn onto her side. The infant should be presented to the breast, with the ventral surface of the infant to the ventral surface of the mother. The infant should not have to turn the head toward the breast. The mother may need assistance in holding her breast so as to present the nipple squarely into the infant's mouth, which is stimulated to open by stroking the center of the lower lip with the nipple.

When the nipple touches the lower lip, the infant will open widely and extend the tongue under the nipple. The breast will be drawn into the mouth, the nipple and areola elongated into a teat, and the suckling reflex initiated.<sup>111</sup>

Both mother and infant will do better if there is an atmosphere of tranquillity in the room.<sup>106</sup> The other risk to the infant is thermal stress. If the room is air-conditioned, it may be necessary to provide a radiant warmer over the infant and mother, especially if the infant is naked for skin-to-skin contact. Some mothers have shaking chills following the strenuous event of labor and cannot provide adequate warmth for the infant without some external source of heat or a blanket.

Chilling an infant may set off a chain of events from hypothermia to hypoglycemia to tachypnea to mild acidosis to the extent of requiring a septic workup. Hypothermia is therefore more easily prevented than treated.

If possible, mother, father, and infant should remain together for the next hour or so. The first hour for the infant is usually one of quiet alertness, a state that will usually recur only briefly again in the next few days. It is important to delay the instillation of prophylactic eyedrops until after this time spent with the mother. If the drops are put into the eyes, blepharospasm will prevent the infant from

opening the eyes and will mar eye-to-eye contact and further adaptation of the neonate. Only if there is a known risk for gonorrhea should the drops be put in immediately. If the mother has delivered in a birthing center, early contact and nursing should be part of the routine; however, it is equally important for all deliveries.

Protocols in delivery rooms for nursing procedures have included the prompt administration of eyedrops before leaving the delivery area, which is not based on medical necessity but rather hospital management and nursing control.

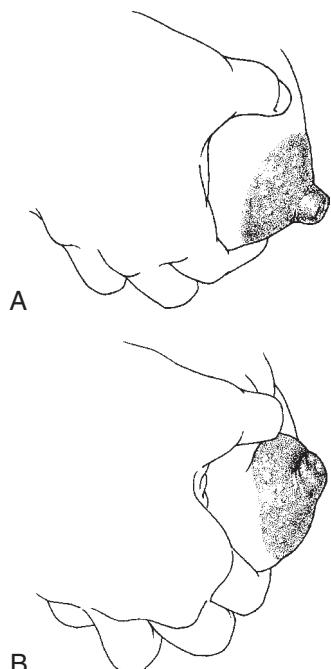

Two natural hand positions for the mother to introduce the breast are used most often. With attention to a few details, either position works (one is not right and the other wrong). The scissor grasp is the placement of the thumb and index finger above the areola and the other three fingers below the breast for support, thus allowing some compression of the areola. Care should be taken that the hand is not in the infant's way of getting sufficient areola into the mouth ([Figure 8-9](#)). This grip has been used for centuries and was shown in sketches and paintings even before the Christian era. It may work better than the palmar grasp if the hand is large or the breast small.

The palmar grasp is the placement of all the fingers under the breast and only the thumb above ([Figure 8-10](#)). This has been called the C-hold but is actually a V-hold, depending on the size of the breast and the size of the hand. This gives firm support to the breast. It permits directing the breast squarely into the infant's mouth and avoids the need to press the breast away from the infant's nose. The palmar grasp is similar to the prehensile grasp of apes when they nurse their young.

Apes, however, are unable to assume another hand posture neurologically or anatomically. If too much pressure is exerted by the human thumb,

**Figure 8-10.** Palmar grasp for initiating breastfeeding.

**Figure 8-11.** Palmar grasp (C-hold). **A**, When palm and fingers cup breast with support and thumb rests lightly above areola, nipple projects straight ahead or slightly downward (correct). **B**, When fingers come forward and thumb presses firmly above, nipple tips up and causes improper positioning. Improper positioning is a common cause of nipple abrasion (lower half) and pain with suckling. (Modified from Higgins K: *The nursing mother's companion*, ed 2, Boston, 1990, Harvard Common Press.)

**Figure 8-9.** Scissor grasp, presenting breast while supporting infant.

the nipple will be tipped upward ([Figure 8-11](#)), causing abrasion of the underside of the nipple. It is preferable that the nipple be directed horizontally as it is placed in the mouth (see [Figure 8-11](#))

or tipped down slightly. The palmar grasp can be used when there is nipple pain, soreness, or trauma. It is also useful when the mother's hand is too small for a large breast. The mother should be encouraged to use the hand position that is most natural and comfortable.

## DAYS IN THE HOSPITAL

A physician should see that patients are permitted to have their infants with them as much as they wish, within the guidelines of reasonable medical care. Only the few patients with difficult deliveries, cesarean delivery with medication, postpartum complications, or eclampsia need to be excluded. The mother's physician should make that judgment.

The influence of mode of delivery on initiation of breastfeeding was examined in 370 primiparas. Cesarean delivery and other surgical delivery procedures (e.g., vacuum extraction) were associated with a sleepy infant, late start to feeding after delivery, increased incidence of bottle supplementation, less frequent night feedings, and delayed milk production in the hospital.<sup>133</sup> Despite many interventions, breastfeeding can succeed with sufficient support. An experienced nursing staff is critical to the management of the nursing mother in the first few days postpartum. Advice should be reasonable and consistent, and nurses should be cautioned against interjecting their own personal opinion or experience. When too many individuals are involved in postpartum care, mothers are easily overwhelmed with information, especially if each person says something different. The hospital should provide at least one staff member who is also a board-certified licensed lactation consultant for every 15 postpartum patients.

Key points in management should include the following:<sup>100</sup>

1. Feed when the infant is showing signs of hunger (Box 8-3).
2. Help the mother find a comfortable position. No rules should exist about sitting up or lying down on her side or on her back.

### BOX 8-3. Signs of Hunger in an Infant

1. Begins to stir.
2. Brings hand(s) to mouth.
3. Shows increasing efforts to root.
4. Increasing activity, arms and legs flexed, hands in fists.
5. If not picked up, progresses to frantic movements, whimpering.
6. Cries (a late sign of hunger).

3. Help the infant to the breast. The infant should be held so that the ventral surface of the infant faces the ventral surface of the mother.
4. Help the mother hold her breast for her baby, choosing the better grasp for the situation, and draw the baby to the breast by moving her arm toward her chest. Note: Never push the infant's head toward the breast because the infant will push back, often arching away from the breast. Holding or pushing the infant's head has been associated with persistent arching by the infant (arching reflex).
5. Help the mother reposition the infant on the second breast if the infant is still interested after releasing the first side. Moving may be difficult for the mother immediately postpartum.
6. If the infant falls asleep after the first breast, the mother should be shown how to break the suction with her finger. Nonnutritive suckling while asleep is especially irritating to the nipple in the first few days. The mother should wait a little, wake the baby, and then move the infant to the second side.
7. When waking an infant to initiate feeding, unwrapping the blanket and using gentle stimulus are appropriate. Jackknifing is never appropriate and may cause regurgitation, aspiration, or trauma to vital organs. Usually infants feed best when they are ready.
8. The infant will nurse on the first breast until satisfied. After gentle burping, if the infant is still awake, the second side can be offered. The next feeding should be initiated on the second side. This will balance the stimulus to the breasts in the critical early days when milk production is just beginning.
9. Signs of satiety: Sounds of swallowing dwindle and stop, nonnutritive suckling occurs in brief bursts, arms and legs relax, and the infant falls asleep and usually releases the nipple.

Stopwatch timing is not appropriate. It takes 2 to 3 minutes for the let-down reflex to produce milk in the early days, so the feeding must allow for the let-down. It is helpful for some mothers to have guidelines or estimates from which to work. Usually, infants nurse about 10 to 15 minutes per feeding in the first days. Nursing continually hour after hour may be counterproductive. Frequent small feedings will provide good stimulation to the breast without stressing the mother. The milk supply, however, is best stimulated by suckling.<sup>98</sup> The policy of the nursery should be to have all breastfed infants taken to their mothers when they awaken during the night,<sup>71</sup> if they are not already rooming-in.

In keeping with the Baby Friendly Hospital Initiative (see Chapter 1), infants should be nursed on

demand around the clock and receive no other food or drink. A mother and infant should be housed together unless there is a medical contraindication. Modern hospitals are a hubbub of activity, though, and with liberal visiting hours, the mother has no time to rest unless naps are scheduled. In the early days of the Rooming-In Unit at the Yale-New Haven Hospital, Barnes et al.<sup>12</sup> insisted that all postpartum mothers have a nap after lunch. Every day the shades were drawn and traffic decreased on the unit for an hour. This is part of mothering the mother. In primitive cultures, mothers are groomed, fed, and protected after delivery, often for weeks. Furthermore, adequate rest is essential to successful lactation. In 1953, Jackson, with Barnes and other colleagues,<sup>12</sup> prepared a classic description of the management of breastfeeding that remains the single most valuable source of information on the subject.

## *Diagnosing Breastfeeding Problems*

To solve the problem of unsuccessful nursing, someone should observe a mother feeding the infant. Often the problem is a simple one, such as a mother so uncomfortable and tense that the let-down reflex will not trigger or perhaps an infant with a poor suck or poor latch. In these cases and others the diagnosis can be made most easily by direct observation.

In addition to a mother's hand position, the manner in which the infant is held or placed to breastfeed is important. There is no one right position. Shortly after birth, lying down may be preferable for the mother. She lies on her side and the infant is placed on his or her side facing the breast, which the mother supports with her upper hand. She can use her lower hand to cradle the infant and bring him or her close. Pillows help sustain the mother's position with one against her back and one between her knees. The pillow between the knees is essential to keep her from rolling over should she drift asleep. She may also lie semiinclined. When a mother is sitting up, the cradle position, with the mother bringing the infant to the breast while cradling the infant in her bent elbow, is the most common and natural position, especially once a mother is home.

Head control can be a problem with the cradle position the first few days, as the infant requires more support to hold the head.

The cross-cradle or cross-over hold works best with mother sitting erect and one to two pillows in her lap so the baby is just at the level of the breast and not above the breast. Short women may only need one small pillow. The infant is held with the opposite arm so that the infant's head and

**Figure 8-12.** Cross-cradle position.

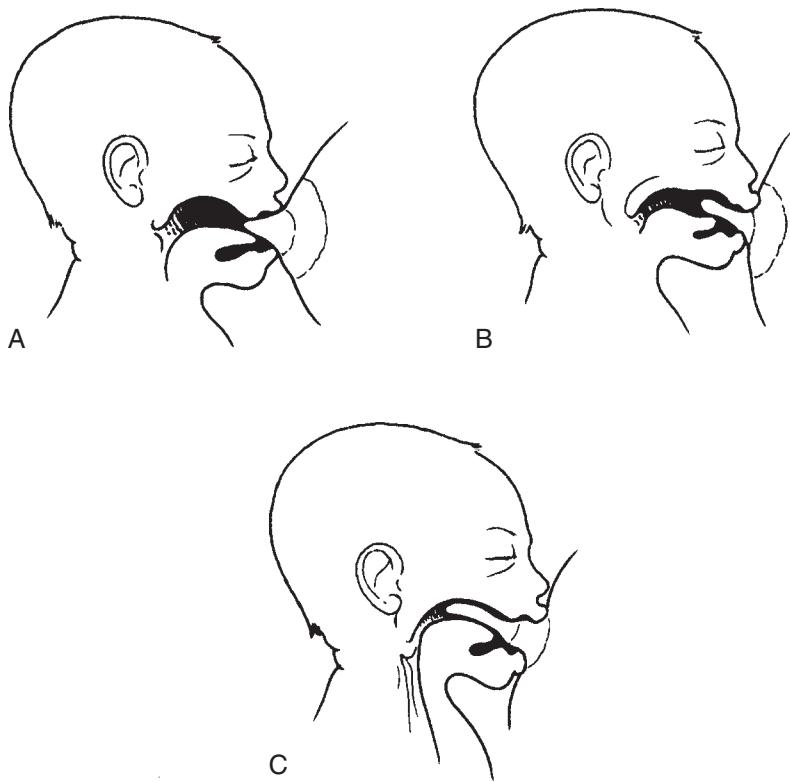

shoulders are held (Figure 8-12). The thumb is below one ear and the fingers are below the other ear. With the head tipped back slightly and the infant brought to the breast, the nipple can stroke the infant's lower lip. Visual demonstration of the latch is available online. "Fifteen-Minute Helper" is a physician-produced video for the physician audience created by Jane Morten, MD, from Stanford University. There is a link at [www.nursingmotherscompanion.com/resources](http://www.nursingmotherscompanion.com/resources).

The football hold is a misnomer; the infant is not tucked under the arm like a football but rather forward so that mother supports the infant's head with her hand and the infant is supported by the mother's arm. The infant must be squarely facing the breast.

These traditional postures were called into question by Colson et al.,<sup>22</sup> who observed less effective breastfeeding and declining duration in spite of aggressive maternal training in their programs. They studied 40 mothers and infants in England and France doing feeding videotapes during the first month. They described and compared primitive neonatal reflexes, investigating whether certain feeding behaviors and positions, termed *biological nurturing*, are associated with the release of these reflexes that they thought were pivotal to establish successful breastfeeding. When mothers chose their own body positions, they selected semiinclined positions, making the infant an abdominal feeder displaying antigravity reflexes, which aid in latching. Gravity pulled the infant's chin and tongue forward, triggering mouth opening to achieve attachment. At the very least, it suggests that alternatives to side lying and sitting upright are viable positions to initiate lactation.<sup>22</sup>

Introducing all the possible positions is overwhelming at first and should be avoided. With a little practice, mothers will find what works best.

Understanding the mechanism of suckling in the neonate (Figure 8-13), however, is essential to recognizing ineffective sucking. As the breast is offered to the infant, the mouth opens wide and

**Figure 8-13.** **A,** As infant grasps breast, tongue moves forward to draw in nipple. **B,** Nipple and areola move toward palate as glottis still permits breathing. **C,** Tongue moves along nipple, pressing it against hard palate and creating pressure. Ductules under areola are milked, and flow begins as a result of peristaltic movement of tongue. Glottis closes. Swallow follows.

**Figure 8-14.** Latch-on response. In response to stimulating infant's lower lip with nipple, mouth opens wide. This response has been called oral searching reflex. It is part of the circumoral rooting reflex. (From Righard L, Alade MO: Sucking technique and its effect on success of breastfeeding, *Birth* 19:185, 1992.)

the tongue is extended as the nipple is drawn into the mouth ([Figure 8-14](#)). In a rhythmic motion, the tongue moves up against the hard palate, as it draws the nipple and areola into the mouth, creating an elongated teat. The cheeks fill the mouth because

of the sucking fat pads and provide further negative pressure because they do not collapse. The tongue undulates along the teat, while remaining in place, compressing the collecting ductules in the areola and "milking" them toward the nipple.

This undulation is peristalsis, which continues from tongue to pharynx and the entire gastrointestinal track. Milk flows from the nipple and is swallowed as the swallowing reflex is triggered, and the peristaltic wave continues to the posterior tongue and pharynx and down the esophagus.

If an infant has a fluttering tongue that is dis-coordinate, it may not be as productive in stimulating ejection. If the infant cannot coordinate suck and swallow, choking occurs. Sometimes, if let-down is strong, the first rush of milk will cause choking. Stopping and starting again should solve the problem. If the mother's milk flows abundantly with first let-down, she may need to express manually (and save) the first few milliliters to avoid choking the infant. Usually the flow moderates in the next few days. This problem is temporary or is limited to times when the infant has not been nursed for an unusually long interval. Positioning the infant over the breast with the mother on her back may diminish the flow due to gravity in these special cases.<sup>22</sup>

If an infant's jaw is slightly receding, the nipple may not stay in place. Gentle support from the mother's index finger at the angle of the jaw, bringing it forward, will help. She may always have to support the breast with her hand (see Chapter 14).

An infant who is given a bottle or rubber nipple to suck can become confused because the milking action is different (see Figure 8-4). The relatively inflexible rubber nipple may keep the tongue from its usual rhythmic action. In addition, the flow from the bottle may be so rapid, even without sucking, that the infant learns to put the tongue against holes in the rubber nipple to slow down the flow. Some infants who have been breastfed gag when the relatively large rubber nipple is put in their mouths. When infants use the same tongue action needed for a rubber nipple while at the breast, they may even push the human nipple out of the mouth. When infants cannot grasp an engorged areola properly, they will clamp down on the nipple with the jaws, causing pain in the nipple and disrupting the ejection reflex. Manual expression of a little milk will soften the areola, permitting compression by the mother's hand and an easier grasp by the infant.

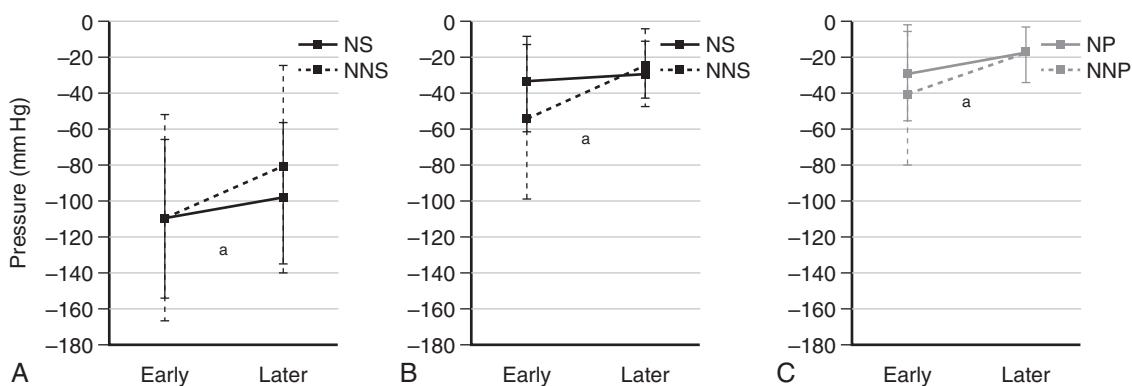

A study of suck-swallow-breathe, oxygenation, and heart rate patterns had not been performed in breastfeeding infants. No measurements had been taken over the first 4 months of lactation in term infants. Fifteen infants were studied by Sakalidis et al.<sup>117</sup>

Simultaneous recordings of vacuum, tongue movement, respiration, swallowing, oxygen saturation, and heart rate were measured at about 1 month and at 2 to 4 months.

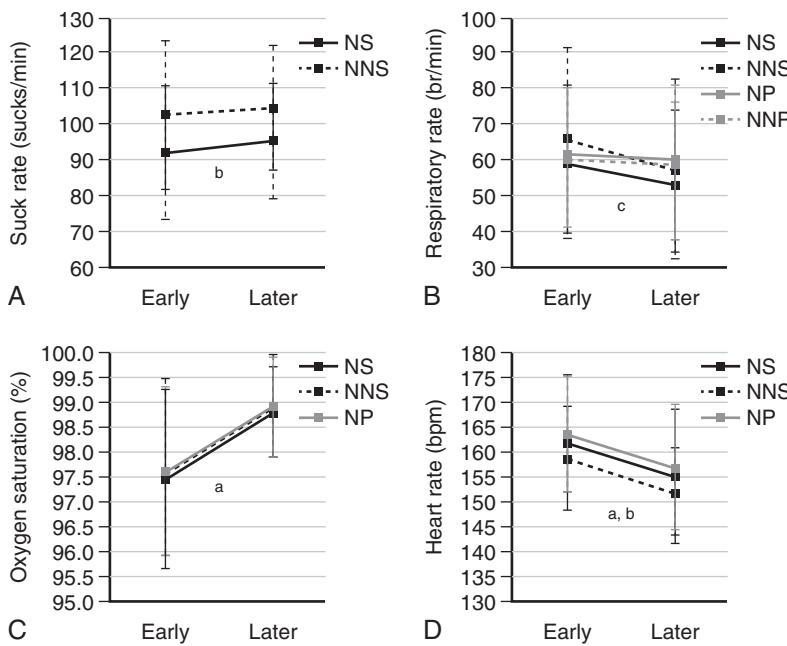

Suck bursts became longer, pauses became shorter, vacuum levels decreased, oxygen saturation increased, and heart rate decreased as the infants matured. They consumed a similar amount of milk in a shorter time period (Figures 8-15 and 8-16).

When observing an infant being breastfed, take note of the following:

1. Position of mother, body language, and tension. Pillows may provide support for the arms or the infant.
2. Position of infant. The infant's ventral surface should be to the mother's ventral surface, with the lower arm, if not swaddled, around the mother's thorax. The infant cannot swallow if the head has to turn to the breast, and grasp of the areola will be poor. The infant's head should be in the crook of the mother's arm and moved toward the breast by the mother's arm movement if cradle hold is used.
3. Position of mother's hand on breast is not in the way of proper grasp by infant.
4. Position of infant's lips on areola about 1 to 1½ inches (2.5 to 3.7 cm) from the base of nipple, thus facilitating the formation of the teat.
5. Lips should be flanged and lower lip not folded in so that the infant does not suck it.
6. Actual events around presenting breast and assisting the infant to latch on.
7. Response of the infant to lower lip stimulus by opening mouth wide (see Figure 8-14).
8. Motion of masseter muscle during suckling and sounds of swallowing.
9. Ratio of sucks to swallows should move to 1:1 as feeding progresses.
10. Mother is comfortable with no breast pain.

**Figure 8-15.** Significant relationships for vacuum between burst type and visit. Average vacuum levels for (A) peak, (B) baseline, and (C) pausing vacuums during early and later lactation. NNP, nonnutritive pausing; NNS, nonnutritive sucking; NP, nutritive pausing; NS, nutritive sucking. <sup>a</sup> $P<0.05$  for interaction with burst type and visit. ## ENGORGEMENT

The best management of engorgement is prevention. The degree of engorgement lessens for a woman with each infant, because the time during which the milk "comes in" seems to shorten in multiparas. The primipara suffers most from engorgement.

Breast engorgement was carefully documented by Humenick et al.<sup>55</sup> for 14 days postpartum in 114 breastfeeding women. Four distinct patterns emerged, varying from minimal engorgement to intense engorgement and including a bell-shaped and a multimodal pattern. Characteristics of mothers, infants, and feeding frequency were similar across all patterns. Engorgement in these women was increased in women breastfeeding for the second time, with women breastfeeding for the first time peaking at about 108 hours and second-time feeders at 100 hours. Engorgement cleared more quickly the second time. Clearly, mothers' experiences differ under seemingly similar circumstances. With early discharge, mothers are already home when it occurs.

A number of often conflicting theories and explanations regarding engorgement have been proposed in the professional and lay literature. The dictionary defines engorgement as "swollen with blood," and pathologists define it as "congestion." Engorgement of the breast involves three elements: (1) congestion and increased vascularity, which is the physiologic response that follows removal of the placenta and does not depend on suckling; (2) accumulation of milk, also a physiologic response to placental

removal; and (3) edema secondary to the swelling and obstruction of drainage of the lymphatic system by vascular increases and fullness of the alveoli. No parallel exists in nature because the underlying process is physiologic. Engorgement is not injury, hemorrhage, or trauma. When the physiologic process proceeds smoothly, no pain, discomfort, or excessive swelling occurs. When edema is identifiable, the surface of the breast pits with pressure. The process is then out of control, and intervention is necessary.<sup>51</sup> It is important to distinguish engorgement from mastitis and gigantomastia, which are discussed in Chapter 16.

Engorgement may involve only the areola, only the body of the breast (so-called peripheral engorgement), or both. A little bit of engorgement is normal. When the breast does not respond with engorgement and "fullness," this is abnormal and requires attention.

## Areolar Engorgement

When the areola is engorged, it obliterates the nipple and makes properly grasping the areola impossible for the infant. If the infant sucks only the nipple, it is exquisitely painful, because this is the only area of the breast with pain fibers. In addition, the collecting ductules are not "milked" and therefore do not empty, and the infant is frustrated by lack of milk.

The treatment is directed toward reducing the engorgement so that the infant can nurse effectively, which will further reduce the overdistended

**Figure 8-17.** Position for manual expression of breast. Thumbs are brought toward areola, compressing areola between thumb and supporting fingers. With areola grasped, pressure is applied toward chest wall, and then pressure is released. This compression and pressure stimulate milking action.

ducts. Gentle manual expression by the mother usually produces a small amount of flow and softens the areola. The presence of milk on the nipple will further encourage the infant's sucking. Warm soaks just before a feeding may facilitate manual expression. Every mother should be taught how to express milk manually (Figure 8-17). When an infant is put to the breast, the mother should compress the areola between two fingers to make it easier for the infant to grasp. Offering the breast this way makes it easier for any infant to grasp, especially when the infant needs encouragement to nurse (Figure 8-18).

### Peripheral Engorgement

Initially after delivery the breasts increase in vascularity and begin to swell. This usually starts in the second 24-hour period after delivery. Engorgement at this stage is vascular, thus pumping mechanically

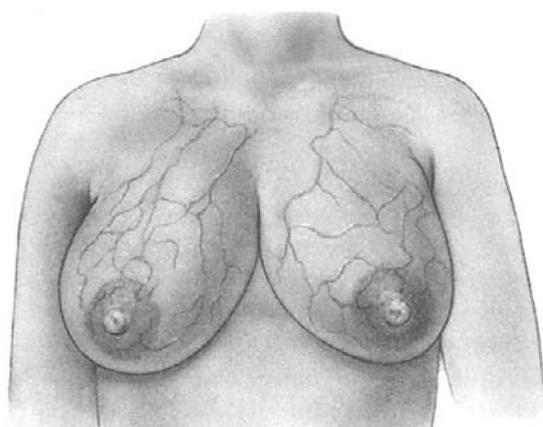

**Figure 8-18.** When breast is offered to infant, areola is gently compressed between two fingers and breast is supported to ensure that infant is able to grasp areola adequately.

briefly to stimulate the breast, when the infant is not nursing adequately, is appropriate. Pumping "to relieve engorgement" will yield little milk and may traumatize the hypervascular breast.

The mother should be advised to wear a well-fitting but adjustable nursing brassiere that does not have thin straps or permanent plastic lining. She should wear it 24 h/day initially. With moderately severe engorgement, the breasts become full, hard, and tender. The swelling starts at the clavicle and goes to the lower rib cage and from the midaxillary line to the midsternum. The breasts may even become hard, tense, and warm. The mother typically complains of throbbing and aching pain and can find no comfortable position except to lie flat on her back and very still (Figure 8-19).

Management centers on making the mother comfortable so that she can continue to nurse and stimulate milk production, as well as nourish the infant. Proper support to elevate the breasts is important. The axillae are particularly painful, probably as a result of the tension on the Cooper ligament. Cold packs reduce vascularity. Warm packs aggravate the swelling. Having the mother stand in a warm shower, however, and manually express some milk at the same time may be the best preparation to feed the infant. Some find comfort in alternating hot and cold water. Other mothers find leaning over a large mixing bowl filled with warm water just before feeding facilitates let-down and milk flow and is less disruptive than taking a shower.

After a feeding, cold packs reduce the swelling, edema, warmth, and pain. Acetaminophen or ibuprofen may give the mother some relief and is safe for the nursing infant. A codeine preparation can be recommended if there is no response to the simple medications. Codeine is cleared well by the mother, peaking in her serum at 30 to 60 minutes.

**Figure 8-19.** Marked mammary engorgement, predominantly vascular in nature.

Breastfeeding should be avoided for approximately 2 hours after dosing. The mother may need some sleep medication. Medications should be timed so that the least amount possible reaches the mother's milk and the baby. With ibuprofen, acetaminophen, codeine, or short-acting barbiturates, if the medication is taken immediately before nursing, the pain will be relieved, but the drug will not reach the milk for more than a half hour.

It is important to maintain drainage of the ducts during this period of engorgement to prevent back pressure in the ducts from developing and eventually depressing milk production. Intraductal pressure can lead eventually to atrophy of both the secreting and the myoepithelial cells and a diminishing milk supply. The best treatment is breastfeeding frequently around the clock, because suckling by the infant is the most effective mechanism for removal of milk. Relief is based on establishment of flow. The infant may have trouble grasping or may not be interested in nursing frequently in the first few days, so manual expression may also be necessary. Every mother should be taught manual expression by the perinatal nursing staff before discharge.<sup>84</sup>

## MANUAL EXPRESSION

The mother should support the breast with her fingers and place her thumbs distally and massage gently toward the areola, rotating gradually around the breast to include all quadrants. Then, once the peripheral lobules have been softened, areolar expression should be used to encourage complete emptying of the collecting ducts in the areola. Placing the thumb and forefinger at the margins of the areola and pressing back in toward the chest and then bringing the fingers together, rhythmically simulating the action of the infant's jaw, will start the flow and soften the tense tissue. This is a procedure best done by the mother, but it takes a skilled and experienced nurse to teach this technique. In women with significant engorgement, it may be helpful to use an electric pump, set at low pressure and rate, which is effective because of its gentle milking action (see Chapter 21). The breast should be massaged distally before and during pumping.

Hand pumps can be used but exert only negative pressure on the areola. Unless accompanied by manual expression of the distal segments, they are only temporizing.

## TREATMENT WITH CABBAGE LEAVES

A favorite treatment for severe engorgement is cabbage leaves. Cabbage leaves have been used in Europe for generations to relieve edema in other

body parts, including the ankles. Chopped fresh leaves are applied to ankles overnight as a poultice and wrapped with a towel. When chilled whole cabbage leaves and chilled gel packs were compared as breast treatments for breast engorgement, no difference was found. Pain was relieved within 1 to 2 hours with both treatments in 68% of women. The mothers preferred the cabbage treatment.<sup>113</sup>

Severe engorgement occurs between the third and seventh day postpartum, and the breasts are described as full, red, hard, and warm. The literature on this therapy is sparse, but two reports have been published. An Australian study involved a series of cases in which the treatment was applied.<sup>115</sup> There were no failures, but in several women the treatment was interrupted by other staff who applied ice and medications for pain without success. When cabbage leaves were reapplied, symptoms were relieved in 2 to 24 hours. Relief was often within 2 hours. Clinicians treated 30 patients and reported on 9 in detail. Rosier<sup>115</sup> tried the treatment first with women who were engorged but were not nursing. No side effects have been reported.

A second randomized, controlled trial was undertaken in South Africa by Nikodem et al.,<sup>89</sup> who studied 120 breastfeeding women. At 72 hours postpartum, they were randomized to control or treatment group. Treatment was application of cool (from refrigerator) cabbage leaves to breasts, leaving just the nipple exposed. The leaves were applied after four feedings for 20 minutes or so until the leaves wilted. The cabbage used was *Brassica oleracea L. var. capitata*. All mothers were also taught routine breast exercises, which consisted of bending the arms at the elbow, moving the arms across the chest, with hands facing the same shoulder, so elbows touched, and swiping across the breast a total of 10 times. This exercise, known by various names, including the Johannesburg salute, is used as a preventive treatment for engorgement. Although the experimental group reported less engorgement, it was not statistically significant. Exclusive breastfeeding at 6 weeks was 76% compared with 58% among controls ( $p=0.09$ ). Mean duration of breastfeeding was 36 versus 30 days in control subjects ( $p=0.04$ ). However, this study had more multiparas in the control group, and engorgement is rarely a serious problem in multiparas.

Whether cabbage leaves have prophylactic value may be challenged, but their value in the therapy of severe engorgement is worth noting. Whether it is the coolness of the leaves or an innate property of cabbage itself that is therapeutic has not been proved. In Duke's *Handbook of Medicinal Herbs*,<sup>38</sup> cabbage (*Brassica oleracea*) is referred to as a *galactagogue*. The most common variety of cabbage, *Brassica capitata* (*B. capitata*), is the one used

in engorgement therapy. This handbook also lists cabbage with other angiosperms as capable of causing hypoglycemia. Cabbage is noted to contain sinigrin (allyl isothiocyanate) and rapine. Herbalists consider rapine to be an antifungal antibiotic. The text lists galactagogues and lactation suppressants found in other plants but does not mention any mammary effects of cabbage when applied to the breasts.

A product is available on the market called Cabbage Gel (Pure Necessities, 15036 Beltway, Addison, TX 75244). This pale green gel has a gentle odor of peppermint, is made of aloe vera, and contains peppermint oil and "herbal infusions," and apparently no cabbage. It is intended for use alone or with fresh cabbage leaves to help keep the leaves in place and cool the engorged breast. Care must be taken to remove the gel before feeding the infant, because aloe vera can be a powerful purgative.

As breastfeeding has become more common, more devices and preparations to solve every problem have become available. Most have not been subjected to any scientific review. Nursing pads and nipple ointments are an example. Lanolin has been modified so that it no longer causes an allergic response (Lasinoh®). Gel pads are also available, some made of glycerin, others of hydrogel, that are applied to the nipple and areola and worn between feedings. ABM Clinical Protocol 20 discusses the diagnosis and management of engorgement.

## *Going Home from the Hospital*

Currently, uncomplicated maternity patients are going home from the hospital in 24 to 48 hours, driven by insurance coverage. This is certainly before lactation is well established and before engorgement is full blown. When maternity floors were run so rigidly that ad lib breastfeeding was an impossible feat, it was often suggested that a mother go home and get away from the negative hospital atmosphere to a place where she could relax and concentrate on feeding the infant and resting. This is the point at which the doula, so well described by Raphael,<sup>104</sup> could make the difference between success and failure. It may be appropriate for the obstetrician to order the mother to have some assistance at home, whether from her husband, her mother, or a friend. "The common denominator for success in breastfeeding is the assurance of some degree of help from some specific person for a definite period of time after childbirth."<sup>104</sup>

Raphael studied mothers in the cycle of anxiety, while she became the doula for them at about 6 to 10 days postpartum. The calm that can be experienced in the presence of a confident, caring

person will relax the mother. The infant senses the calm and confidence and sleeps. When feeding again, the infant nurses well. Breaking the cycle of panic that seizes a new mother when she finds herself home alone with a new infant who needs frequent feeding requires someone to instill confidence. This individual does not need to be a health professional but should be a calm, reassuring, nonthreatening person who is supportive of breastfeeding.

Although physicians are rarely the doula, they can be sure that a family understands the need and can suggest community resources if no personal ones are available. A lactation consultant should be available in the office or the community. Successful breastfeeding is not automatic, as demonstrated by the failure rate. Some problems have been generated by the disturbance of the synchronized interaction between mother and infant by rigid hospital protocol. A Baby Friendly certified hospital will avoid these problems, but does not protect against lack of local support services. The office practice should be available by telephone. Ideally, the office nurse practitioner makes a home visit in the first week. The AAP recommends that an office visit with the pediatrician be scheduled within a week of birth, or sooner if a problem exists, especially for a weight check or hyperbilirubinemia.

Most communities have an international board certified lactation consultant (IBCLC) available for new mothers or any mother with a problem. The physician should be familiar with the available lactation consultants if the practice does not have one on its staff.

## *The First Visit to the Baby's Physician*

According to the ACOG and AAP,<sup>6</sup> the first postpartum visit to the infant's physician should take place at 3 to 5 days of age and certainly before the seventh day. When the caregiver has been specially trained in lactation, the breastfeeding outcome for mothers and infants shows more prolonged breastfeeding.<sup>68</sup> Studies have demonstrated the value of postresidency training in breastfeeding when practitioners did not receive such training in residency.

### **NIPPLES**

#### **Painful Nipples**

Presumably, the nipples will adapt to the nursing experience naturally; however, discomforts often arise. The initial grasp of the nipple and first suckles

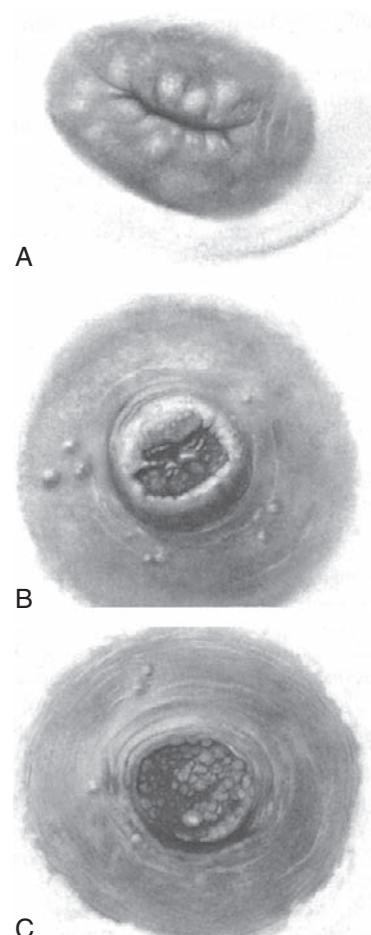

typically cause discomfort in the first few days of lactation because it is a new experience for the mother. This is not cause for alarm but does require maternal reassurance. The sensation is created by the negative pressure on the ductules, which are not yet filled with milk. Later, when lactation is well established and the let-down reflex has matured, mothers describe a turgescence, which is the increased fluid pressure being relieved by suckling. If the pain persists throughout the feeding, the situation demands immediate attention. It should not hurt to breastfeed.<sup>85</sup>

Nipple pain was studied in 102 women in the first 96 hours postpartum.<sup>71</sup> Engorgement was most closely associated with nipple discomfort, which may be enhanced by the general discomfort of the breast. Prenatal breast preparation was unrelated to soreness. Length of time spent suckling was also unrelated. No record was kept on nonnutritive suckling, although others have found suckling without swallowing to be more traumatic early in lactation. How the breast is presented to the infant is the most critical factor (maternal hand position and infant squarely facing breast).<sup>35,33</sup> This is the time actually to observe the feeding, to check the latch, and to look for malpositioning or other abnormalities.

The most common cause of painful nipples in the first few days is positioning. This should be reviewed in detail, making sure that the areola is softened sufficiently to have the infant grasp adequately.<sup>34,33</sup> The infant's lower lip is checked to ensure it is flanged around the breast and not drawn into the mouth, which can abrade the nipple. The tongue should be under the teat and cupped around it.

Specific areas of pain may have specific causes. Soreness on the top of the nipple or on the tip usually results from poor latch-on or from tongue thrusting in an infant who is also bottle-fed. Soreness can also be caused by tipping the nipple upward so that it grazes the hard palate from overzealous use of the palmar grasp or C-hold. Pain on the underside of the nipple is caused by presenting the breast with the nipple tipped up, usually because of more pressure by the mother's thumb on top than the fingers below the breast, so the infant "strokes" the underside of the nipple. The tip of the nipple may also graze the hard palate. The nipple may be bruised, scabbed, or blistered, depending on how long the problem has continued (Figure 8-20). Normally, the peristaltic motion of the tongue below the nipple is not uncomfortable.

If no abnormality is found, the pain may be caused by a " barracuda baby" with a vigorous suck. Occasionally, an infant will have a discordant suck, clamping down on the nipple. This may have a

**Figure 8-20.** Various types of cracks in abraded lactating nipples. **A**, Crack across nipple. **B**, Multiple cracks (stellate). **C**, Crack at lower base.

neurological cause. Suck training may help.<sup>1</sup> The breast will gradually adapt, and this pain will not last indefinitely. Sometimes the maternal tissues are unusually tender and delicate. Brief dry heat may help between feedings in humid climates. The mother should remove the waterproofing from her brassiere and expose her breasts to air briefly after each feeding. Vitamin A and D ointment may help in dry climates.

Even more effective, especially in humid climates, is the use of an electric hair dryer set on warm and fanned across the breast about 6 to 8 inches (15 to 20 cm) away for 2 to 3 minutes only

<sup>1</sup>Suck training is a special technique developed to help an infant who cannot coordinate the undulating (peristaltic) movement of the tongue. It involves using the gloved finger of the lactation consultant and stimulating the infant's tongue with the finger pad to the tongue. The infant will gradually learn to suck. Using a feeding tube attached to a syringe of milk along the finger will provide the infant with milk when sucking is correct. This is called finger feeding.

to avoid overdrying. This brings remarkable comfort and can be done sitting, standing, or lying down. In dry climates, however, wetting the tissues is the preferred treatment. The breast will be moist with milk right after a feeding. This should not be wiped away but allowed to dry on the skin. Many primitive cultures treat irritations of the skin with human milk.<sup>99</sup> The surface-drying effect of the treatment helps counteract the increase in moisture experienced in the first days of lactation.<sup>100</sup>

Stabbing pain that radiates through the breast so the mother feels like the ducts are liquid fire may be associated with *Candida* infection of the breasts, often seen after antibiotic treatment. This deserves special attention by the physician.<sup>31</sup> Not all burning pain is due to *Candida* infection. Sore nipples that occur beyond the first weeks of breastfeeding may be caused by infections such as *Staphylococcus* or by vasospasm. These causes are discussed in Chapters 13 and 16.

## Ointments

The appropriate treatment of sore nipples is based on removing the cause and facilitating healing. Positioning is the most common cause, but repositioning will not heal a seriously damaged nipple without some medical intervention. The most appropriate application depends not only on cause but also on environmental conditions. With high humidity, greasy moisture-sealing ointments aggravate the skin. If the atmosphere is dry (e.g., at high altitudes or in desert climates), creams may be appropriate.

All treatments are not appropriate to all lesions. Cool, wet tea bags, for instance, serve as an astringent because of the tannic acid, causing drying and cracking, and are not usually recommended.<sup>70</sup>

The routine application of ointments to the nipple, areola, or breast should be discouraged, however, except in cases of extremely dry skin where the tissue needs to be lubricated.

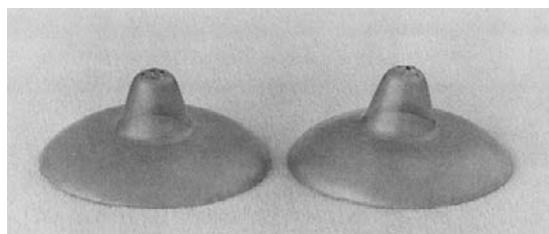

Lanolin is most hazardous to anyone with a wool allergy. Lansinoh is a purified, alcohol-free, and "allergen-free" ointment, however, and should be safe if an ointment is indicated. Some ointments and creams contain irritants. The sebaceous and Montgomery glands of the areola and nipple are easily plugged by repeated applications of oily substances during pregnancy and lactation. Preparations with vitamins A and D are innocuous, but those with vitamin E or hormones are unsafe unless prescribed for a specific problem by the physician.

Moist wound healing for sore or cracked nipples has been proposed by some dermatologists and is comparable to treatment for other areas of the body. Early soreness may be caused by insufficient moisture present in the skin, coupled with the

friction of malpositioning.<sup>107</sup> Wetness on the surface caused by the milk and occlusive plastic-lined nursing pads does cause irritation. The moisture within the tissue, however, should be preserved by the application of a nonirritating ointment after a feeding when the nipple has been gently dried.<sup>122</sup> Local anesthetic creams should not be used because they can lead to allergic reactions. More important, they can interrupt the let-down reflex and dangerously affect the infant by numbing the infant's mouth and throat. The use of ice to numb the pain before feeding does not correct the cause and may interfere with the let-down reflex, which is easily intercepted by cold as well as by pain. If ice numbs the areola, it may numb the nervous response. Irritation or rash should first be treated by discontinuing any ointments or other self-medicating material. This is usually the first step in the treatment of any dermatologic problem. Chronic or intractably sore nipples require more aggressive intervention. It may be necessary to discontinue breastfeeding and resort to manual expression or gentle pumping with an electric pump. A Silastic flange is the least irritating kind of pump attachment. The milk must be removed from the breast frequently. When positioning has been ruled out as a cause as well as infection with *Staphylococcus* or *Candida albicans*, the clinician must determine a means of healing. Some clinicians use all-purpose nipple cream, which contains an antifungal, an antibiotic, a corticosteroid, and a local anesthetic. The contraindications for these constituents have been discussed. Dermatologists almost never use a cream with more than one active ingredient because the bad effects often outweigh the good. The cause of the nipple pain should be determined and the appropriate treatment used. Some clinicians recommend plastic wrap over the ointment to reduce the friction of clothing. The patient should be reminded to use a large piece and to remove it before pumping or feeding. Vaseline gauze can be used in severe cases much as it is used in burn therapy. If antiinflammatory treatment is indicated, preparations of halobetasol propionate (e.g., Ultravate) are best and much more effective than hydrocortisone cream. Usually 2 to 3 days of treatment is sufficient. A tiny amount is rubbed into the nipple after each feeding. It is absorbed promptly and does not need to be removed to feed the infant.

## Nipple Shields

A nipple shield is a device made of rubber or synthetic materials that is worn over the nipple and areola while an infant is suckling. A makeshift shield of a nursing-bottle nipple should never be used. Shields differ from the shells designed to

**Figure 8-21.** Nipple shield made of tasteless, odorless silicone in very thin flexible form referred to as “Mexican hat.”

evert nipples (Figure 8-21). Shells should never be worn while breastfeeding, and any milk that drips into them should not be saved to feed the infant because it is heavily contaminated and of lower fat content. A study of the effect of a thin latex nipple shield on suckling showed no difference in length of suckling time and no difference in cortisol levels or prolactin levels in maternal serum, which were correlated with length of time suckling. Wearing the shield without suckling had no effect on prolactin levels. The amount of milk received by the infant, however, was significantly reduced.

Nipple shields should not be used. The infant becomes confused in learning the sucking routine; the only known advantage is that the mother can see the milk being transferred. Glass or plastic shields with a rubber nursing nipple never work and should be abandoned. The thin latex shield reduces milk by 22% but has no effect on sucking patterns. Many lactation experts consider the use of a breast shield a sign of failure of proper lactation guidance and a preventable situation. In the case of a very large maternal nipple, however, the shield tapers the nipple so the infant can grasp it as an elongated teat. There are only a few situations in which a shield may be useful.

### Small or Flat Nipples

When the nipples are small or flat, special attention to compress the breast and areola between two fingers to provide as much nipple as possible to the infant will assist the infant in getting a hold. Using the breast shell between feedings can help draw the nipple to greater prominence. Softening the areola with massage before a feed to make it more compressible also helps.

Drawing the nipple out with a hospital electric pump before each feeding should help facilitate latch-on and train the infant to establish a proper grasp. A day or two of such preparation with the pump is usually sufficient if the infant is full term with a good suck. Once engorgement is diminished and nursing is well established, small or flat nipples are usually no longer a problem.

### Large Nipples

Large nipples are occasionally a problem with a small infant or an infant with an indecisive suck. The shells do not help the infant cope, and it is best just to work patiently with the infant. Manual expression, which softens the areola to make it more pliable before putting the infant to the breast, often helps. Preparation with an electric pump may also facilitate the infant’s latch-on by drawing the nipple into a teat. A thin Silastic nipple shield may facilitate a latch with very large nipples.

### Cracked Nipples

When a mother complains of nipple pain on nursing, the nipple should be examined in good light to look for cracks or subepithelial petechiae, which may be the precursor to cracking. Taking a thorough history about care of the breast is important to identify the use of soaps, oils, ointments, or other self-prescribed treatments. Watching the nursing process may identify abnormal positioning at the breast. The position of the crack also may identify the problem (Box 8-4).

Cracks straight across the tip of the nipple are caused by excessive dryness after original irritation of the nipple tip by poor nipple positioning against the infant’s palate (see Figure 8-20A). Pain may be eased by correct positioning, and healing may be promoted by application of therapeutic ointments such as vitamins A and D, purified lanolin, or a synthetic hydrocortisoid (preparations of mometasone furoate or Elocon ointment). In extreme cases in which the crack is wide, a “butterfly” bandage that brings the edges of the crack together between feedings may be necessary. Local anesthetics are not appropriate, nor are nipple shields, which draw and pull the nipple. Star-shaped cracks respond to similar treatment (see Figure 8-20B). Cracks at the

#### BOX 8-4. Management of Sore, Painful, or Cracked Nipples

1. Examine the breast, nipple, and nursing scene.
2. Recommend manual expression before feeding and softening of areola.
3. Check for infant position on breast.
4. Suggest nursing on unaffected breast first with affected side exposed to air.
5. Let expressed breast milk dry on skin between feedings.
6. Recommend appropriate ointment.
7. Rarely, temporarily stop nursing on affected side and replace with manual expression or pumping.
8. If necessary, give acetaminophen, ibuprofen, or codeine (for serious pain unresponsive to milder drugs) in short-acting preparations just before nursing (see Chapter 12).

base of the nipple (see [Figure 8-20C](#)) are usually caused by sucking of the lower lip and biting, which originate with poor positioning but require checking the lower lip. Mother can gently pull the lip out with her thumb or relatch the infant.

Therapy is indicated for true cracks. In the pre-cracked stage, letting the milk dry on the skin for a few moments and applying a cream between nursings are most effective. When true fissures have developed, opening both sides of the nursing brassiere at feedings and beginning to nurse on the less painful side first will permit the initial let-down to occur "atraumatically"; then the infant can be put carefully to the affected breast. When nursing must be stopped on a given breast, it sets up a chain reaction of engorgement, reduced flow, and plugging of the ducts. Changing the infant's position, such as using a football hold or cross-cradle, may help healing by redistributing the pressure of sucking.

In women with severe nipple cracking, the physician may prescribe topically applied synthetic corticoids, which are preferred by dermatologists. When position has been corrected and bacterial and fungal infections ruled out, application of Elocon 0.1% cream or ointment, which is antiinflammatory, antipruritic, and vasoconstrictive, can be rapidly healing. Less than 0.5% of a dose of corticoids is absorbed topically. As mentioned previously, halobetasol propionate (Ultravate) 0.05%, another synthetic corticoid ointment, is also available by prescription. Usually a 2-day treatment is adequate, and the ointment does not need to be removed before feeding. It is important to treat the underlying cause of the original trauma to the nipple.

The application of any ointment that must be removed before nursing has disadvantages because removal is traumatic. Vitamins A and D ointment, which does not have to be removed, is occasionally effective. It contains vitamins A and D from fish liver oils in a petrolatum base. An individual would have to consume several large tubes of it in one sitting even to approach toxicity. The indiscriminate use of ointment, however, can be the cause of nipple pain, and, as with many dermatologic problems, the initial treatment prescribed may be to discontinue previous treatments. Some ointments suggested as breast creams contain antibiotics, astringents, bismuth subnitrate, or petrolatum, all of which are contraindicated. These creams are available over the counter without a prescription; thus a physician should inquire about their use by the patient.

Premoistened towelettes that contain benzalkonium chloride 1:750 in 20% alcohol should not be used on a nipple or areola, with or without soreness or cracks, or used to cleanse. The infant could accumulate benzalkonium chloride by suckling. The infant might reject the breast because of the flavor

or burning sensation in the mouth. Also, benzalkonium is usually painful for the mother.

## *Infant in the Hospital*

### **FEEDING CHARACTERISTICS**

Infants have been aptly classified by their feeding characteristics by Barnes et al.<sup>12</sup> as "barracudas," excited "ineffectives," procrastinators, gourmets or mouthers, and resters. These descriptions have stood the tests of time and serve to demonstrate that infants are different, and the management of the nursing experience will vary accordingly. Herein lies the secret to appropriate counseling: recognizing the differences among infants and developing management that fits each situation.

### **Barracudas**

When put to the breast, barracudas vigorously and promptly grasp the nipple and areola and suck energetically for 10 to 20 minutes. There is no dallying. Occasionally, this type of infant puts too much vigor into the nursing and hurts the nipple at first, but this passes.

### **Excited Ineffectives**

Some infants become so excited and active at the breast that they alternately grasp and lose the breast. Then they start screaming. The nurse or mother often must pick up and quiet the infant first, then put the infant back to the breast. After a few days the mother and infant usually become adjusted. Having some expressed milk ready on the nipple and areola helps to focus the infant.

### **Procrastinators**

Procrastinators often seem to put off until the fourth or fifth postpartum day what they could just as well have done from the start. They wait until the milk "comes in." They show no particular interest or ability in sucking in the first few days. It is important not to prod or force these infants when they seem disinclined. They do well once they start. The mother would do well to pump after each feeding so that her supply builds.

### **Gourmets or Mouthers**

Gourmets insist on mouthing the nipple, tasting a little milk, and then smacking their lips before starting to nurse. If hurried or prodded, the infant will become furious and start to scream. Otherwise, after a few minutes of mouthing, the infant settles down and nurses very well.

## Resters

Resters prefer to nurse a few minutes and then rest a few minutes. If left alone, they often nurse well, although the entire procedure will take much longer. They cannot be hurried.

## WEIGHT LOSS

Newborns usually lose some weight, which tends to be a function of whether they are appropriate, large, or small for gestational age, as well as how many kilocalories they ingest in the first few days. Breastfeeding infants of multiparas often lose little weight because the milk "comes in" so quickly. Conversely, the normal primipara may not have a full supply for 72 to 96 hours. If the weight loss is more than 5% (150 g in a 3-kg infant), evaluate the process to identify any problems before they become serious. A 7% loss is maximum, and weight should plateau by 72 hours. A 10% weight loss is acceptable only if all else is going well, voiding 6 × daily and stooling 1 × daily, and the physical examination is negative. It should be justified in the record, and the infant should be seen shortly after discharge from the hospital to ensure resolution of the problem. An increasing number of mothers are receiving epidurals and having caesarian deliveries, which are usually accompanied by intravenous (IV) fluids. These added fluids will affect the fluid volume of the fetus and ultimately the birth weight of the newborn, who has to excrete the extra fluid. Increasingly, infants are dropping 10% of their birth weight in 72 hours as a result of the fluid load and not of failed breastfeeding. IV fluids during labor are an important part of the evaluation history of apparent excess weight loss after birth. If discharge home has taken place in 48 hours or less, it is imperative that the pediatrician's office keep in touch with the mother.

Many offices have a nurse practitioner who makes the follow-up telephone calls or a home visit.

Newton<sup>86</sup> described a simple observation of breastfeeding mothers that was an accurate predictor of ultimate lactation success (Table 8-2). All the observations were related to the milk-ejection reflex (i.e., uterine pain, milk dripping on sight of baby, and relief of nipple discomfort on initiation of sucking). Successful breastfeeders had significantly more uterine pain during suckling on day 2 postpartum ("afterpains"), more dripping of the opposite breast, more dripping on sight of infant, and cessation of nipple discomfort.<sup>106</sup> In further evaluation, Newton<sup>87</sup> compared the amount of milk left in the breast after feeding that was available with a dose of synthetic oxytocin (Pitocin) and pumping. Successful breastfeeding women had only 27% left, and unsuccessful breastfeeding women had 47% left. This technologic measurement is no better measure of success than the simple observations of the let-down reflex (see Table 8-2). This observation parallels the observations by ultrasound of Hartmann on storage capacity of the breast, which varies from woman to woman.<sup>45</sup>

Provision of early formula supplementation in the hospital was also associated with less successful lactation.<sup>143</sup> A strong predictor of the need for supplementation was excessive time from delivery to first breastfeeding. When water and sugar water were routinely provided, there was greater weight loss in the infant and a lower lactation success rate.<sup>66</sup>

Early weight loss nomograms for exclusively breastfeeding newborns were developed by Flaherman et al.<sup>38</sup> at University of California San Francisco following 161,471 term newborns, of which 83,433 were delivered vaginally and 25,474 by C-section. Differential loss by delivery mode was evident in 6 hours and persisted over time. Only 5% of vaginally delivered infants and more than

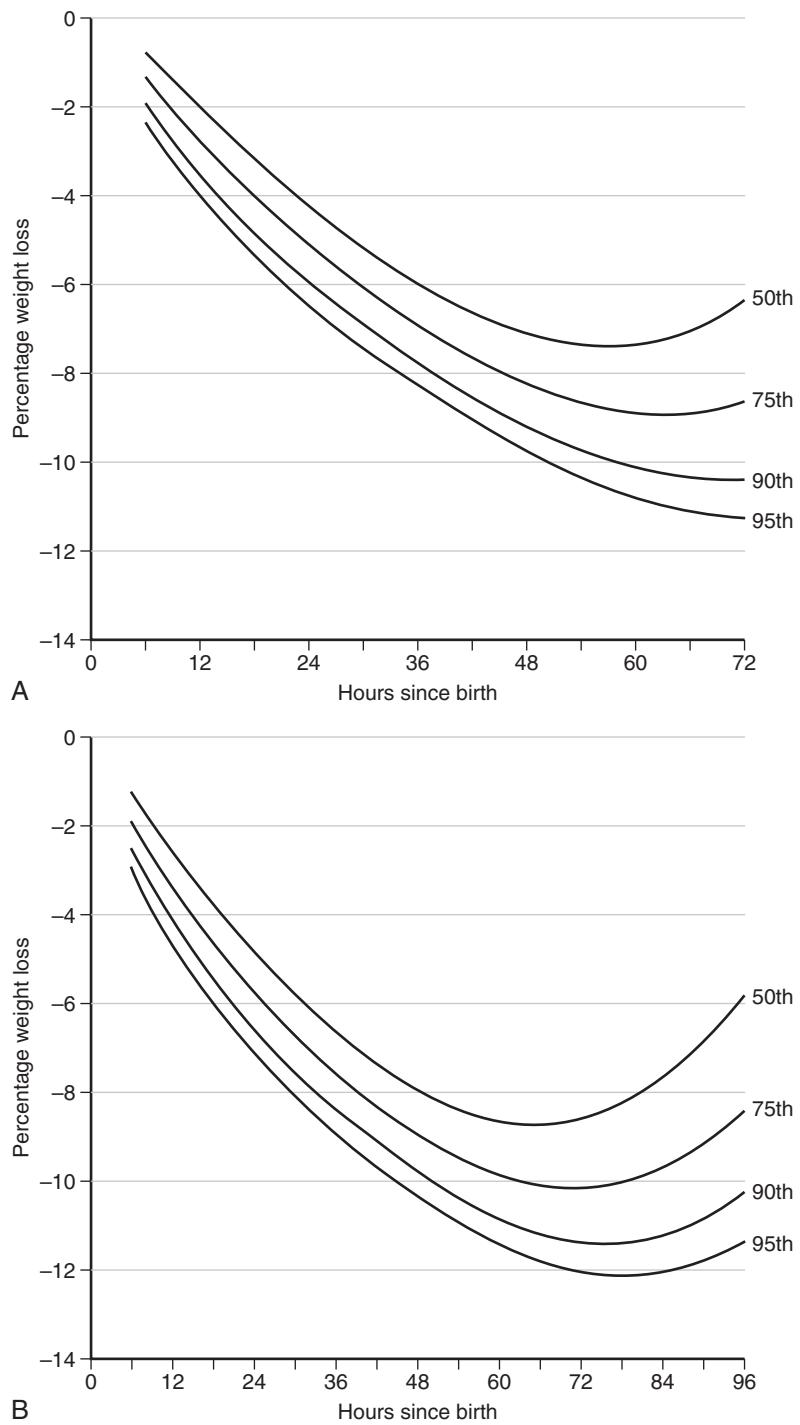

**TABLE 8-2** Percentage of Women Reporting Symptoms of Milk Ejection With Significant Difference Between Successful and Unsuccessful Breastfeeders

Symptoms	Successful Breastfeeders (%)	Unsuccessful Breastfeeders (%)	Probability ( <i>p</i> )
Uterine pain (cramps) during suckling: day 2	64	38	<0.05
Dripping from opposite breast during suckling: day 6	95	67	<0.01
Dripping before suckling (as oxytocin is triggered by sight or expectation of baby or other times): day 5	78	56	<0.05
Cessation of nipple pain (as milk flow counteracts negative pressure produced by suckling)			
Day 4	89	69	<0.05
Day 5	89	69	<0.01
Day 6	89	69	<0.05
All symptoms: all days	59	48	<0.01

From Newton N: The quantitative effect of oxytocin (Pitocin) on human milk yield, *Ann NY Acad Sci* 652:484, 1992.

10% of C-section-delivered infants had lost more than 10% of their birth weight in 48 hours. The nomograms from this study are seen in Figure 8-22 and can be used for early identification of neonates on a trajectory for greater weight loss and possible morbidities.

Breastfeeding duration and weight gain trajectory in infants who were followed with weight and length measurements ( $n=595$ ) were noted to have short breastfeeding periods. The authors developed an obesity risk index, which included maternal BMI, education, and smoking during

**Figure 8-22.** A, Estimated percentile curves of percent weight loss by time after birth for vaginal deliveries. B, Estimated percentile curves of percent weight loss by time after birth for cesarean deliveries. (From Flaherman VJ, Scharfer EW, Kuznieciewicz MW, et al.: Early weight loss nomograms for exclusively breast-feeding newborns, *Pediatrics* 135(1): e16-e23, 2015, Figure 2.)

pregnancy. Infants who breastfed for 2 months or less were more likely to belong to the obesity risk group and had rising weight trajectories early in life.

Weighing the infant before and after feedings produces tremendous anxiety in the mother and affords little information if it is inaccurate.<sup>140</sup> Weighing has been improved, however, by the introduction of electronic digital readout scales that are accurate to 1 g and are especially helpful in the intensive care nursery for infants less than 1000 g.<sup>18</sup> Most newborn nurseries use these extremely accurate scales. Test weighings can be done when medically indicated. With the development of similar equipment, scales are practical for home use. Their accuracy in before-and-after weighings has been verified by several investigators using comparison techniques. When ordinary balance scales are used, the margin of error has been shown to be greatest with the smaller volumes. In volumes of milk less than 60 mL, the error can be  $\pm 20\%$ .

Sequential breast volume measurements have been used to study short-term rates of milk synthesis.<sup>25</sup> By using a rapid, computerized breast measurement system, a close correlation was established between amount of milk the infant consumed and change in breast volume. The volumes measured varied between 11 and 58 mL/h.<sup>25</sup> At some point, this technique may be applied to clinical assessment of milk production.

This technology and the work of others have led to new insights into lactation physiology.<sup>99</sup> Mothers know that the breasts fill gradually to a certain degree between feedings. When feedings are delayed or missed, breasts can be uncomfortable, with relief achieved when the infant nurses.<sup>10</sup> The rate of synthesis appears constant, as confirmed by topographic imaging. Prentice et al.<sup>99</sup> identified a factor that is released into the milk space and inhibits milk synthesis locally by direct action. The action of this local inhibitory factor imposes a more phasic pattern of milk production, having its greatest effect when the breast has the least milk and slowing to a minimum as the breast fills.<sup>10,99</sup> "Empty breast" is a misnomer and is physiologically unattainable.<sup>148</sup>

## *Voiding and Stooling*

In addition to monitoring weight, voiding and stooling are important barometers of breastfeeding adequacy. The rule of thumb, after the first week of life, for the first month is six voids a day and at least three stools. Stooling with every feeding reflects a strong gastro-colic reflex. The infant with infrequent stools after a month of age is of significant

clinical concern. Infrequent stools are defined as an interval of over 24 hours between bowel movements. Evaluating 198 mothers by questionnaire, one third of the group of mothers reported at least one episode of infrequent stools.<sup>23</sup> Those who were already aware of the condition were less likely to seek intervention. In a continuation of the study on the Internet, involving 85 French-speaking mothers, the median duration of time of all episodes of infrequent stools was 10 weeks (range 1 to 34 weeks). Maximum duration of an episode was 28 days. The most frequent treatment tried for the infant was massaging the abdomen. The most frequent treatment the mother initiated was to add fruit juice, mineral water rich in magnesium, and vegetables to her diet. The authors recommend a wait-and-see attitude.

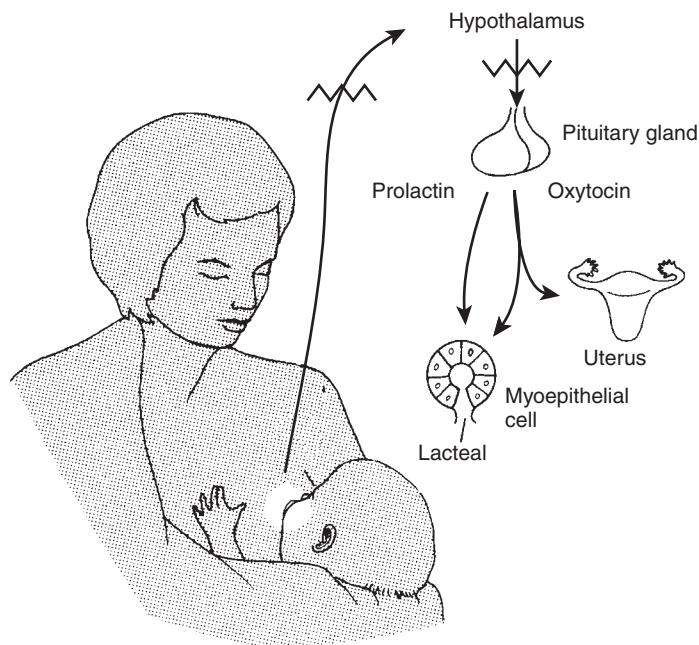

## *Vomiting Blood*

A breastfed baby who vomits blood should have the blood evaluated for fetal or adult hemoglobin by the Apt test (blood suspended in a small amount of saline solution and an equal amount of 10% sodium hydroxide added; adult hemoglobin turns brown; fetal hemoglobin stays pink). If it is adult hemoglobin, the nipple may be bleeding. Sometimes this bleeding is painless and unknown to the mother, and sometimes she is afraid to report it. If it is fetal hemoglobin, the infant needs evaluation. Breastfeeding can continue with maternal milk if the infant retains it, and the cause of the bleeding has been addressed.

Greenish or brown milk is occasionally described in the first few days if the mother is pumping or her infant vomits. It usually results from old blood in the ducts, a residual of rapid growth and vascularization during pregnancy. This milk is usually harmless and clears spontaneously in a day or two. It usually goes unnoticed if the infant is nursing well at the breast. If being pumped, it may be discarded. Breastfeeding does not need to be interrupted. This has been referred to as *rusty pipe syndrome*.

## **LET-DOWN REFLEX**

The most important single function that affects the success of breastfeeding is the let-down reflex. A mother may produce the milk, but if she does not excrete it, further production is suppressed. Much has been written on this single reflex by physiologists, endocrinologists, biochemists, pathologists, anatomists, psychologists, psychiatrists, obstetricians, and pediatricians. It is a complex function that depends on hormones, nerves, and glands,

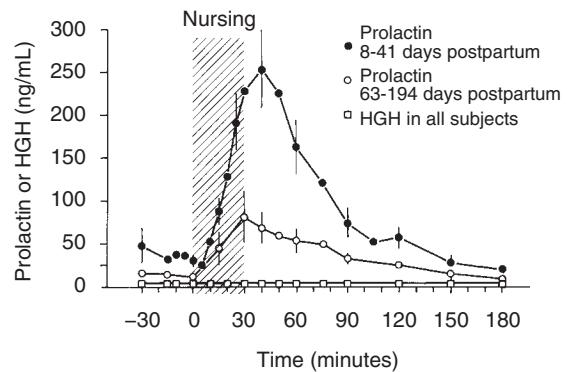

**Figure 8-23.** Diagram of ejection reflex arc. When infant suckles breast, mechanoreceptors in nipple and areola are stimulated, which sends a stimulus along nerve pathways to hypothalamus, which stimulates posterior pituitary gland to release oxytocin. Oxytocin is carried via the bloodstream to breast and uterus. Oxytocin stimulates myoepithelial cells in breast to contract and eject milk from alveoli. Prolactin is responsible for milk production in alveoli. Prolactin is secreted by anterior pituitary gland in response to suckling. Stress such as pain and anxiety can inhibit let-down reflex. Sight or cry of infant can stimulate release of oxytocin but not prolactin.

which can be inhibited most easily by psychological block (Figure 8-23).<sup>87</sup>

The hormonal mechanism of milk ejection is described in Chapter 3. The reflex stimulation of milk ejection has been meticulously studied. The more efficient stimulus for the milk-ejection reflex is suckling the nipple. The frequency of suckling is 70 to 120 strokes per minute, and the mean pressure is –50 to –150 mm Hg. The maximum recorded was –220 mm Hg. Within 1 minute of the onset of suckling, the first contraction of the mammary myoepithelium is recorded, but it may take 2 or more total minutes for a full response.

As in other species, the human response is undulating or spurt-like in release, although the level of oxytocin tends to reach a peak and to plateau at 6 to 10 minutes during a feeding.<sup>138</sup> Some studies show no episodic secretion. When oxytocin levels are measured before the feeding, there is a response to the baby's crying or other anticipation of feeding. No prolactin response occurs before actual suckling (Figure 8-24). A second release of oxytocin occurs when suckling begins.<sup>27</sup> No direct correlation exists between levels of oxytocin and the volume of milk released at a given feeding. The average pituitary gland contains 1000 mU of oxytocin; only 0.5 mU is required for the let-down reflex.

Uterine contractions are also stimulated by suckling, because the oxytocin released into the bloodstream also affects the target receptors in the uterine myoepithelial cells. These target receptors diminish over time as the uterus involutes

**Figure 8-24.** Plasma prolactin and growth hormone concentrations during nursing in postpartum women. Eight women were studied 8 to 41 days postpartum and six women 63 to 194 days postpartum. Prenursing prolactin levels in the latter group were within normal range. Plasma growth hormone showed no change in any subjects during nursing. *HGH*, Human growth hormone. (From Noel GL, Suh HK, Frantz AG: Prolactin release during nursing and breast stimulation in postpartum and nonpostpartum subjects, *J Clin Endocrinol Metab* 38:413, 1974.)

postpartum.<sup>90</sup> Amplitude and frequency may increase over time during nursing. Mechanical stimulation of the nipple can produce the same effect on the breast and uterus. The milk-ejection reflex is inhibited centrally by cold, pain, and emotional stress. Ejection response can be elicited by seeing the infant or hearing the infant cry. Also, overwhelming evidence indicates that the neuropeptide oxytocin is centrally involved in activating

maternal behavior at the appropriate time and plays a significant role in sustaining maternal behavior during lactation.<sup>96</sup>

The milk-ejection reflex can be at least partially blocked by large amounts of alcohol, which seems to have a central effect preventing the release of oxytocin, because the mammary gland and uterine response to injected oxytocin are not changed by alcohol. Studies on mothers with diabetes insipidus suggest that the patient retains the ability to synthesize and release oxytocin despite being unable to produce antidiuretic hormone (ADH, vasopressin) in response to stimuli. Artificial cervical dilatation postpartum will also cause milk ejection. Vaginal stimulus also initiates let-down in all species.

Injection of oxytocin reproduces the effect of suckling. A rapid series of injections of 1 to 10 mU IV will simulate suckling. A continuous drip is less effective. Use of Pitocin as a snuff or nasal spray is the best method for home use of oxytocin to initiate let-down. The oxytocin concentration in the blood rises with suckling, which supports the hypothesis that suckling elicits the release of oxytocin.

The data on the question of ADH release during suckling are contradictory, but it would seem that release of oxytocin and of ADH are independent.

In the first weeks of lactation, the threshold dose of oxytocin to cause let-down is low, averaging 0.65 mU from the fifth day (see Figure 8-23). Thirty days after weaning, it is 100 mU. Vasopressin is not as effective and requires 100 times the dosage of oxytocin to produce the same effect during lactation. Deaminoxytocin is 1.5 times as potent as oxytocin on the third postpartum day, but the difference disappears over time, probably because of the rapid breakdown of natural oxytocin by oxytocinase early in the postpartum period.

An objective assessment of milk ejection can be obtained by using ultrasound as described by Hartmann and Prosser.<sup>45</sup> The diameter of the milk ducts just below the nipple area can be visualized. In

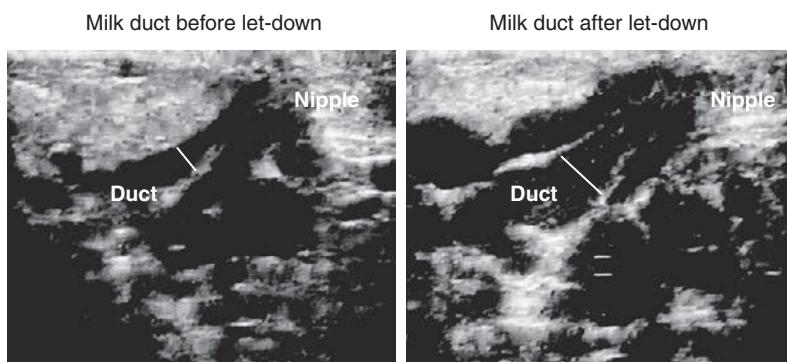

mothers who carried to term, there is an acute increase in milk duct diameter in the free breast while the infant feeds from the other (Figure 8-25). The same is true if one breast is pumped. The visualization of the increase in diameter, Hartmann and Prosser indicate, is positive evidence of the effect and the let-down reflex.<sup>45</sup>

Prostaglandins (PGs) have been shown to have a number of physiologic effects, including an effect on mammary epithelium to increase mammary duct pressure. In a blinded crossover study, oxytocin, IV PG, and nasal PG were given and the intraductal pressures measured. The most effective IV PGs were 16-phenoxy-PGE2 and PGF<sub>2α</sub>, which were then tried nasally, but only PGF<sub>2α</sub> was effective nasally. The potential of nasal PGF<sub>2α</sub> treatment in engorgement and failure of let-down is possible but is as yet unexplored clinically.<sup>16</sup>

## PRACTICAL ASPECTS OF MILK-EJECTION REFLEX

When the nipple is stimulated, the receptors in the nipple and areola are stimulated, and nervous impulses are transmitted to the hypothalamus via the somatic afferent nerves.<sup>130</sup> The hypothalamus stimulates the pituitary gland to secrete prolactin, which induces the alveoli in the breast to produce and secrete milk. The cell membranes release fat globules and protein into the lumen. This produces the hind milk, which has a higher protein and fat content. Part of the foremilk has been present since the previous nursing and is released first. It is a more dilute, less fatty solution. The ejection reflex induces the holocrine excretion of milk from the cells. The posterior pituitary gland secretes oxytocin, which stimulates the myoepithelial cells to contract and eject the milk from the ducts.<sup>131</sup>

Early in lactation, if engorgement is marked, the ejection reflex may be inhibited by the congested blood flow to the target organ, the myoepithelial cell. Therefore, when suckling is initiated and oxytocin is released into the bloodstream, the ejection

**Figure 8-25.** Ultrasonography of breast before (left) and during (right) let-down, demonstrating the filling of the duct system with milk. Before milk ejection the ducts near the nipple are 2 to 8 mm in basal diameter. (Courtesy Peter Hartmann, PhD, University of Western Australia, Perth, Australia.)

**TABLE 8-3** Milk-Ejection Reflex\*

Modified from Newton M, Newton N: The let-down reflex in human lactation, *J Pediatr* 91:1, 1977.

reflex message is delayed in reaching the myoepithelial cell with the message because of vascular congestion. Preparing the breast with warm soaks, gentle massage, and manual expression of a little milk may facilitate let-down.

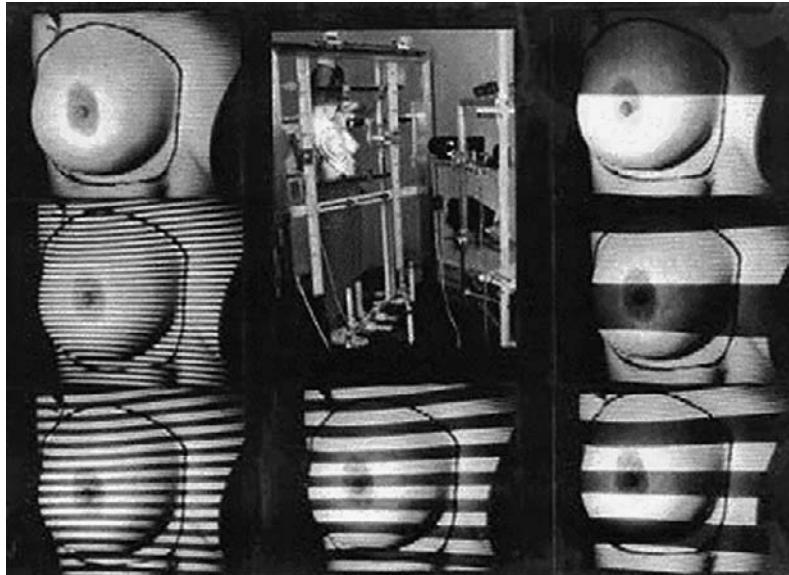

Newton<sup>87</sup> studied the milk-ejection reflex and clearly showed the effect of distraction on the let-down reflex. In the clinical experiment, distractions included immersing feet in ice water (reported to be the worst); being asked mathematic questions in rapid series, which resulted in an electric shock if a wrong answer was given; or having painful traction on the big toe (Table 8-3). In practice, pain, stress, and mental anguish interfere with let-down in some mothers. When simple adjustments such as making the mother more comfortable, playing soft music or leaving the mother in a quiet room do not work, other techniques should be tried.

Gentle stroking of the breast may help to decrease anxiety and stimulate flow. Use of tactile warmth as opposed to cold may improve release. Ice should not be used to make the nipple erect because it interferes with let-down. Cold is known

to interrupt the neuropathway and cause vasoconstriction.<sup>88</sup> Hyperactive let down can produce such a flood of milk that the infant is overwhelmed and often chokes and coughs. This overactivity occurs in the early days of lactation and gradually diminishes. The best approach is to have mother express and save the first 5 to 10 mL of milk before putting the infant to the breast. The expressed milk can be frozen for later use. If the second breast is exposed when the infant latches on, it too will let down and then will be defused when the infant attempts to latch on.

Excessive milk supply is more common in primiparas and is characterized by continued dripping between feedings, excessive amounts released during a feeding, and let-down at the slightest stimulus. Treatment is a firm, well-constructed brassiere. If necessary, a Velcro binder and cool packs can be applied between feedings. Dripping between feedings can be reduced by folding the nipple over before applying the breast pads. If it persists beyond 2 to 3 weeks, the mother should be evaluated for hyperprolactinemia or hyperthyroid or hypothyroid state (see Chapter 3).

A rapid computerized breast measurement system has been developed by Hartmann and his laboratory<sup>45</sup> for the determination of breast volume. Using patterns of 64 horizontal light stripes (moiré topography) projected onto the breast and chest wall allowed the calculation of volume by a digitized camera image analysis (Figure 8-26). The technique was verified by before and after test weighing of both the infant and the mother. Using this technology, they have been able to measure the amount of milk present, the storage capacity, and the amount of milk removed.

**Figure 8-26.** The computerized breast measurement system. Mother is positioned in the ultrasound machine. The breast images demonstrate the use of moiré patterning to measure change in breast volumes. (Courtesy Peter Hartmann, PhD, University of Western Australia, Perth, Australia.)

The average milk yield was more than 1100 mL every 24 hours for the first 6 months according to Hartmann and Prosser,<sup>45</sup> compared with previous estimations of 700 to 900 mL every 24 hours reported by other investigators. They also noted acute changes in the concentrations of lactose, glucose, sodium, potassium, and chloride 5 to 6 days before and 6 to 7 days after ovulation.

Studies of women to determine short-term rates of milk synthesis revealed that a close relationship exists between the removal of milk by the infant and the change in breast volume. The rates of synthesis in this study varied from 11 to 58 mL/h. The amount of milk available in the breast was not necessarily a determinant of the amount removed by the infant at a feeding.<sup>25</sup>

The use of ultrasound by experienced mammographers can be useful in evaluating mammary response to let-down, as well as to determine the presence of abnormality of the ductal system. Ultrasound is a noninvasive, objective technique that can measure milk duct diameter and milk duct flow. A significant increase in milk duct diameter is seen when let-down occurs (see Figure 8-25). When the mother sensed let-down or when infant swallowing increased, a corresponding change in duct diameter occurred. After initial let-down, subsequent surges were observed by ultrasound as ducts intermittently dilate. Pulses of oxytocin occurred every 45 seconds or so. The number of milk ejections influenced the amount of milk consumed.<sup>102</sup> A maximum duct expansion appears to happen regardless of pressure or oxytocin release. Milk intake is not related to the degree of dilation or the maximum duct diameter in these studies but to the number of milk ejections.

Ultrasound has also been used for treating plugged ducts (see Chapter 16).

## DRUG-ENHANCED LACTATION

The most direct therapy to enhance let-down is oxytocin. When simple supportive measures fail, oxytocin can be prescribed at home as a nasal spray. Oxytocin is no longer available as a packaged nasal spray and must be obtained by prescription as Pitocin, a synthetic oxytocin. Oxytocin is a polypeptide hormone of the posterior pituitary gland; the synthetic preparation avoids the risk for contamination with vasopressin, an ADH. The hormone is destroyed by gastric juices and therefore is not effective orally. The available preparation is intended for intramuscular or IV use and contains only 10 units of oxytoxin hormone per milliliter. The original nasal spray brand, Syntocinon, contained 40 units/mL. The currently available prescription is written for a 15-mL nasal spray or nasal dropper using standard oxytocin. The dose

is one or two sprays or four to six drops in the nares, followed by feeding or pumping within 2 to 3 minutes. The dose may be repeated in the other nares if let-down falters or the infant is nursed on the other breast. In most cases, it is effective within one or two feedings, and the prescription rarely needs refilling. Let-down will usually continue without medication.

The efficacy of metoclopramide in enhancing milk production in women pumping for infants unable to nurse or in women whose infants have significant failure to thrive because of inadequate milk supply has been reported. The dose is 10 mg of metoclopramide three times per day until milk volume increases (i.e., 4 to 6 days, then taper over 4 to 6 days). When the infant is actively suckling, this stimulus is usually adequate. Mothers who are pumping for a premature or ill infant may find the effect totally disappears when the drug is discontinued. The original studies did not explore long-term use. Metoclopramide is used in adults for various forms of reflux for 4 to 12 weeks. It is also used for reflux in infants, especially premature newborns (0.1 to 0.5 mg/kg of body weight per day). The amount transferred to the infant through breast milk is reported as only 28 to 157 mg/L (1 to 13 mg/kg/day). Side effects do occur and tend to be dose related (i.e., greater than 40 mg/day in adults). Mothers may experience diarrhea, sedation, or nausea, but no symptoms have been observed in neonates. Torsades de pointes has been reported to be unrelated to dose. The extrapyramidal tract symptoms are associated with large or chronic doses of metoclopramide. Caution should be used in hypertensive women. It is not recommended for long-term use.

Domperidone, which is not approved in the United States, is available in Canada and other countries under the names Motilidone and Motilium. It has been reported anecdotally that 10 to 20 mg three to four times per day will increase prolactin levels and increase milk production.<sup>31</sup> Women have taken it for months because the effects stop when the drug is stopped. Any mother contemplating using domperidone should check with her physician. Screening for any medical conditions, such as a personal or family history of cardiac arrhythmias or concurrent use of other medications that may prolong the QT interval or inhibit the metabolism of domperidone (macrolide antibiotics and triazole antifungals), is essential.

Many herbal preparations have been credited as galactagogues but there are no controlled studies even though many of these preparations have been used for centuries. Fenugreek is probably the best known. As an herb, it is used as a "maple syrup" substitute and causes secretions in mother and infant to smell like maple syrup. As a galactagogue, large

amounts (three capsules three times per day) are required. It has a cross-allergy to peanuts and may cause colic in the infant. Further discussion can be found in [Chapter 12](#).

### SIDE EFFECTS ASSOCIATED WITH LET-DOWN

The let-down reflex has been associated with headache, which occurs transiently at time of initial let-down and then on changing breasts, related to surges in oxytocin. See [Chapter 16](#) for discussion of cephalgia.

Nausea has also been associated with let-down and specifically with release of oxytocin. Women compare it with the waves of nausea of pregnancy. Treatment is taking food before initiating the let-down and breastfeeding. Dry crackers work well. The symptom is more effectively prevented than cured. Usually the symptom disappears in 3 to 4 weeks. Wearing pressure wristbands, which are effective for motion sickness, can be effective if applied before starting to nurse.

Marshall et al.<sup>78</sup> used thermal probes on the mother and infant to document hot flashes. Skin conductance increased, followed by increased skin temperature. Women also experienced night sweats and hot flashes during lactation, especially in the early weeks postpartum. They were most notable during night feedings. The phenomenon is also associated with oxytocin releases.

### *Phantom Let-Down*

Postlactation phantom let-down is described by women who breastfed their children but are no longer lactating. It is described as the sensation of let-down, including the tingling and turgescence when they hear a newborn baby cry, visit the nursery, or have some other encounter with infants. It is usually bilateral and transient. It does not produce milk. If it were to do so, the women should be evaluated for a prolactinoma. Women well past menopause have described being able to induce the sensation. No treatment is usually necessary, although vitamin E has been suggested for other breast pain at 800 mg/day for a week and then reduced to 400 mg/day until pain is gone (courtesy Kathy Leeper, MD, Milkworks, Lincoln, Nebraska).

### *Postnatal Period*

Hospitals have gradually returned to "rooming-in" or birthing centers for uncomplicated deliveries.<sup>109</sup> Easy access of an infant to the mother has been shown to facilitate lactation success. The

value of a well-trained, knowledgeable, and empathetic nursing staff should not be underestimated. The knowledge and attitude of the staff have been two of the most important variables in successful breastfeeding. This style of postpartum care better prepares parents for discharge, because they will know their infants' cues. All hospitals should incorporate the WHO/UNICEF ten steps. Ideally, hospitals should become Baby Friendly.

The family's transition from hospital to home can be stressful.<sup>136</sup> The parents hear the infant, who has been passive and content, wake up and cry for the first time. Because of all the procedures necessary to discharge an infant from the hospital (discharge physical examinations, blood tests, etc.), the well-planned discharge is often delayed and everyone is frantic, including the infant. A mother should be reassured about this and not be alarmed if she has to feed the infant frequently the first day at home.

When 1075 infants were assessed for cessation of breastfeeding, 113 were identified as having stopped breastfeeding. Using a multiple logistic regression analysis, eight variables were significantly predictive of breastfeeding cessation—maternal age, previous breastfeeding experience, latching difficulty, breastfeeding interval, and number of bottles of formula—when scored 0 to 2. The lower the score the greater the risk for stopping breastfeeding by 7 to 9 days ([Tables 8-4](#) and [8-5](#)).<sup>44</sup> A breastfeeding assessment score can be used in whole or in part to determine the potential for problems and therefore the intensity of the follow-up plan after discharge.

**TABLE 8-4** Breastfeeding Assessment Score\*

Variable	Score		
	0	1	2
Maternal age (yr)	<21	21-24	>24
Previous breastfeeding experience	Failure	None	Success
Latching difficulty	Every feeding	Half the feeding	<3 feedings
Breastfeeding interval, every hour	>6	3-6	<3
No. of bottles of formula before enrollment	>2	1	0

\*Two points should be subtracted for the presence each of the variables of previous breast surgery, maternal hypertension during pregnancy, or vacuum vaginal delivery.

Breastfeeding Cessation Rates (%) at 7 to 10 Days by Breastfeeding Score			
Score	No. of Patients	Cessation Rate	
		Predicted	Actual
10	173	3.2	1.7
9	288	5.1	5.6
8	244	8.1	7.4
7	183	12.7	16.4
6	101	19.2	17.8
5	49	28.1	26.5
4	18	39.0	33.3
3	13	51.2	38.5
2	5	63.2	80.0
1	1	73.8	100.0
<1	0	—	—

## The Role of the Clock

Many women today who work in demanding careers live by the clock and have trouble when advised to let a new baby give the cues. Anthropologist Millard<sup>80</sup> examined pediatric advice on breastfeeding and noted that major textbooks on pediatrics focus on timing. She points out that "once the clock is seen as inherent in human behavior, adherence to the timetable becomes a standard for judging competence, adequacy, and normality." The clock is a central touchstone in our cultural system. Pediatric literature reinforces pressures on women regarding their infants and leads pediatricians to a role of shaping public views of infancy, motherhood, and

humanity in general. In breastfeeding, the pediatrician can help the mother break her bonds to timing and move to the central issues of successful breastfeeding, responding to infant cues.

## Feeding Frequency

Many hospital schedules are on a 4-hour feeding program, which were originally based on the feedings of bottle-fed infants, whose slow emptying time of the stomach with formulas requires up to 4 hours. The emptying time for breast milk is about 1½ hours; thus frequent feedings are not unusual. Pediatric textbooks at the beginning of the twentieth century described 10 to 12 feedings per day as normal.<sup>63</sup> Comparison of mammalian care patterns and composition of milk shows an inverse relationship between protein content and frequency of feedings. From this, it might be deduced that a human infant might need to be fed more frequently than every 4 hours (Table 8-6).<sup>68</sup> Infants who sleep 5 to 6 hours at a stretch at night may make up for skipped feedings during the day. Fewer than 8 feedings per 24 hours in the first month of life is rarely associated with successful lactation.

When milk intake and feeding patterns of thriving, exclusively breastfed infants were documented from birth for the first 4 months of life by Butte et al.,<sup>19</sup> two feeding patterns emerged. In one, the authors describe the feedings as distributed throughout the 24-hour day. In the other, feedings were excluded from midnight to 6 AM, although all infants were feeding ad lib. Total intake was the same in 24 hours. Milk intake per feeding decreased over the day. Frequency and duration declined over the 4-month period. Weight gain was similar in the two groups. There is not a perfect pattern for all infants.

**TABLE 8-6** Mammalian Care Patterns and Composition of Species Milk

	Pinnipedia: Seal, Sea Lion	Tree Shrew	Rabbit	Rat	Black Rhinoceros*	Chimpanzee	Human
Infant care pattern	Return to ocean after birth	—	Cache	Carry, hibernate	—	Carry	?

Fat (%)	53	6.5	18	8	1.4	1.2	1.2
Carbohydrate (%)	0-0.90	3.2	2.0	2.6	6.1	7.0	7.0

\*The rhinoceros has an anatomic variation in the stomach that provides four pouches that fill during a feeding and provide a constant trickle of milk to the central groove leading to the small intestine, thus creating a constant feed.

The pattern of intake during a feeding is different between breastfed and bottle-fed infants. A bottle-feeding infant sucks steadily in a linear pattern, receiving 81% of the feed in 10 minutes. Howie et al.<sup>54</sup> showed that a breastfed infant has a biphasic pattern, which includes the first 4 minutes on the first breast and the first 4 minutes on the second breast (between 15 and 19 minutes into the feed). The infant receives 84% of the total volume in those 8 minutes. In another study, 50% of the feed on each breast was consumed in 2 minutes and 80% to 90% by 5 minutes. Milk flow was minimal during the last 5 minutes. All these observations were made on the fifth to seventh day of life (see *Figure 8-2*). In clinical settings, some infants are satisfied in 8 to 10 minutes, and others take 30 minutes to consume the same volume.

Switch nursing is often suggested to increase total intake of an infant when milk production needs stimulating, especially if the infant is not gaining adequately (see *Figure 8-2*). However, this may be counterproductive. When mothers fed 10 minutes on each breast (10 + 10), they produced the same amount of milk as they did nursing 5 minutes on a side and switching back (5 + 5 + 5 + 5). The suckling-induced prolactin is similar with both patterns as well. A major concern of switch nursing is not feeding long enough on either breast to obtain the full calories of hind milk. Even if this improves volume, total calories may be decreased. The infants do not nurse for a full 20 minutes in some cases, and the nutritive feeding time is less than 15 minutes. The duration of feeding should be determined by the infant's response and not by time. Enough time must be spent on a single breast to assure getting the fat-rich, calorie-rich hind milk.

The wide range in breast milk volume in well-nourished mothers was shown by Dewey and Lönnerdal<sup>29</sup> to be caused by a variation in infant demand rather than an inadequacy of milk production. They stimulated milk production with postfeeding pumping for 2 weeks, but the infants failed to continue to take more than previously. Although milk production was augmented by pumping, the infants regulated their own intake. It is difficult to overfeed a breastfeeding infant.

New mothers are often most insecure and most concerned about lack of scheduling, especially if an ad lib program of feeding has been suggested. Other mothers seem to thrive on random scheduling. Some physicians continue to instruct mothers rigidly about adhering closely to a schedule designed for the bottle-fed infant. This can lead to failure of lactation unless the mother is sufficiently confident to follow her infant's demands and feed more frequently and on demand.<sup>63</sup>

When a mother expresses concerns about frequent feedings and worries about the adequacy of her milk (she is often disturbed that it looks thin and blue after the luxurious color of colostrum), she may find that keeping a record of feeding times and duration, as well as sleep and wakeful times, is helpful.<sup>16</sup> The mother is usually surprised to find how quickly her infant develops a schedule. Often the infant is sleeping longer than she thought. The chart is also reassuring to the physician, especially if weight gain is marginal. In some cases, it will highlight a problem not previously identified, such as a poor gainer who sleeps all night, missing several feedings. This approach serves to refocus attention on the infant and cues and not on the clock. Such charting is often suggested to problem solve.

Milk production is influenced by the frequency, intensity, and duration of suckling by the infant, especially in the early postpartum period. Infant weight has been associated with the volume of milk intake. Greater suckling strength, frequency, and duration of feedings apparently play a part in weight gain, according to cross-cultural studies.<sup>99</sup> Self-regulation of milk intake has been studied by several investigators with similar conclusions. When mothers increased their milk supply by pumping after a feed, infants took a little extra milk for a few days but gradually dropped back to their previous intake. Residual milk volumes were noted by Dewey and Lönnerdal<sup>29</sup> to average about 100 g/day when women compared the amount extracted by pump with the infant's intake. The volume available in the second breast in a given feeding is about 60% of the volume of the first breast.

A study of 71 mother-infant pairs, in which the infants were 1 to 6 months of age and exclusively breastfed on demand, test weighed the infants before and after each feeding and collected milk samples. Frequency varied from  $11 \pm 3$  times in 24 hours (range 6 to 18) and volume was  $76.0 \pm 12.6$  g (0 to 240 g). Left and right breast volume was different. The fat content was  $41.1 \pm 7.8$  g/L (range 22.3 to 61.6 g/L) and was independent of frequency as was volume per 24 hours.<sup>62</sup>

A mother's age and parity have little effect on milk production once full lactation is established. The data available from adolescent women are sparse, but healthy, well-nourished adolescents produce adequate milk for normal growth of their infants. Stress, lack of support, and acute illness have been associated with decreased volumes, especially in relationship to poor let-down.

## *One-Breast/Two-Breast Feedings*

The dogma of more than 50 years had been that an infant should feed at both breasts at each feeding,

until the case report of Woolridge and Fisher<sup>149</sup> concerning an infant who failed to thrive when fed by both breasts at each nursing. The authors demonstrated that this mother did not produce high-fat milk until well into the feeding and thus switching to the second side deprived the infant of fat-rich, calorie-rich milk. Confining the feeding to a single breast solved the problem. The authors also pointed out that consuming volumes of low-fat milk meant relatively high-lactose milk, which caused diarrhea and further calorie loss.

When a study compared the two patterns of feeding in 12 mother-infant pairs, Woolridge et al.<sup>150</sup> found that the two patterns led to different milk volumes and mean feed-fat concentrations. The mean fat intake in 24 hours, however, was the same. Infants appeared to regulate their fat intake quickly; thus the authors recommended "baby-led" feeding. In other words, a mother should initiate feeding at one breast and continue until the infant discontinues feeding. If, after burping, the infant wants more, the mother offers the second side. The next feeding time is started on the opposite breast. In a study by Evans et al.,<sup>34</sup> an experimental group of 150 newly delivered mothers were instructed to breastfeed on one breast per feeding, alternating the breast offered first. The control group ( $n=152$ ) offered both breasts each feed for 8 days. There was significantly less engorgement in the one-breast group (61.4%) than the two-breast group (74%). Infant weight gain was no different, nor was there incidence of mastitis. Less colic occurred in the experimental group (12%) versus the control group (23%). Duration of breastfeeding was the same.<sup>34</sup> Other investigators report similar findings.<sup>112</sup>

These studies and observations were done after the infants were 1 month of age.<sup>112,149</sup> When a mother is establishing her milk supply in the first days and weeks, switching to the second breast for each feed allows frequent, short stimuli to both the breasts. If an infant drifts to sleep after the first side and will not latch on the second side, the infant should be started on the "second side" when waking for the next feeding. Most successful nursing mothers adapt to their own infants' cues instead of following arbitrary rules. Switching prevents full hind milk fat production and lowers energy content. More high-calorie milk may be produced by nursing at only one breast per feeding.

The identification of a factor that exerts a direct and local inhibitory action on further milk synthesis may explain why some women nurse only on one breast as a cultural mode. In situations in which the infant rejects one breast, some inhibition of milk production may precipitate the rejection.<sup>132</sup> The inhibitory factor decreases the production in the "abandoned" breast, while the other breast

continues to function and completely sustain the infant's growth. There is no reason a woman cannot continue nursing on one breast indefinitely. This has been suggested in cases of recurrent mastitis in one breast that is unresponsive to repeated antibiotic therapy or after lumpectomies for cancer.

van Gelderen and Goosen<sup>132</sup> describe two cases of unilateral breastfeeding. A 41-year-old woman had nursed seven infants only on the left breast after an abscess in the right breast early with the first child. A mammogram while nursing her youngest, an 18-month-old infant, showed the left breast apparently lactating and the unused right breast normal and nonlactating. A 27-year-old mother was breastfeeding her second child at 2 years old when mammography was done. The feeding breast appeared to be lactating, and the unused breast was larger and cystic. She had also nursed only on the left breast for 4 years with the first child. The rejected breast in some cases, such as these, has been found to have some pathology.

## Adequate Rest

If nursing is not going well, a common cause of problems is maternal fatigue. The mother may need to be ordered by her physician to nap and rest. She must learn to nap when the infant is napping. This becomes more difficult when she has other young children, but a simultaneous nap for all the little ones and mother may have to be organized. Otherwise, she may have to go to bed with the children at night and just concentrate on resting and feeding the infant. When the need for rest is acute, the father should be assigned infant care, with the possible inclusion of bottle or cup feeding in extreme cases, while the mother sleeps undisturbed for a few hours. Fatigue also contributes to depression.

## Sore Breasts and Plugged Ducts

Tender lumps in the breasts in a mother who is otherwise well are probably caused by plugging of a collecting duct. Some women on high-calcium diets have excreted grains of white sand that are thought to be minute calcium stones plugging a duct. The best treatment is to continue nursing. Increasing fluids and decreasing high dietary calcium is recommended. Manually massaging the area to initiate and ensure complete drainage should be recommended. Hot packs before feedings may help. If the breast is especially tender, initiating nursing on the opposite breast first permits the affected breast to let down without the pressure of suckling. The affected breast should be completely emptied by nursing or manual

expression. The brassiere may be cutting off an alveolus because of pressure from a narrow strap. Changing the infant's position may also help. Gentle, persistent massage to relieve the lump usually clears the problem.<sup>39,70,133</sup>

## *Repeated Plugging*

When plugging is recurrent, one needs to look for a major cause, such as exhaustion and fatigue. Several women have come to a lactation center's attention with repeated lumps in their breasts with poor flow of milk, often as if the ducts were plugged. The condition responded fairly well to manual expression before each feeding, often with the expulsion of small plugs. These plugs were fatty, in contrast to the hard, white "grains of sand of calcium." The condition dramatically improved by limiting the mother to polyunsaturated fats and adding lecithin to the diet. It was also necessary for subsequent pregnancies in all three cases. Lecithin, a lipid constituent of human milk, is an oily substance that can be used as an oil on salads or taken by spoon, 1 tablespoon per day. It is also available in capsule form. A case of recurrent plugged ducts was reported by Fetherton et al.<sup>37</sup> to be immunoglobulin A deficiency. On more complete history, the mother had a history of recurrent infections as a child as well.

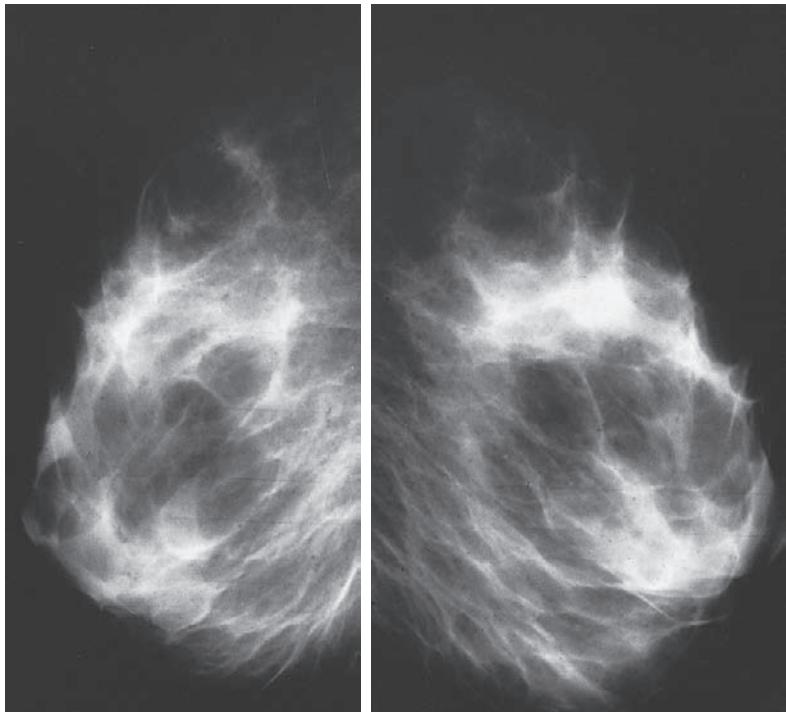

## *Galactocele*

Milk-retention cysts are uncommon and, when found, are almost exclusively a problem in lactating women. The contents, at first, are pure milk. Because of fluid absorption, they later contain thick, creamy, cheesy, or oily material. The swelling is smooth and rounded, and compression of it may cause milky fluid to exude from the nipple. Galactoceles are thought to be caused by the blockage of a milk duct. The cyst may be aspirated to avoid surgery, but will fill up again. It can be removed surgically under local anesthesia without stopping breastfeeding. Thus its presence does not require cessation of lactation. A firm diagnosis can be made by ultrasound; a cyst and milk will appear the same, whereas a tumor will be distinguishable. If it is recurrent or persistent, it can be surgically removed after weaning is over.

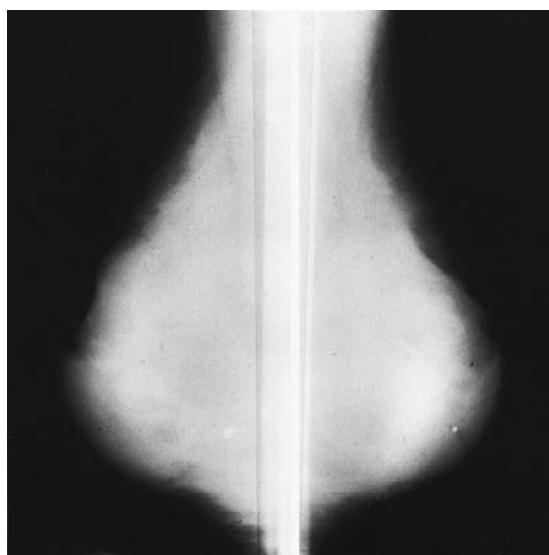

Figures 8-27 and 8-28 illustrate mammography of the lactating breast.

## *White Bleb on Nipple (White Dot)*

Often described as a "white dot," a white bleb on the nipple has frequently been a source of considerable discomfort for the mother and concern for the health professional. The solitary bleb appears on the surface of the nipple, usually at the opening of a duct, has a shiny, smooth surface, and is a

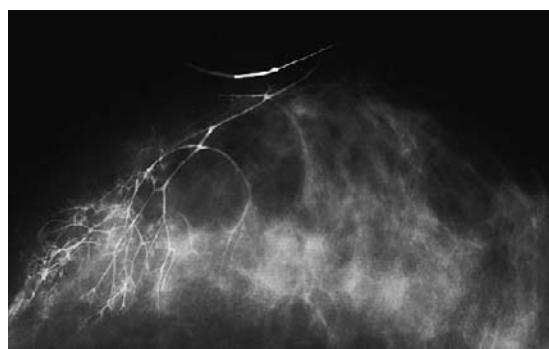

**Figure 8-27.** Normal breast tissue visualized by mammography. Tissue is one third fat and appears cystic in nature. (Courtesy Dr. Wende Logan-Young, MD, University of Rochester School of Medicine, Rochester, New York.)

**Figure 8-28.** Breast tissue during pregnancy and lactation is visualized by mammography. Fat is replaced by lactation tissue and presents a solid appearance. Tumors would be easily distinguished by this procedure in the lactating breast. Mammography is a safe, noninvasive technique that does not interfere with nursing. (Courtesy Dr. Wende Logan-Young, MD, University of Rochester School of Medicine, Rochester, New York.)

millimeter or less in diameter. The mother usually describes exquisite pinpoint pain when the baby nurses. The bleb does not break or disappear with proper grasp and suckling. It may be "curved" or disappear when the health professional opens it with a sterile needle. It may reappear and have to be opened again. A home treatment for a bleb is reported to be used in some cultures (Hmong). It involves taking a human hair, doubling it on itself, and rolling it until it forms a stiff fine rope. It is then inserted into the duct until the plug is freed.<sup>2</sup> A more sterile adaptation of this would be to take a strand of sterile heavy (0-00) suture and cannulate the duct, threading the suture up the duct until the plug is released. Sterile suture is available in the average medical office (Figure 8-29). The bleb probably represents a small pressure cyst formed at the end of the duct from milk seeping into this elastic tissue. The bleb is different from the sucking blister that appears early in lactation associated with vigorous suckling or malposition. The blister covers a larger area and is not associated with a duct or exquisite pain. The bleb also should be distinguished from *Candida* infection, especially if there is more than one. Although a nipple with *Candida* infection is usually pink and painful with suckling, a nipple can have small caseous lesions similar to oral *Candida* infection. This requires specific treatment for *Candida albicans*.

<sup>2</sup>Courtesy International Board of Lactation Consultant Examiners network.

**Figure 8-29.** A 38-year-old patient's craniocaudal mammography view shows segmental duct draining a lobe in the medial aspect of the right breast. Ductal patterns differ among women. (From Logan-Young W, Hoffman NY: *Breast cancer: a practical guide to diagnosis*, Rochester, New York, 1994, Mt. Hope Procedures, vol. 1.)

This painful white bleb is the end of a plugged duct. If "needling" has not cured it, rubbing lecithin into the nipple after each feeding may be effective here as well as with frank plugged ducts. A lactation consultant reports curing white blebs with multiple applications of lecithin. If, however, it is a buildup of cells like seborrheic dermatitis or cradle cap, lecithin works. The best treatment for cradle cap is oil or greasy ointment.

## Breast Rejection

Infants have been observed to reject the breast intermittently, most often at 3 to 4 months, and then to go back after several feedings or a day or so. A bottle can be substituted, or cup feedings, if the situation becomes extreme, as described in Chapter 15. Total rejection of both breasts may follow the return of menstruation. A mother may notice that the infant will reject the breast for a day or so with each period. Other infants seem unaffected. Strong foods in the diet may cause rejection of milk, which usually occurs 8 to 12 hours after ingestion and disappears by 24 hours after ingestion. Occasionally one breast is permanently rejected so that the milk supply dwindles. One-breast nursing can be done, as noted previously.

Refusal to nurse may not be a nursing strike or abrupt weaning. (Nursing strikes are discussed in Chapter 10.) It may be a change in milk flavor. Onions and garlic have been cited as culprits and vindicated by research, but a case was reported of refusal to nurse after maternal ingestion of mint candies in especially large quantity.<sup>41</sup> Strong flavors may pass into the milk. A dietary history including beverages and herbs is an important part of discovering problems.

## *Unilateral Breast Rejection*

Some infants prefer one breast and even refuse the other. When this occurs, manual expression or softening the nipple for easier grasp may help, thus enticing the infant to suckle. Holding the infant in the same position (i.e., on same side in same direction, so-called cross-cradle hold) for the other breast may lead the infant to be tricked into taking the second breast. Sometimes applying syrup or honey to the rejected nipple will help. Unilateral breastfeeding is a custom in some parts of China. Sodium and chloride levels may rise in milk after mastitis. If the problem persists, it is wise to taste the milk or have sodium and chloride levels measured in milk from both breasts to be sure no reason exists for the rejection.

Goldsmith<sup>43</sup> reported five cases of lactating women whose infants suddenly rejected a single breast. Weeks or months later, the mother noted a mass, and biopsy revealed a malignancy. It would be wise to examine any patient who complains of unilateral breast rejection that does not respond to simple measures to rule out a tumor. Ultrasound followed by a mammogram, if necessary, can be performed without discontinuing lactation.

## *Other Causes of Nipple and Breast Pain*

Classification of mastalgia, or breast pain, includes cyclic causes (67% of cases), noncyclic causes (i.e., not related to menstrual cycle, 26% of cases), and Tietze syndrome (painful lateral costochondral junction, 7%). Mastalgia in young women may spontaneously disappear with pregnancy. This has been associated with higher basal levels of prolactin (unrelated to lactation) and low plasma levels of essential fatty acid  $\alpha$ -linolenic acid and its metabolites, which are important components of cell membranes. Administration of  $\alpha$ -linolenic acid improves the pain, according to Gateley and Mansel.<sup>39</sup> Evening primrose oil (Efamast) is a rich source of  $\alpha$ -linolenic acid. This is a safe, even nutritious solution to the problem and a safe herbal treatment. Colchicine 0.6 mg has been utilized for persistent breast pain, but no reports on its use are available in the literature. It has an effect on leukocyte inflammatory response, as well as treatment for gout. It should only be used in extreme cases of pain.

## **ANKYLOGLOSSIA**

Ankyloglossia, or tongue-tie, is a change in the appearance or functions of the tongue because

the frenulum is shortened, inelastic, thickened, or positioned toward the tip of the tongue or close to the gingival ridge. Its incidence is 3% to 5% of newborns and may be associated with breastfeeding difficulties. There is considerable controversy regarding the diagnosis, indications for treatment, and need for antibiotic prophylaxis. The ABM has a protocol for dealing with the situation, which thoroughly reviews the issues.<sup>121</sup> It is available at [www.abm.com](http://www.abm.com) (see also discussion in Chapter 14).

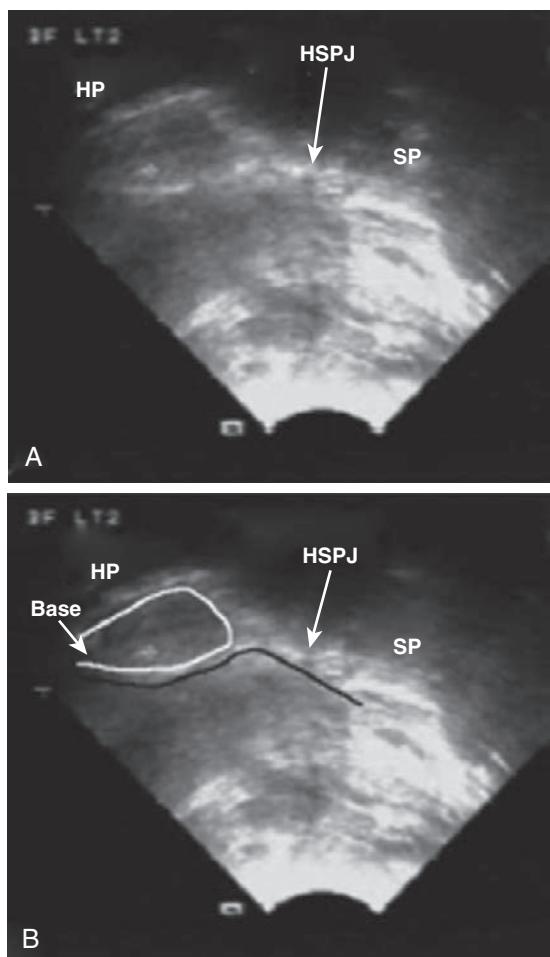

Although rare, tongue-tie or a tight-tongue frenulum may be a cause of severe nipple pain and inadequate milk supply. With ankyloglossia, an infant cannot protrude the tip of the tongue over the gums, the tip is tied to the floor of the mouth by a tight cord of a thick frenulum, and the tongue becomes heart-shaped when effort is made to extend it. When the infant tries to draw the teat into the mouth, it will not be possible, and nipple trauma results. The physician should consider cutting the frenulum once the diagnosis of ankyloglossia (short lingual frenulum) is confirmed by oral examination (Box 8-5).<sup>57,91</sup> The procedure is simple, but the cut should be carefully placed to avoid the artery, nerves, and other anatomic sites. It is usually bloodless, and the infant can be nursed immediately, now in the correct position. Antibiotic prophylaxis is not indicated for the procedure unless the infant has significant cyanotic cardiac disease or is 6 months or less after cardiac repair. Anesthesia is usually not required, nor is suturing. Observation for bleeding is brief. In the rare case of bleeding beyond 3 minutes a strip of gelatin foam can be applied to achieve rapid hemostasis and removed before feeding (Figure 8-30).

## **ECZEMA**

Women who have eczema elsewhere may also have it on the breast, especially the nipples and areolae. Breastfeeding can be initiated with continuation of

### **BOX 8-5. Identification of Ankyloglossia (Tongue-Tie)**

1. When tongue protrudes, tip is anchored behind alveolar ridge.
2. When infant cries, tongue remains anchored.
3. Tongue is notched or heart-shaped when protruded.
4. Tongue cannot be manually extended by examiner.
5. Frenulum is short (less than 1 cm [ $\frac{1}{2}$  inch]) and inelastic.
6. Tongue is attached close to alveolar ridge.

**Figure 8-30.** **A**, Ultrasound image of the oral cavity of a breastfeeding infant with ankyloglossia prefrenulotomy. The tongue is up in contact with the palate. The hard palate (HP), soft palate (SP), and hard and soft palate junction (HSPJ) are marked. **B**, Note the compression of the base of the nipple (outlined in white). Compression of the nipple is caused by upward movement of the distal portion of the tongue (outlined in black). (From Geddes DT, Langton DB, Gollow I, et al.: Frenulotomy for breastfeeding infants with ankyloglossia: effect on milk removal and sucking mechanism as imaged by ultrasound, *Pediatrics* 122:e188–e194, 2008.)

the mother's standard treatment. Most women can nurse successfully.

Eczema of the nipples, and sometimes also the areolae and breasts, presents as a red, dry, sore, even burning, flaking rash. The flakes often appear as "oily potato chips" in women who do not have eczema elsewhere. Common causes are washing nipples with soap or applying ointments that have irritants. Some creams contain peanut oil, which should be avoided by those allergic to peanuts (the most common food allergy); lanolin, for those allergic to wool; and cocoa butter, for those allergic to chocolate. A physician should instruct the mother to remove all irritants, including breast

shields and plastic-backed breast pads. Lesions usually clear quickly with proper treatment and avoidance of the irritant. A short course of halobetasol propionate ointment (Ultravate) rubbed sparingly into the area after each feeding will clear a persistent case in a few days.

### NIPPLE BLANCHING

Blanching of the nipples may cause burning pain during suckling. A vigorous "barracuda baby" can cause blanching of the nipple from pressure. Later in lactation (i.e., after 4 months, when teething begins), infants may bite down to relieve gum pain and cause nipple blanching and burning pain. The mother should be instructed to keep her finger ready to break the suction if pain becomes extreme or biting becomes frequent.

Blanching of the nipple to pure white with no apparent mechanical cause can also occur. This has been associated with some maternal medications, such as theophylline and terbutaline. Other medications that cause vasoconstriction may be associated.

Factors that control vasomotor tone in the mammary gland have not been well studied. Mammary blood vessels are exquisitely sensitive to epinephrine and norepinephrine, as well as serotonin and PGF<sub>20C</sub>, as vasoconstrictive agents.

Other causes of nipple blanching are cold, especially when ice is applied, and maternal smoking. Nicotine is a vasoconstrictor, as is caffeine, especially in sensitive individuals.

In some women, warm compresses to the areola before nursing will prevent the reaction and thus the pain. Heat applied after a feeding, such as the use of a small heating pad, is often effective. A "rice sock"—a sock filled with uncooked rice—can be warmed in the microwave, and held against the nipple for relief of spasm. Not all cases of nipple blanching have been relieved by heat; some have been relieved by cold, which is actually contrary to usual physiologic theory (see Chapter 16 for discussion of Raynaud disease).

### SUPPLEMENTARY FEEDINGS

Supplementary feeding of a breastfed infant continues to be controversial in pediatric circles. For the normal full-term infant, it is not necessary. Evaluation of serial blood glucose levels in breastfed and bottle-fed infants from birth reported by Heck and Erenberg<sup>48</sup> demonstrated a significant number of bottle-fed infants with hypoglycemia, presumed to be a rebound phenomenon from dextrose and water feeding early in life. Some breastfed infants had a value less than 40 mg/dL on the second day. No significant differences were found in serum

bilirubin and weight loss between supplemented and unsupplemented breastfed infants in a study by Herrara.<sup>48</sup> At age 3 months, a significant number of supplemented infants were no longer breastfeeding (still breastfeeding, 81% unsupplemented versus 53% supplemented). Even in hot, dry climates, water supplements were not found to be necessary.<sup>4,9,42</sup> Urine osmolarity remained within physiologic ranges in unsupplemented breastfed infants studied by Goldberg and Adams.<sup>42</sup> This has been demonstrated by a number of other investigators. The supplementation with water did not influence the "coming-in" of mother's milk, according to Schutzman et al.<sup>120</sup> They did observe, however, that infants in the group being supplemented took very little water after nursing (less than 4 oz total in the first 3 days).

Many physicians suggest to mothers that a supplementary bottle can be added any time. Actually, when lactation is going well, it is not needed, and when it is not going well, a bottle may aggravate the problem. During hospitalization, giving a substitute bottle may confuse a new infant, who may be having trouble sucking at first. Infants who are given water or glucose water in the hospital do less well and usually lose more weight. A significant relationship exists between supplements in the hospital and early discontinuation of breastfeeding. It is a marker of impending trouble and of insufficient milk production, which is best treated with frequent feedings at the breast and some intervention from an experienced lactation consultant.

The effect of formula supplementation on the outcome of breastfeeding was observed in two nurseries, one used as a control and the other supplemented. Mothers could request supplements in either group, and any baby put to the breast only twice was called "breastfed." It was clear that mothers who requested formula in the hospital and requested a going-home formula package were more likely to discontinue breastfeeding. They considered this early behavior a marker of high risk for failure. These patients, therefore, should have received follow-up and considerable support when identified as high risk. Supplementing with water, glucose water, or formula continues to be reported as the most likely cause of early termination of breastfeeding. Analysis of a nationally representative survey, Listening to Mothers II, clearly pointed to supplementation as the prime reason for a mother to fail to reach her breastfeeding goals.<sup>28</sup> A study of Russian maternal home routines also demonstrated that supplementing resulted in poor weight gain and breastfeeding outcome. The investigators also noted a negative effect on breastfeeding when the infant was swaddled compared with those who were dressed.<sup>20</sup> Other risks of supplementation include introduction of bovine protein

and the allergic response due to early exposure to foreign protein. Supplements interrupt the delicate balance of immune modulation and early intestinal priming and clearly change the gut flora.

Indications to supplement are noted in protocol three hospital guidelines for the use of supplementary feedings in the healthy term breastfed neonate, available on the ABM website. Indications include unresponsive hypoglycemia, separation of mother and child by illness, severe congenital malformations, rarely maternal medication, and the rare metabolic syndrome of galactosemia. Supplements should be by physician order and be documented in the chart to include volume, content, timing, and medical indications.

Nipple confusion can occur in some sensitive infants whose suckling is not well established. It is not possible to identify the infant who will be confused ahead of time. Other infants can switch back and forth effortlessly. The use of complementary bottles, that is, those given after a breastfeeding to "top off" the feeding, is the beginning of a downhill course that may doom lactation to failure. It would be better to take the infant to breast more often or switch back to the first breast if the baby is still hungry. If the mother must be away at feeding time, she can pump a feeding ahead of time and save it in the refrigerator or freezer for someone else to give by bottle or cup.

## EXPRESSION OF MILK TO FEED

Women express their own milk for various reasons, such as for feeding the infant while the mother is at work, school, or other activities. This mode usually involves time when mother and infant are apart. It may be done temporarily because of illness or the need to take a contraindicated drug. A small group of women never feed their infants at the breast but only by bottles with their own expressed milk. A small group of women with HIV or HTLV express their milk so that it can be pasteurized at home and fed to the infant without exposing the infant to the disease.<sup>116</sup>

The trends in the use of expressed milk in Australia from 1993 to 2003 clearly demonstrated an increased use of pumped milk, with the rates doubling in a decade, although the rate of women in the work force increased only 4.3%.<sup>13</sup> Most of the women expressed because of engorgement, mastitis, or convenience. A similar study by Win et al.<sup>144</sup> reported that mothers who expressed their milk regularly were more likely to continue breastfeeding exclusively for 6 months than those who did not express their milk. The authors concluded that expressing milk gave women more lifestyle options.

## SOLID FOODS

Successful nursing mothers are rarely as impatient to start the baby on solid foods as mothers who bottle-fed frequently are. Milk, and especially human milk, supplies the appropriate nutrients. At approximately 6 months, a normal infant begins to deplete iron stores. This is probably an appropriate time to start solid foods, especially iron-containing ones. This permits the entire process of weaning to cup and solid foods to be gradual. An infant does not need teeth to eat baby food and, conversely, does not have to be weaned from the breast because teeth have erupted. By 6 months, the number of feedings usually decreases. The timing and volume begin to cycle to a schedule that resembles three meals per day and some snacks.

## EXCLUSIVE BREASTFEEDING FOR 6 MONTHS

There is no objective evidence that solids are needed before 6 months, according to a WHO/UNICEF meta-analysis.<sup>65</sup> Solids do not solve any problems. A reduced morbidity rate due to GI infections was observed in infants breastfed exclusively for 6 months or more and no observable deficits in growth. No benefits of introducing solids between 4 and 6 months have been identified, except for iron needs in special infants, which are best treated by iron drops. A breastfed infant usually starts some solids by 6 months of age.<sup>65</sup>

## CARRYING AND HOLDING

Carrying and holding young infants have been considered by some, in the era of peak bottle feeding, as predisposing to spoiling the infants. In many cultures around the world, infants are carried with the mother night and day.<sup>77</sup> In Western cultures, infants are tightly swaddled, that is, wrapped up like a package and put down. In a randomized controlled study of primiparous breastfeeding women, Hunziker and Barr<sup>56</sup> showed that increased carrying reduces infant crying and colicky behavior. Conversely, they showed that lack of carrying predisposes to crying and colic.

## SLEEPING

Sleeping through the night has been assumed to be an important developmental milestone dependent on maturation. First-time parents ( $n=26$ ) of exclusively breastfed infants were randomly assigned to a treatment or control group.<sup>97</sup> The treatment group was instructed to offer a "focal feed" between 10 PM

and midnight and then offer reswaddling, diapering, walking, and rocking to postpone the next feeding to 5 AM, minimizing light and sound. By 3 weeks, the treatment group was sleeping significantly longer. By 8 weeks, 100% of the treated group, compared with 23% of control infants, was sleeping at least from midnight to 5 AM. They fed more frequently during the day, especially early morning. Milk intakes for 24 hours between the two groups were not different. Pinilla and Birch<sup>97</sup> concluded that parents can teach their breastfed infants to lengthen nighttime sleep periods. Parents should be encouraged to develop management plans that they find most comfortable. Whether they share the family bed or keep the newborn in the same room or in the next room is their decision. Continuing night feeds is associated with longer duration of breastfeeding and more abundant milk supply.

Milk composition influences infant sleep latency. Tryptophan concentrations are higher in human milk than in formula. Tryptophan is known to increase sleep in adults. When breastfed and formula-fed infants were compared using formulas with different levels of tryptophan, they had shorter sleep latency with high levels of tryptophan.<sup>125</sup> In a survey of new mothers nationally, almost one in five mothers (18%) indicated that their infant always slept in bed with them in the first 6 months; 10% more reported the infant often did, and 16% said they sometimes did. Thirty-six percent of black non-Hispanic women reported always, but 30% of Hispanic mothers, and only 12% of white mothers, reported always sleeping with their baby. The AAP has spoken out against co-sleeping and has launched a vigorous campaign against co-sleeping. The ABM has developed a protocol regarding the issue.

In the report by Hauck et al.,<sup>47</sup> the main reasons for bed-sharing were to calm a fussy baby, facilitate breastfeeding, and help both mother and infant sleep better. The rates of bed sharing were 42% at 2 weeks, 34% at 3 months, and 27% at 12 months. Failure to comply with supine sleeping arrangements at night was 26% at 3 months, 29% at 6 months, and 36% at a year. Non-Hispanic black mothers were more likely to use nonsupine positions and to bed share. SIDS was not included in the report.

## *Colic and Crying*

By definition, colic is spasmodic contractions of smooth muscle causing pain and discomfort. It can be experienced in many organs, such as the GI or genitourinary tract, and at all ages. When the term *colic* is used in reference to infants, it

usually means a syndrome in which a young infant has unexplained paroxysms of irritability, fussing, and crying for a prolonged period, often at the same time of day, in the early months of life. The infant usually draws the legs up as if in pain. A myriad of remedies are directed at various possible causes, including allergy, hypertonicity, and hormone withdrawal. However, it may be a matter of parenting style and expectations that brings a parent to complain about colic. Colic does occur in premature infants but usually not until they reach 42 weeks' adjusted gestation.<sup>49</sup>

Infantile colic has been reported to occur equally among breastfed (20%), formula-fed (19%), and mixed breastfed and formula-fed (21%) infants in a study of almost 1000 infants.<sup>1</sup> Fecal  $\alpha$ -antitrypsin and fecal hemoglobins were not different in colicky infants. The series had no evidence of dietary protein hypersensitivity.<sup>129</sup> Lactose as a cause of colic has also been ruled out in several studies.<sup>72</sup>

Characteristically, an infant will cry and scream as if in pain from 3 to 4 hours at a stretch, often between 6 and 10 PM. The infant will nurse frequently and then scream and pull away from the breast as if in pain, only to cry a few minutes later. Sometimes the infant can be comforted by another adult such as the father or grandmother. The infant will respond to gentle rocking when held against a warm shoulder. If the infant is put down, the screaming starts again. If the nursing mother holds the infant, the infant is frantic unless nursed and yet does not need to be fed. This may disturb a new mother, who wonders why she cannot console her infant (Is her milk weak? Does it disagree with her infant? Is she an inadequate mother?). None of these is true, but smelling the mother's milk makes the infant behave as if it needs to nurse. Anyone who is not nursing can quickly quiet the infant. Picking up the infant does not spoil the child, and rocking and cuddling are appropriate. Warm pressure is usually palliative; a warm hot water bottle or warm shoulder with some pressure or massage is comforting. The use of rhythmic incessant sounds or lights (e.g., vacuum cleaner, TV out of focus so it is a changing pattern) has variable success.

A carefully taken history and physical examination are always in order to rule out other pathologic conditions, such as otitis media, anal fissure, hair tourniquet, or hernia before a diagnosis of colic is made. Hunger should be ruled out. Sometimes an infant who was just fed needs to be fed again. True colic, however, is characterized by an inconsolable infant who continues to fret, fuss, and cry. If true colic is diagnosed because of the consistency of the screaming for several hours each day at the same time, treatment is in order.<sup>61</sup>

## INFLUENCE OF COW MILK IN MATERNAL DIET

The literature is not straightforward on the issue of the effect of cow milk in the maternal diet and infantile colic. Information was first published on congenital sensitization to food, especially eggs and cow milk, in humans in the early twentieth century, which was manifested as clinical allergy in breastfed infants. Research techniques are far superior today, and information is accumulating. Gerard and Shenassa<sup>41</sup> report sensitization caused by substances in breast milk thought to be due to two types of food allergies one is immunoglobulin E (IgE) mediated and triggered by trace amounts of antigen, and the other is not IgE mediated and is triggered by large amounts of antigen. GI transport of macromolecules in the pathogenesis of food allergy is under investigation, as is T-cell-mediated immunity in food allergy. However, the present state of scientific knowledge has not resolved the issue of colic and cow milk for clinicians.

Clinical studies have been done to test the association of dairy products in mothers who breastfed and their babies with colic. Jakobsson and Lindberg<sup>58</sup> described a cause-and-effect relationship in a group of 18 mothers, which was criticized because it was not a double-blind study. Evans et al.<sup>34,35</sup> then reported that they found no such relationship when they did a double-blind crossover study in which mothers received cow milk protein for 2 days and then a placebo for 2 days. Jakobsson and Lindberg<sup>59</sup> repeated their work using a double-blind crossover study design in the mother-baby pairs in which the infants had colic; 35% of the infants improved on maternal diets free of cow milk. A torrent of mail to the journals confirmed these conclusions in small clinical practice trials as well.

Jakobsson et al.<sup>60</sup> found bovine  $\beta$ -lactoglobulin in the milk of 18 of 38 mothers chosen at random. Three mothers had high amounts, and their infants had colic that was relieved by a maternal diet free of bovine milk products. Dietary modification with a low-allergen diet should be considered in the mothers of healthy breastfed infants with colic, according to Hill et al.,<sup>50</sup> who reported a community-based study. They also restricted the diet by eliminating artificial color, preservatives, and milk, eggs, wheat, and nuts.<sup>50</sup>

Colic has been investigated in breastfed and formula-fed infants by measuring breath hydrogen ( $H_2$ ) production, a product of lactose metabolism.<sup>82</sup>  $H_2$  levels were significantly higher at both 6 weeks and 3 months of age in infants who developed colic. The authors suggest that increased lactose malabsorption may be related to colic. Studies that used lactase to minimize the effect of

lactose did not result in improvement. Nursing long enough to obtain high-fat hind milk and relatively less lactose could improve colic, however.

Lothe et al.<sup>75</sup> reported macromolecular absorption using human  $\alpha$ -lactalbumin as a marker. Breastfed infants with colic had significantly higher levels of macromolecules than infants without colic. The authors conclude that gut mucosa is affected in infants with colic. Further study by this laboratory reported that infants who later developed colic had increased levels of motilin from the first day of life, indicating the GI tract is affected even before symptoms appear.<sup>75</sup>

With a clinical picture of colic, a history of allergy in the family, especially to cow milk, is suggestive. A diet free of cow milk should be tried for at least a week (2 days rarely produces significant improvement) for any case of severe colic. Usually a mother eliminates drinking milk, and for some babies that is enough. If not, all milk products are then eliminated. If mild improvement results with elimination of dairy products, elimination of all bovine protein (i.e., beef) may make a difference. For the group of infants who have a cow milk allergy, the treatment is impressive. However, not all colic is caused by cow milk. It may be associated with other dietary items, such as eggs or chocolate, or it may be totally unrelated to maternal food intake.<sup>35</sup>

Acute 24-hour colic in a breastfed infant may result from other particular items in the maternal diet. If a strong vegetable (e.g., beans, onions, garlic, rhubarb) is taken for the first time and the infant starts to cry within a few hours and continues for 20 to 24 hours, this may be transient colic. This colic is self-limited and needs no treatment. The colic-inducing foods are different for different infants. Mailed questionnaires to 272 mothers, when their infants were approximately 4 months old, asked about symptoms related to colic. A high correlation was found between 24-hour colic and the mother's consumption of cruciferous vegetables, onions, cow milk, and chocolate and less so with beans, legumes, spicy foods, and caffeine.<sup>76</sup>

## MANAGEMENT OF COLICKY BEHAVIOR

No type of crying should go untended in a young infant. Holding and rocking do not spoil infants. Crying levels normally increase from birth to 6 to 8 weeks. Most infants spend 2 to 2½ h/day crying at this age.<sup>124,126</sup>

During the period of colic, the infant may need frequent small feedings and much cuddling. Sometimes the infants overfeed, then vomit, and settle down and go quietly to sleep, just as an overfed bottle-fed infant does.

The distress or discomfort may be caused by tension, and "colic" has been noted to be more common in the first infants of high-strung mothers.<sup>126</sup> Colic has been associated with withdrawal from maternal hormones and has been treated with progesterone. In breastfed babies, this is a less likely cause because of the presence of hormones in breast milk. Colicky breastfed infants who are weaned to formula are usually much worse. Weaning is not an appropriate treatment for the colicky breastfed infant in most cases. Colic usually diminishes in the third month of life, when the infant's GI tract matures.

Type A behaviors during pregnancy were measured by a self-selected cohort of primiparas.<sup>94</sup> After delivery, their infants were assessed at 48 hours and 3 months of age. The women who were type A had infants who cried more during neurobehavioral assessment compared with infants of type B women. At 3 months, the infants were more intense and less predictable in their responses to the environment. Type A women, however, were more likely to be still breastfeeding.<sup>94</sup>

In a thorough review of infantile colic, Miller and Barr<sup>81</sup> conclude that colic is still poorly understood. Causes in the GI tract include sensitivity to dietary components, excessive gas, hypermotility, and hormonal factors.<sup>35</sup> Social causes include normal crying behavior, atypical parenting, and problems of parent-infant interaction. The authors conclude that colicky infants are not a homogeneous group and that it is a variation of normal behavioral and biologic factors and not pathology.<sup>81</sup> A breastfeeding mother needs to know it is not her fault.

Weizman et al.<sup>139</sup> studied an herbal tea preparation, and found it improved colic in 57% of infants compared with only 26% of infants who received the placebo of warm glucose-flavored water. The herbal tea, however, contained chamomile, verbain (*Verbena officinalis*), licorice, fennel, and balm mint, several of which are not recommended for infants (see Chapter 12). Unfortunately, the dose of active ingredient is never predictable in herbal preparations, even when obtained from a reliable source. A traditional treatment for colic is gripewater, which is an extract of fennel and ginger, both of which are safe herbs for infants.

Another explanation for colic and failure to thrive has been suggested by Woolridge and Fisher.<sup>149</sup> They note that when an infant is taken from the first breast and switched to the second, this may decrease the amount of fat and energy received.

In addition, it will take the infant more volume to receive enough calories, which may cause symptoms of hunger with crying and fretfulness. The increased lactose and less fat cause increased gas.

When mothers were randomly assigned to use only one breast or both breasts at a feeding, Evans et al.<sup>34</sup> found that one-sided breastfeeding was associated with less colic and less postpartum engorgement. Later, most mothers felt they needed to feed on the second side to satisfy their infants' hunger.

Lower fat causes rapid gastric emptying with less digestion of lactose, thus producing diarrhea. It may be appropriate for such an infant to empty the first breast before switching. Colicky infants are often given more to eat, first one breast, then the other, which will increase volume but will also increase lactose and discomfort.

The sleep tight method of calming crying and colicky infants was developed by Karp,<sup>61</sup> who produced an illustrative video demonstrating the technique. He compares the first few months of life to the fourth trimester and suggests that creating a "womb-like" atmosphere is very calming. His "five S" system consists of the following:

**Swaddling:** Tight swaddling provides the continuous touching and support the fetus experienced while in the mother's womb.

**Side/stomach position:** Place the baby, while holding her, either on her left side to assist in digestion or on her stomach to provide reassuring support. Once the baby is happily asleep, you can safely put her in her crib on her back.

**Shushing sounds:** These sounds imitate the continual whooshing sound made by the blood flowing through arteries near the womb. This white noise can be in the form of a vacuum cleaner, a hair dryer, or a fan.

**Swinging:** Newborns are used to the swinging motions that were present when they were in utero. Rocking, car rides, and other swinging movements can help.

**Sucking:** "Sucking has its effects deep within the nervous system and triggers the calming reflex and releases natural chemicals within the brain"; this "S" can be accomplished with breast, bottle, pacifier, or even a finger according to Karp.<sup>61</sup>

All or some of these steps can be incorporated into an infant's management.

## ESOPHAGEAL REFLUX

Although less common than in bottle-fed infants, esophageal reflux can occur in breastfed infants and may be a cause of colic. The pattern of colic may be different. Crying begins at the end of the feeding, or the infant falls asleep and is put down, only to wake up crying inconsolably. Esophageal reflux also tends to occur around the clock with little relief. The diagnosis can be confirmed by an esophageal probe test for reflux or by a trial of

therapy with metoclopramide. Sleeping in a semi-upright position is often palliative. Because reflux is overdiagnosed, a complete assessment is indicated before reflux medications are prescribed.

## PACIFIERS

Pacifiers have become the subject of controversy for full-term healthy infants. A bottle-fed infant may have nonnutritive sucking with a pacifier and avoid overeating. Pacifiers in breastfed infants risk interfering with proper suckling at the breast. Conversely, some breastfed infants go back and forth with artificial nipples without a problem. Infants are born with some self-comforting mechanisms, including resuming the fetal position and sucking a thumb, finger, or fist.

When 354 children in Brazil were studied,<sup>134,135</sup> it was found that when a pacifier was used, there was a greater probability of early weaning. Mothers had introduced pacifiers to decrease crying. Victora et al.<sup>135</sup> followed an additional 650 infants for 6 months; 85% of infants had pacifiers by 1 month of age, and some started and abandoned them. Mothers seemed anxious to introduce them to increase the interval between feeding. Intense pacifier use was associated with weaning by 6 months. Nonwhite mothers and those with infant girls seemed more confident and less concerned about feeding difficulties. The authors concluded that epidemiologic and ethnographic factors influenced the complex relationship between pacifier use and breastfeeding.<sup>134</sup>

In a positive approach to pacifiers, it is thought they reduced stress in the infant and did not negatively influence feeding. In another study, 602 healthy newborns in 10 centers were randomly assigned to a UNICEF group with restrictive fluids, no bottles, and no pacifiers during the first 5 days or to a control group liberalized to have bottles and pacifiers.<sup>119</sup> Fluid supplements by bottle, with or without the use of pacifiers, were not associated with lower frequency or shorter duration of breastfeeding in the first 6 months of life. When Righard<sup>109</sup> studied 52 healthy mother-infant pairs with breastfeeding problems, however, he noted a clear relationship between a faulty nursing pattern and introduction of bottle feedings and pacifier use, when compared with a control group who were successfully breastfeeding.

In a randomized clinical trial of pacifier use and bottle feeding or cup feeding and their effect on breastfeeding, Howard et al.<sup>53</sup> studied 700 breastfed newborns for 52 weeks. Cup feeding for those needing early feeding made no difference in long-term outcome, except in cases in which multiple feedings were given. However, introduction of pacifiers early in the neonatal period was

detrimental to exclusive breastfeeding, shortening overall duration. Findings support the recommendation to avoid exposing breastfeeding infants to artificial nipples in the neonatal period.

In a systematic review of pacifier use and its impact on breastfeeding, 1098 reports were identified, but only 29 fit the inclusion criteria for review. Measuring breastfeeding duration and/or exclusivity, the authors concluded that pacifier use was not detrimental to breastfeeding outcomes. However, they did not speak to the issue of optimal timing for the introduction of pacifiers.<sup>93</sup> The Task Force on Sudden Infant Death of the AAP has recommended pacifier use at sleep times, making the suggestion that pacifiers be introduced immediately in bottle-fed babies, but delayed until breastfeeding is well established in breastfed infants. Breastfeeding has been recognized as protection against SIDS (see Chapter 14).

In a national survey of women's postpartum experiences, 48% of babies had used a pacifier on a regular basis, and the average duration of pacifier use was 13.6 months.<sup>134</sup>

Clearly, pacifiers are a parental decision. A pacifier should not be introduced by hospital staff unless the mother requests it. Exclusion of pacifiers is part of the Baby Friendly Hospital Initiative, a program initiated by UNICEF.

## STOOL PATTERNS FOR BREASTFED INFANTS

In the first week of life the pattern of an infant receiving adequate colostrum, which has a cathartic effect on the gut, is to have a stool with most feedings. All the meconium will be passed in 48 hours, and after a few transitional stools (24 hours), the stool becomes yellow. The stools are loose and seedy in consistency. Breastfed infants have a strong gastrocolic reflex and continue to have stools with feedings, with a minimum of four seedy yellow stools per day. Over the next month, a breastfed baby should have a stool every day. When this does not happen, the physician needs to confirm that all is well. This means a check of urine output (six to eight wet diapers per day and at least one really soaked) and urine specific gravity, as well as a review of breastfeeding patterns. The purpose is to identify the potential failure-to-thrive situation before it becomes serious. Many wet diapers and no stool can indicate "low-calorie, low-fat milk." This requires a minor adjustment in breastfeeding to increase the amount of high-fat hind milk by allowing the infant to nurse until satisfied on the first breast. Ultraabsorbent diapers make assessing voiding patterns difficult and should be avoided in breastfed infants in the first few weeks

**TABLE 8-7** Patterns in Breastfed Infants

	First 24 h of Life	Second 24 h of Life	Third 24 h of Life	First 30 Days of Life
Weight	Loss	Loss 27%	Plateau	Regain birth weight by 10-14 days
Stools	1 ×	2 ×	3 ×	Minimum of 3 × daily
Voids	1 ×	2 ×	3 ×	6-8 × daily
Feeds	8-12 ×	8-12 ×	8-12 ×	At least 8/day

of life. Alternatively, a tissue can be placed in the diaper to confirm voiding (Table 8-7).

Weight gain after the first week of life should be 15 to 30 g daily (0.5 to 1 oz). Birth weight should be regained in 2 weeks, at most. The mother will observe milk leaking from her breasts, especially from the opposite breast while nursing. Feedings should occur every 2 to 3 hours for 8 to 12 day<sup>-1</sup>. Length of feedings will vary throughout the day, from short and "businesslike" to dawdling and prolonged, or a series of snacks. Mother and infant are symbiotic in this relationship. In most cases, the infant's cues guide the schedule. Successful breastfeeding is an infant-led process.

## INSUFFICIENT MILK SYNDROME

Perceived lack of milk is the most common reason women report for early termination of lactation.<sup>83</sup> As with all health problems, it is preferable to prevent a problem than to have to cure it. The medical care of infants and children is based on prevention. How can we prevent lactation problems, especially with early discharge from the hospital? Anticipatory care includes encouraging parents to attend breastfeeding classes prenatally and a breast examination by the obstetrician to identify any anatomic issues that might interfere with breastfeeding and need for remedial care. The delivery service should have breastfeeding policies and practices that support and promote breastfeeding (rooming-in) and trained staff to provide one-on-one care. Good hospital-quality breast pumps should be readily available for the mother who cannot nurse her infant immediately. A clinician should schedule appropriate follow-up for pediatric care within 48 hours of discharge and offer peer support group referrals. All of these recommendations are also part of the Baby Friendly Hospital Initiative (see Chapter 1, Box 1-2, and Tables 8-8 and 8-9).

Several screening instruments have been developed. Box 8-6 shows a simple screening tool for mothers, as developed by the Health One Alliance Lactation Program, Denver, Colorado. Neifert and

**TABLE 8-8**

Factors, Possible Causes, and Potential Treatments Associated with Delayed or Inhibited Lactogenesis II in Term Mothers

Factor	Cause	Treatment
Retained placental fragments	Elevated progesterone	Dilation and curettage
Previous surgery or radiation treatment	Distortion/severing of innervations and ducts	?
Inadequate stimulation	Absence of milk ejection	Use gentle hand massage, pump near baby, double pump
Cesarean delivery	No labor, disturbed endocrine balance?	Informed support
Anesthetic agents	Poorly researched	?
Maternal obesity	Delayed progesterone withdrawal	Progesterone antagonist?
Type 1 diabetes	Intracellular signaling?	Informed support
Prolactin deficiency	Prolactin activates milk genes	Domperidone, metoclopramide
Drugs/hormones	Milk ejection and milk synthesis inhibited	Reduce exposure, oxytocin?
Colostrum/milk not removed	Autocrine inhibition due to milk stasis	Commence breastfeeding and/or breast expression
Glandular insufficiency	Unknown	?

Modified from Hartmann PE, Ramsay DT: Mammary anatomy and physiology. In Jorc E, Ring C, editors: *Feeding and nutrition in the preterm infant*, New York, 2005, Churchill Livingstone.

Seacat<sup>84</sup> recommend providing this at discharge from the hospital to be completed by all breastfeeding mothers, when infants are 4 to 6 days of age, after the initial follow-up visit. The use of galactagogues is discussed in Chapter 12. (Further discussion of this topic can be found in Chapter 14.)

## OVERSUPPLY OF MILK

Oversupply of milk is a situation often encountered but not studied or written about in medical references. In the Infant Feeding Practices Study II,<sup>36</sup> it is noteworthy that 23.9% of mothers who had stopped breastfeeding in less than a month said it was because their breasts were too full or engorged,

**TABLE 8-9**

Additional Factors, Possible Causes, and Potential Treatments Associated With Delayed or Inhibited Lactogenesis II in Preterm Mothers

Factor	Cause	Treatment
Poor breast development	Shortened gestation	Increase frequency of pumping
Stress, fatigue	Inhibition of milk ejection	Stress management and relaxation techniques
Maternal-infant separation	Inadequate stimulation for milk ejection leading to ineffective pumping	Pump near baby and practice kangaroo care
Inadequate frequency of pumping	Autocrine inhibition due to milk stasis	Increase frequency of pumping, double pumping

## BOX 8-6. Early Breastfeeding Screening Form

Please complete this screening form when your baby is 4 to 6 days old. If you circle any answers in the right-hand column, call your baby's doctor to arrange for further evaluation. The earlier problems are identified, the easier they are to correct. Your doctor may refer you to a lactation consultant who can observe your breastfeeding technique and provide assistance.

- Do you feel breastfeeding is going well for you so far? Yes No
- Has your milk come in yet? (That is, did your breasts get firm and full between the second and fourth postpartum days?) Yes No
- Is your baby able to latch on to both breasts without difficulty? Yes No
- Is your baby able to sustain rhythmic sucking for at least 10 min total per feeding? Yes No
- Does your baby usually demand to feed? (Answer "No" if you have a sleepy baby who needs to be awakened for most feedings.) Yes No
- Does your baby usually nurse at both breasts at each feeding? Yes No

Continued

**BOX 8-6. Early Breastfeeding Screening Form—Cont'd**

7. Does your baby nurse approximately every 2 to 3 h, with no more than one longer interval of up to 5 h at night? (At least eight nursings each 24 h?)	Yes	No
8. Do your breasts feel full before feedings?	Yes	No
9. Do your breasts feel softer after feedings?	Yes	No
10. Are your nipples extremely sore? (For example, causing you to dread feedings?)	No	Yes
11. Is your baby having yellow, seedy bowel movements that look like cottage cheese and mustard?	Yes	No
12. Is your baby having at least four good-size bowel movements each day? (That is, more than a stain on the diaper?)	Yes	No
13. Is your baby wetting his/her diaper at least six times each day?	Yes	No
14. Does your baby appear hungry after most feedings?	No	Yes
15. Do you hear rhythmic suckling and swallowing while your baby nurses?	Yes	No

and 14.1% said they leaked. These reasons persisted to some degree to 9 months.

Temporary oversupply occurs when the mother has an active let-down and rapid flowing the first few days of lactation. The problem is usually solved by expressing a little milk from the first breast before offering to the infant. While the infant is nursing at the first breast the second breast can be exposed and let drip into a towel or a vessel and be frozen. This situation is self-limited, usually correcting itself within a week. Drip milk is usually low in fat.

True overabundant supply presents in various ways. Most easily noted is the flooding of milk that causes the baby to cough, choke, and release the breast when feeding. When the infant finally latches on, milk runs out of the corners of the mouth. Feedings become difficult, and yet the infant is gaining well. Sometimes the situation is more subtle. The infant will not coordinate suck and swallow or will be thought to regurgitate milk. A diagnosis of reflux is made, and multiple medications for reflux are tried with no improvement. Because of the large supply of milk, and therefore lactose, some infants develop diarrhea, which was described by Woolrich as due to overabundant low-fat milk.<sup>149</sup> Because of the fussing and choking at feeding and colicky behavior, a diagnosis of allergy may be made. The mother is placed on a restricted diet, beginning with dairy products, but no improvement is seen. Observing a feeding is critical to a proper diagnosis.

With the rise in the incidence of autism and autism syndrome, an infant's behavior may be

identified as autism. Some infants do develop a very sensitive mouth, taking to solids poorly at 6 months. They accept solids only later when they can feed themselves. They have been described as "orally defensive." Possible causes of oversupply include early pumping, which can overstimulate the breasts. It is occasionally associated with using only one breast at a feeding. In most cases, it goes unexplained. It may result in recurrent mastitis. Treatments include tight, well-fitting brassieres worn 24 h/day. If there is leaking after a feeding, the nipple can be folded over, a nursing pad applied, and the flap of the bra put in place firmly. That only solves the leaking.

In extreme cases a contraceptive containing estrogen can be prescribed with close follow-up to be sure the milk supply is not completely suppressed. Thyroid function should also be checked; both hypothyroidism and hyperthyroidism can cause abundant milk. Prolactin levels can be obtained just before a feed and after 10 minutes of feeding or pumping. Random prolactin levels are not diagnostic.

Oversupply is part of the differential diagnoses for several infant symptom complexes, such as reflux, allergy, colic, diarrhea, poor suck, and autism. Management while feeding is repositioning. If the mother is semiinclined, the infant is placed over the breast. The infant draws the breast up in to the mouth, which leads to reduced flow, allowing the infant to draw the breast during low flow and more effectively control the flow against gravity.

## *Office Practice of Breastfeeding Management*

### BREASTFEEDING HEALTH SUPERVISION DURING WELL-CHILD VISITS

A pediatrician's role is to create a breastfeeding-friendly atmosphere in the office, including the acceptance of breastfeeding in the waiting room or providing a special space for a mother to relax and feed her infant. The pediatrician should provide accurate information and realistic options for solutions when problems arise. If accurate information is not immediately available, physicians should know where to look and with whom to consult. Opening questions should target breastfeeding: How is breastfeeding going? Are there any questions? Is help needed with any aspect of breastfeeding? Age (of infant)-appropriate discussion should be initiated on the usual issues encountered at the age. If the physician is too busy for in-depth discussion of these issues, the office should have a nurse practitioner available who is trained and certified in lactation and who can discuss a variety of issues (e.g., sore nipples, family support, preparing to return to work).

A model overview of breastfeeding health supervision for the mother and infant from the prenatal period to 18 months postpartum for office practice was developed by Black.<sup>14</sup> It identifies appropriate assessment, guidance, and interventions. The ABM has developed a protocol for a Baby Friendly Office practice.<sup>101</sup>

## CHAPTER 9

# *Maternal Nutrition and Supplements for Mother and Infant*

---

Lactation is the physiologic completion of the reproductive cycle. The maternal body prepares during pregnancy for lactation, not only by developing the breast to produce milk but also by storing additional nutrients and energy for milk production. The transition to fully sustaining an infant should not be complex or require major adjustments for a woman. After delivery, mothers usually note an increase in appetite and thirst and a change in some dietary preferences. In some cultures, anthropologists have noted that, traditionally, the birth of a baby means that members of the community take gifts of special foods—usually high in protein, nutrients, and calories—for the mother to ensure she will make good milk for the infant. This tradition may have affected some early studies in which relatively malnourished women were noted to produce milk comparable with that produced by well-nourished women in industrialized countries.

After an exhaustive study of the world's literature and current scientific evidence, the Subcommittee on Nutrition During Lactation of the Committee on Nutritional Status During Pregnancy and Lactation of the Food and Nutrition Board of the Institute of Medicine at the National Academy of Sciences<sup>112</sup> published its first report. The subcommittee stated that breastfeeding is recommended for all infants in the United States under ordinary circumstances. Women living in a wide variety of circumstances in the United

States and elsewhere are capable of fully nourishing their infants by breastfeeding them. Furthermore, exclusive breastfeeding is preferred for the first 4 to 6 months. The report further stated that mothers with less than perfect diets could make good milk.

The overwhelming evidence indicates that women are able to "produce milk of sufficient quantity and quality to support growth and promote the health of infants—even when the mother's supply of nutrients is limited." Nonetheless, the depletion of the mother's nutrient stores is a risk if efforts to achieve adequate food intake are not made to replace maternal stores.

Most material for nursing mothers regarding maternal diet during lactation set up complicated "rules" about dietary intake that fail to consider the mother's dietary stores, normal dietary preferences, and cultural patterns. Thus, one barrier to breastfeeding for some women is the "diet rules" they see as being too hard to follow or too restrictive.<sup>40</sup> All over the world, women produce adequate and even abundant milk on inadequate diets. Women in cultures with modest but adequate diets produce milk without any obvious detriment to themselves and with none of the fatigue and loss of well-being that some well-fed Western mothers experience. Insufficient milk is a problem in Western cultures and rarely in developing countries.

## *Impact of Maternal Diet on Milk Production*

Although much has been learned about dietary requirements for lactation by studying women from many cultures and various levels of poor nutrition, some of the information is conflicting, principally because of varying sampling techniques and the improvement over time in laboratory analysis. Extensive reviews of the current literature on various nutrients in human milk and the influence of maternal dietary intake have been referenced.\* Those readers needing access to the original studies are referred to the bibliographies from these reviews, which include hundreds of items, a listing beyond the scope of this text.

### MILK VOLUME

The volume of milk produced varies over the duration of lactation from the first few weeks to 6 months and beyond but is remarkably predictable except during extreme malnutrition or severe dehydration. In periods of acute water deprivation, manifested in a healthy mother by an acute bout of vomiting and diarrhea, the volume of milk will diminish only after the maternal urine output has been significantly compromised (10% dehydration).

Malnutrition, however, is complex, and single-nutrient deficiencies are rare. Malnutrition does seem to have an effect on the total volume of milk produced. In the extreme, when famine occurs, the milk supply dwindles and ceases, with ultimate starvation of the infant. The classic study is the report of Smith<sup>105</sup> on the effects of maternal undernutrition on the newborn infant in the Hunger Winter in Holland in 1944 to 1945. It was reported that the volume of milk was slightly diminished, but the duration of lactation was not affected. The latter is a testimony to courage rather than diet. Analysis of milk produced showed no significant deviations from normal chemical structure. Milk was produced at the expense of maternal tissue.

These data from the Dutch famine in the 1940s during World War II were reexamined by Stein et al.,<sup>109</sup> who pointed out that women who conceived during the famine did develop some maternal stores in anticipation of lactation that were not accounted for by the fetus, placenta, or amniotic fluid, even though the fetus was a pound lighter at birth. They reported fetal weight down by 10% but maternal weight down by only 4%. This demonstrates the maternal body's strong biologic commitment to preparing for lactation during pregnancy.

There is a wide range of volume of milk intake among healthy breastfed infants, averaging 750 to 800 g/day and ranging from 450 to 1200 g/day.<sup>13</sup> Any factor that influences the frequency, intensity, or duration of suckling by an infant influences the volume.<sup>85</sup> In a study of wet nurses in the 1920s, Macy et al.<sup>75</sup> reported human capacity at 3500 mL/day. Compared with the 800 mL from mothers with singletons, studies of mothers producing for multiples, done by Saint et al., confirmed production of 2 to 3 L/day for twins and triplets. At 3 months of age for all populations, the volume averages 770 g/day (range 500 to 1200 g/day).<sup>61,88</sup> The self-regulation of milk supply by the infant has been confirmed by a study by Dewey et al.<sup>29</sup> in which additional milk was pumped after each feeding for 2 weeks, thus increasing the milk supply. The infants, however, remained at baseline consumption during the pumping. The residual milk supply of healthy women (i.e., that which can be extracted after a full feeding) is about 100 g/day, even when an infant consumes comparatively low volumes of milk.<sup>29,84,86</sup>

Topographic computer imaging has been used to study breast production and storage capacities in the laboratory of Hartmann. Using moiré patterns projected onto the breast, it has been possible to calculate the volume of milk produced. As the breast expands with increasing milk, the moiré patterns change. By correlating the maternal weights before and after a feeding and the imagery patterns, data were converted to accurate milk volumes. This technique has remarkable potential for clinical use. Hartmann reports the normal range of milk production from 1 to 6 months postpartum to be between 440 and 1220 g/day for mothers who gave birth at full term.

Prentice and Prentice<sup>99</sup> described "energy sparing adaptations" that were associated with normal lactation when energy intake is limited. These were decreases in basal metabolic rate, thermogenesis, and physical activity.

When well-nourished mothers reduced their intake by 32% for 1 week, consuming no less than 1500 kcal/day, no reduction in milk volume occurred, although plasma prolactin levels increased. Mothers who consumed less than 1500 kcal/day for a week did experience decreased milk volumes compared with those of the control group and the group consuming more than 1500 kcal.

Exercise, manual labor, and losing weight do not usually alter an established milk volume. Milk production will increase with infant demand, but infant demand will only increase with growth, which depends on sufficient nourishment.<sup>61</sup> Having the mother take supplements could improve production and stimulate the infant's appetite.

\*References 40,80,83,87.

## ENERGY SUPPLEMENTATION AND LACTATION PERFORMANCE

When women received supplements during the last trimester of pregnancy, no effect was noted in their milk production. This suggests that short-term supplementation may be ineffective. Other studies that provided supplementation of a maximum of 900 kcal/day for 2 weeks resulted in an increase in milk production (662 to 787 g/day).<sup>114</sup> No increase in infant weight compared with the control group's infants was seen in this period of 2 weeks.

The problem of insufficient milk supply for a baby is reported in well-nourished as well as poorly nourished populations, but in cross-cultural studies it appears to be unrelated to maternal nutrition status.<sup>116</sup> The effect of supplementation may be more psychologic than physiologic.

In countries where food supplies vary with the season, milk supplies drop 1 dL/day during periods of progressively greater food shortages. Studies continue on lactation performance of poorly nourished women around the world, including Burma, The Gambia, Papua New Guinea, and Ethiopia as well as among Navajo people. Results continue to reflect an impact on quantity, not quality, of milk.<sup>13,23,65,105</sup>

The interrelationship of milk volume, nutrient concentration, and total nutrient intake by the infant must be considered.<sup>29</sup> The reason for low protein content in a given sample may be lack of protein stores, lack of total energy content, or lack of vitamin B<sub>6</sub>, a requirement of normal protein metabolism.

Of concern, however, is the report of dietary supplementation of Gambian nursing mothers in whom lactational performance was not affected by increased calories (700 kcal/day).<sup>100</sup> The supplement produced a slight initial improvement in maternal body weight and subcutaneous fat but not in milk output. Whether the mothers utilized the increased energy to work harder farming or whether the infants did not stimulate increased milk production is unresolved. Food supplementation of lactating women in areas where malnutrition is prevalent has generally had little, if any, impact on milk volume.<sup>112</sup> Such supplementation improves maternal health and is more likely to benefit the mother than the infant except where milk composition had been affected by specific deficiencies.

## PROTEIN CONTENT

Since the work of Hambraeus reestablished the norms for protein in human milk to be 0.8 to 0.9 g/dL in well-nourished mothers, figures from previous studies have been recalculated to consider

that all nitrogen in human milk is not protein; 25% of the nitrogen is nonprotein nitrogen (NPN) in human milk, and only 5% of the nitrogen is NPN in bovine milk. The protein content of milk from poorly nourished mothers is surprisingly high, and malnutrition has little effect on protein concentration. An increase in dietary protein increases volume but not overall protein content, given the normal variations seen in healthy, well-nourished women.

Observations made over a 20-month period of continued lactation showed that milk quality did not change, although the quantity decreased slightly, which has been attributed to the decreasing demand of a child who is receiving other nourishment. Therefore, the total protein available with the decreased volume of milk and increased weight of the child decreased from 2.2 g/kg of body weight to 0.45 g/kg. The need for additional protein sources from other foods for the child after 1 year of age becomes obvious.

The composition of human milk is maintained even with less-than-recommended dietary intake of macronutrients. The concentrations of major minerals, including calcium, phosphorus, magnesium, sodium, and potassium, are not affected by diet. Maternal dietary intakes of selenium and iodine, however, are positively affected: an increase in the diet increases the level in the milk. The proportion of different fatty acids in human milk varies with the maternal dietary intake.

In Zaire,<sup>83</sup> lactating mothers with protein malnutrition were given 500 kcal (2093 kilojoules [kJ]) and 18 g of protein as a cow milk supplement for 2 months, after which their nutritional status improved significantly.<sup>31</sup> The volume of milk did not change (607 versus 604 mL). Their breastfed infants, however, did show significant improvement in their mean serum albumin levels, and their growth matched that of healthy infants of the same age.

The effect of very-low-protein (8% of energy) and very-high-protein (20% of energy) diets on the protein and nitrogen composition of breast milk in three healthy Swedish women "in full lactation" was significant.<sup>50</sup> High-protein diets produced higher production and greater concentrations of total nitrogen, true protein, and NPN. The increased NPN was caused by increased urea levels and free amino acids. The 24-hour outputs of lactoferrin, lactalbumin, and serum albumin were not significantly higher.

When marginally nourished women were provided a mixed-protein diet predominantly from plant sources up to 1.2 g/kg/day, equilibrium was achieved at a protein intake of 1.1 g/kg. In a study of healthy women given marginal protein intakes, Motil et al.<sup>82</sup> reported that maternal milk production and the

protein nitrogen, but not the NPN, fraction of human milk were relatively well preserved in the short term.

The practical significance, except as related to fat diets, of these results is limited because the diets were extreme and were maintained for only 4 days. The impact on human nutritional physiology, however, was significant.<sup>50</sup>

Taurine, an amino acid found only in animal products, is the second most abundant free amino acid in human milk. Even milk of women who have no animal foods in their diet contains some taurine at levels (35 mg/dL) that are lower than those in women who consume animal products (54 mg/dL).<sup>102</sup> Taurine is singularly important as the principal protein in the human brain. Cow milk does not contain taurine.

Of practical significance for counseling healthy women in the industrialized world is the work of Butte et al.<sup>13</sup> investigating the effect of maternal diet and body composition on lactational performance; 45 healthy lactating women were followed for 4 months from delivery with detailed measurements of milk production, dietary intake, and maternal body composition. The overall mean energy intake was  $2186 \pm 463$  kcal/day. Milk production averaged 751, 725, 723, and 740 g/day for months 1, 2, 3, and 4. Average maternal weight reduction was from 64.6 to 59.3 kg. Energy was calculated to be sufficient for maintenance and activity, yet the mothers achieved gradual weight reduction. The authors conclude that energy intakes of approximately 15% less than those currently recommended are compatible with full lactation, full activity, and gradual weight reduction to prepregnant weight (Tables 9-1 and 9-2). Diets otherwise contained recommended daily allowances for lactation. Other investigators studying the impact of weight loss noted that the rate of postpregnancy weight loss affected the level of elaidic acid in milk and of trans fatty acid level.<sup>15</sup> This

is explained by the mobilization of fatty acids from maternal adipose tissue.

## FAT, CHOLESTEROL, AND OMEGA-3 FATTY ACIDS

Mature human milk contains about 50% of its energy as fat. This fat is necessary for the tremendous growth of the newborn and is essential to the structural development of the brain, retina, and other tissues. Both  $\omega$ -6 and  $\omega$ -3 fatty acids are essential components of the phospholipids of cell membranes. They are critical to the fluidity, permeability, and activity of membrane-bound enzymes and receptors. During the first 4 to 6 months of life, an infant accumulates 1300 to 1600 g of lipids.

Considerable attention has been focused on the impact of dietary fat and cholesterol on the composition of human milk. Fat is the main source of kilocalories in human milk for the infant. The fatty acid composition of the triglycerides, which make up more than 98% of the lipid component of human milk, can be affected by maternal diet. Diets with different lipid composition, caloric content, proportion of calories from fat, and fatty acid composition have been studied.

In a classic work that was carefully controlled, Insull et al.<sup>58</sup> fed lactating women in a metabolic ward diets that differed in caloric content, proportion of calories from fat, and fatty acid composition. Neither milk volume nor total milk fat was affected by diet. When the high-calorie, no-fat diet was fed, milk triglycerides were higher in fatty acids 12:0 and 14:0 and lower in 18:0 and 18:1, which indicated that when fatty acids were synthesized from carbohydrate, more intermediate-chain fatty acids were produced. With the low-calorie, no-fat diet, the fatty acid composition of the milk resembled the maintenance diet and the depot fat. When corn oil was the fat source, milk levels of 18:2 and 18:3

**TABLE 9-1** Milk Production over First 4 Months of Lactation

	Month 1 (n = 37)	Month 2 (n = 40)	Month 3 (n = 37)	Month 4 (n = 41)
Human milk* (g/day)	751 (130) <sup>†</sup>	725 (131)	723 (114)	740 (128)
Feedings (no./day)	8.3 (1.9)	7.2 (1.9)	6.8 (1.9)	6.7 (1.8)

were higher, with a major increase in linoleic acid, than when lard or butter was used. Multiple studies have shown that medium-chain fatty acids, lauric and myristic acid (12:0 and 14:0), are not affected by diet, indicating synthesis by the mammary gland.<sup>34</sup>

Trans fatty acids are produced in hydrogenation reactions and appear in human milk as a reflection of dietary intake, so that women who eat margarine rather than butter have high levels in their milk.<sup>65</sup> Elaidic acid (18:1 trans) is found in margarine, for instance. Because of the high level of trans fatty acids in hydrogenated vegetable oils such as margarine, the milk of women in the United States is high in trans fatty acids, whereas the milk of women in West Germany who do not use margarines is low in trans fatty acids.<sup>34</sup> Considerable controversy surrounds the biologic effects. The recommendations for substituting margarines were reversed in 1997. In mammals, trans isomers have been noted to alter permeability and fluidity of membranes, inhibit a number of enzyme reactions of lipid metabolism, and impair synthesis of arachidonic acid (AA) and prostaglandins.

The concern about fat composition in terms of the polyunsaturated fatty acid (PUFA) to saturated fatty acid ratio (P/S ratio) and the high level of cholesterol normally found in breast milk have led to monitoring mothers on altered lipid intakes. Lactating women were placed on one of two experimental diets after a period of a study of their normal Australian diet, which included 400 to 600 mg of cholesterol per day and fat that was rich in saturated fatty acids. After this baseline study, the mothers were given either diet A, with 580 mg cholesterol and a high level of saturated fats, or diet B, with 110 mg cholesterol and a higher level of polyunsaturated fats from vegetable oils. A second study was

carried out with the two diets high in either saturated or unsaturated fats, but the cholesterol remained the same, 345 to 380 mg/day.<sup>95</sup>

The low-cholesterol diets lowered the maternal blood cholesterol but not the triglyceride levels. The cholesterol level of the milk, however, was unaffected in any diet combination.<sup>69</sup> The increase in PUFA in the diet rapidly increased the levels of linoleate in the milk to twice the previous level at the expense of myristate and palmitate. Protein levels remained the same in the milk throughout the study. Infant plasma cholesterol levels decreased in response to an increase in the concentration of linoleate in the milk. The significant dietary change seemed to depend on the consumption of high PUFA and low cholesterol to alter the levels in the milk and thus in the infant's plasma (Table 9-3).<sup>95</sup>

Cholesterol levels remain relatively stable throughout at least 16 weeks of lactation. The presence or absence of phytosterols influences both the accuracy of analysis (i.e., overestimated level of cholesterol) and the physiologic significance of cholesterol. Phytosterols are those sterols derived from plant sources. They are distinguishable from cholesterol, which is of animal origin. During a given feeding, the concentration of cholesterol in the milk may increase more than 60%, although the total for the feeding is constant. The effect of maternal diet on cholesterol and phytosterol levels in human milk was measured by Mellies et al.,<sup>77</sup> who reported no change in cholesterol but a dramatic increase in phytosterols on high-cholesterol and phytosterol diets. The level of phytosterol in infant plasma did not change, however. These observations further confirm that cholesterol is synthesized at least in part in the mammary gland, whereas phytosterol is not.

**TABLE 9-3** Lipid Concentrations of Mature Human Milk

Study	Plan	Diet		Lipid Concentration in Milk		
		Saturation of Fat*	Cholesterol (mg/day)	Cholesterol (mg/dL)	Triglyceride (g/dL)	Phospholipid (mg P/dL)

From Potter JM, Nestel PJ: The effects of dietary fatty acids and cholesterol on the milk lipids of lactating women and the plasma cholesterol of breast-fed infants, *Am J Clin Nutr* 29:54, 1976.

Thus, no evidence is available that concentrations of cholesterol and phospholipids can be changed by diet. Milk cholesterol is stable at 100 to 150 mg/L even in hypercholesterolemic women and increases only in severe cases of pathologic hypercholesterolemia, according to Jensen.<sup>60</sup> The fat globule membrane contains both cholesterol and phospholipids, and their secretion rates are related to the total quantity and are not influenced by diet. This supports the conclusion that cholesterol is essential to the diet of the infant.

Where maternal undernutrition is commonplace, the percentage of maternal body fat may influence the concentration of fat in the milk.<sup>96</sup> Milk fat concentrations in Gambian women were positively correlated with maternal skinfold thickness and decreased over the course of lactation. Women with parity of 10 and above appear to have a decreased capacity to synthesize milk fat and thus have lower milk fat concentrations in their milk.

The synthesis of fatty acids up to the carbon number of 16, as well as the direct desaturation of stearic acid into oleic acid, can take place in the mammary gland, whereas longer-chain fatty acids come directly from plasma triglycerides<sup>55,61</sup> (see Chapter 4). The intake of both carbohydrate and fat must be taken into account when evaluating maternal diet because high-carbohydrate diets increase lauric acid and myristic acid and moderate levels of carbohydrate influence linoleic acid.

When serum lipids are measured in African women accustomed to a low-fat intake, the levels are relatively low and the women are virtually free of coronary heart disease.<sup>3,100</sup> Among long-lactating (1 to 2 years minimum) African mothers, the amount of fat in their daily milk is of the same order as that ingested in their habitual diet.<sup>120</sup> Despite this, they are not significantly hypolipidemic when compared with nonlactators.

Human milk samples obtained from women living in five different regions of China showed the

great diversity of milk fatty acids. The docosahexaenoic acid (DHA) concentrations in women from the marine region were twice as high as those from rural areas.<sup>91</sup> The milk concentrations of DHA varied greatly (0.44±0.29 to 2.78±1.20 g/100 g total fat), with pastoral regions being lowest and the marine region highest. Seafood consumption was high in the marine group. Similarly, AA, when stated as a ratio (AA/DHA, g/g), was 2.77 in pastoral areas and 0.42 in the marine region. AA has been associated with infant growth and DHA with brain and retinal growth. Similar findings are reported in Alaskan Inuit people who have a diet high in fish and fish oil. When women's diets were supplemented with fish and fish oils, the blood concentrations of DHA in the maternal plasma and red blood cells (RBCs) were increased.<sup>23</sup> Infants showed a 35% DHA increase in RBCs and 45% increase in plasma, which supports the concept that maternal diet can influence the DHA levels in newborns. The fatty acid patterns of human milk correlate with the current American diet, which has a high P/S ratio; there is a shift toward higher levels of C18:2 fatty acids, linoleic acid, and C18:3 linolenic acid.<sup>61,69,70</sup> Depot fat reflects dietary fatty acid patterns and thus the pool for mammary gland synthesis of milk fats. The mammary gland can dehydrogenate saturated and monosaturated fatty acids.<sup>103</sup>

Diet composition affects milk fat synthesis. When a woman is in energy balance, the fatty acids from the diet account for about 30% of the total fatty acids in her milk.

The habitual diet of healthy primiparas in Finland was associated with breast milk containing 3.8% fat.<sup>118</sup> Their diet was 16% protein, 39% fat, and 45% carbohydrate. Half the fatty acids of the diet and the milk were saturated, and one third were monoenoic. PUFAAs were 15% of the diet and 13% of the breast milk, with a P/S ratio of 0.3 for both. The maternal diet had no effect on total fat content of the milk except for the low level of oleic acid, which is apparently peculiar to Finnish breast milk.

DHA, a long-chain fatty acid (22:6, omega-3), has attracted attention because deficiency has been associated with visual impairment in offspring of rhesus monkeys. Essential *n*-3 fatty acids in pregnant women have been linked to visual acuity and neural development in their term infants. Some pregnant women in the United States have been found to be deficient in DHA.<sup>57</sup> A descriptive meta-analysis of 106 studies worldwide was culled to 65 to include only those utilizing modern analysis methods to obtain fatty acid profiles. The highest DHA concentrations were found in coastal populations and associated with consumption of fish. DHA was 0.32% + 0.22% and 0.47% + 0.13% for AA, representing the mean concentrations worldwide. Omega-3 DHA is important to the fetus and to the offspring through breastfeeding, and emerging science suggests it may protect against preterm delivery, and postpartum depression as well.<sup>12</sup>

## FISH CONSUMPTION DURING LACTATION

Maternal fish consumption during pregnancy has been correlated with cognitive and visual abilities in offspring. Maternal omega-3(*n*-3) LCPUFA supplementation during pregnancy was evaluated comparing early childhood cognitive and visual development in mother's with and without supplementation. A systematic review and meta-analysis of randomized controlled trials failed to prove or disprove that omega-3 LCPUFA supplementation in pregnancy improves cognitive and visual development of the children.<sup>45</sup>

Fish oil is an excellent dietary source of DHA, and women who consistently eat fish have higher levels in their milk. In a study, Finley et al.<sup>34</sup> found that vegetarians have higher DHA levels in their milk than omnivore control subjects. Many formulas have been supplemented with synthetically derived DHA in an effort to mimic human milk. They do not, however, contain cholesterol, and no data support the concept that synthetically derived DHA is as effective as natural DHA in human milk.

A strong association exists between the body fat of the mother and lipid in her milk. Lovelady et al.<sup>73</sup> found that the best predictor of milk lipids was overall "fatness" rather than the distribution of that fat. Dietary fat was not associated with milk fat in the "fat" women (27% or more body fat) but was positively correlated with diet in lean women (less than 27% body fat).

When healthy pregnant women are supplemented with fish oil capsules from the thirtieth week of gestation, the fatty acid compositions of

the phospholipids isolated from umbilical plasma and umbilical vessel walls differ from those of un-supplemented mothers, with more *n*-3 and less *n*-6 fatty acids.<sup>117</sup> This suggests that DHA status can be altered at birth.

A group of lactating women were given supplements of different doses of fish oil concentrates rich in omega-3 fatty acids, including DHA.<sup>53</sup> Receiving 5 g/day for 28 days, 10 g/day for 14 days, and 47 g/day for 8 days, each experienced significant dose-dependent increases in DHA in their milk and plasma. Baseline levels in milk were 0.1% of total fatty acids, and levels rose from 0.8% to as high as 4.8% on the 47 g/day diet. This suggests that relatively small supplements of DHA can enhance levels in the milk. Preformed dietary DHA is known to be better synthesized into nervous tissue than that synthesized from linolenic acid, and other essential fatty acids can inhibit this transformation to DHA. The consumption of fish during pregnancy and lactation is an important dietary consideration in preference to fish oil capsules. The concern rests with possible mercury contamination. Fish, however, provides lean protein, and an abundance of vitamins B, zinc, iodine and selenium as well as naturally rich sources of long-chain omega-3 fatty acids and vitamin D. It has been recorded that women who do not eat fish during pregnancy put their infants at risk for suboptimal visual, cognitive, motor, and behavior skill outcomes.<sup>57</sup> International studies have shown the value of fish in pregnancy and lactation. The most thorough was a 15-year follow-up of infants breastfed on the Seychelles Islands by mothers with a high intake of fish, measurable mercury levels, and developmental growth scores that were higher with greater consumption of fish and greater levels of breastfeeding. The Food and Drug Administration (FDA) has stated that, while fish oil supplements are beneficial for those who cannot eat fish, fish has the full range of nutrients. The FDA recommends a minimum of two meals of fish per week (up to 12 ounces) during lactation.<sup>89</sup>

Studies of linoleic acid supplementation from 20 weeks' gestation in normal women showed that levels increased in those with low linoleic acid levels to match those with high levels.<sup>1</sup> The neonatal linoleic acid status did not change. Linoleic acid supplementation did result in slightly but significantly higher total amounts of *n*-6 long-chain polyenes in umbilical plasma. Linoleic acid (18:2, *n*-6) is essential to the maintenance of the epidermal water barrier and is the ultimate dietary precursor of eicosanoids, which include leukotrienes, prostaglandins, and thromboxanes. Linoleic acid is not synthesized by humans and must be supplied by diet.

A diet deficient in omega-3 fatty acids leads to a triad of signs in the rhesus monkey: visual impairment, electroretinographic abnormalities, and polydipsia. Profound biochemical changes in fatty acid composition of the membranes of the retina, brain, and other organs are seen experimentally. Low concentrations of omega-3 fatty acids occur at birth in the placenta, RBCs, and neural tissues when the mothers are fed deficient diets. Studies in monkeys confirm that the most critical period of life for providing omega-3 fatty acids is during pregnancy and during lactation in early infancy.<sup>19</sup> In humans, supplementation of the maternal diet with fish and fish oils has increased the levels of omega-3 fatty acids, especially DHA. Humans can synthesize DHA from linolenic acid, but this is limited in both infants and adults. Supplementing with linolenic acid does not significantly increase DHA in the blood.<sup>17</sup> No evidence suggests that supplements in normal women with good diets are beneficial. Excesses of DHA affect AA levels and interfere with the AA/DHA ratio. The content of conjugated linoleic isomer and trans-vaccenic acid in human milk was found to be higher in women who consumed organic dairy and organic meat products. The health effects of conjugated linoleic isomer and trans-vaccenic acid on human newborns are pending but the effects in animals and in human adults show immunomodulating properties such as on influenza and other viruses. The recommendations of the Committee on Nutrition of the American Academy of Pediatrics (AAP) regarding cardiovascular health in childhood have no comment about infants until they are weaned from formula. They do not mention the value of being breastfed. For children 12 months to 2 years who are obese or have a family history of obesity, dyslipidemia, or cardiovascular disease, skim milk is suggested (Figure 9-1).

## LACTOSE

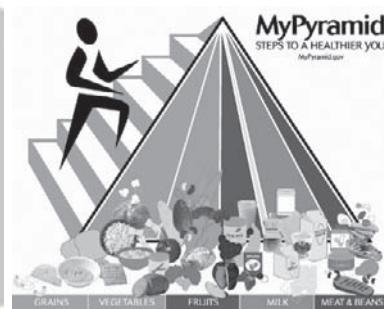

In human milk the principal carbohydrate is lactose, present at approximately 70 g/L and second only to water as a major constituent. The milk of all species is isotonic with maternal plasma, and 60% to 70% of the osmotic pressure is created by lactose. Lactose provides twice the energy value per molecule or unit of osmotic pressure. Because milk volume is driven by available lactose, its concentration is stable.<sup>29</sup> Changes in the carbohydrate levels in the diet have been studied. Comparison of mothers on diets with three different levels of carbohydrate shows that the amounts of protein, fat, and carbohydrate in their milk are similar. No evidence indicates that dietary manipulations affect lactose.

## WATER

No data support the assumption that increasing fluid intake will increase milk volume, and restricting fluids has not been shown to decrease milk volume. Forcing fluids, however, has been shown to affect milk production negatively in a controlled crossover-design study of breastfeeding mothers. Thus, women taking excessive fluids produced less milk, suggesting that drinking to thirst and heeding body cues is more physiologic than prescribing a specific amount of fluid per day. This observation was first demonstrated in a 1939 study that concluded, "Forced, excessive drinking is therefore neither necessary nor beneficial as far as the nursing is concerned and may even be harmful." Hypogalactia cannot be arrested by forced drinking beyond the natural dictates of thirst. Urine output in these studies was proportional to intake. A similar study of 210 postpartum mothers, half of whom drank ad lib, taking an average of 69 oz daily, while the other half were forced to take 6 pt and averaged 107 oz

A

B

**Figure 9-1.** ChooseMyPlate (A) and MyPyramid (B) are tools for ensuring adequate nutrition in both children and adults. See [ChooseMyPlate.gov](http://ChooseMyPlate.gov) and [Nutrition.gov](http://Nutrition.gov) for more information. (From the U.S. Department of Agriculture.)

daily, showed that the mothers forced to drink beyond thirst produced less milk, and their babies gained less well.

From a practical standpoint, mothers have increased thirst. When fluids are restricted, mothers will experience a decrease in urine output, not in milk. Sharply decreasing fluids to prevent engorgement in the mother who is not lactating is ineffectual, however, and only adds another inconvenience and discomfort.

## KILOCALORIES

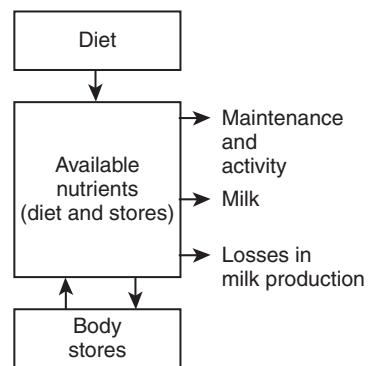

The caloric content, sample by sample, of milk from well-nourished mothers does vary but averages 75 kcal/dL. Because fat is the chief source of kilocalories, the fat content has the greatest impact on total kilocalories, with lactose and protein also contributing to the total. Thus, in malnourished mothers with low fat stores the caloric content may be reduced.

Body fat increases during pregnancy and decreases during lactation. Changes in the adipose depot primarily result from a change in fat cell size, not number. Adipose tissue fatty acid synthesis remains low throughout pregnancy, as does lipoprotein lipase activity. Conversely, mammary lipoprotein lipase activity increases and remains high during lactation.<sup>111</sup>

How does this correlate with the caloric needs of the mother to produce milk? The calculations for energy requirements have been made by comparing the energy intakes of nursing mothers and nonnursing mothers who were matched for other variables. Nursing mothers consumed 2460 kcal daily and nonnursing mothers consumed 1880 kcal, a net difference of 580 kcal.

Lactation will not produce a net drain on the mother if the amount of energy available and the requirement of any given nutrient are replaced in the diet. There is only a small energy cost of milk production because the breasts work at remarkable efficiency. During pregnancy, fat and other nutrients are stored for the fetus and in preparation for lactation. Lactation is subsidized, as is fetal growth, by maternal stores, even though the diet on any given day may be relatively deficient in a specific nutrient. This can be clarified by Figure 9-2, which shows that diet and stores are available for milk, as well as for maintenance of the mother.

A study of 26 healthy, normotensive, nonsmoking, euthyroid women—12 of whom were breast-feeding, 7 bottle-feeding, and 7 nonpregnant, nonlactating control subjects—was reported by Illingworth et al. Energy expenditure at rest and in response to a meal and to an infusion of noradrenaline was measured. During lactation, the

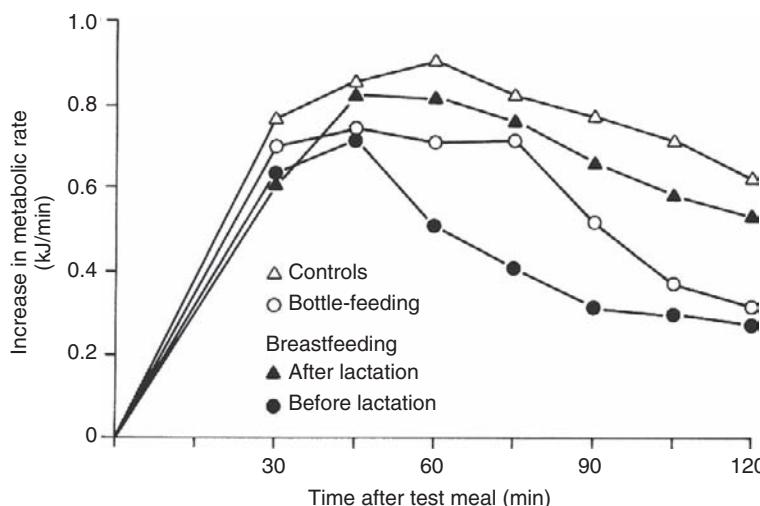

**Figure 9-2.** Energy utilization during lactation, showing availability of body stores and dietary sources.

resting metabolic rate was unaltered, but a reduced response to infusion of noradrenaline and to a meal was observed. These responses returned to normal control values in these women postlactation. Women who bottle fed were similar to control subjects. The woman's metabolic efficiency is greatly enhanced during lactation and results in a reduction in the nonlactational component of maternal energy expenditure (Figure 9-3).

When comparing dietary intake during lactation at 6 weeks postpartum to the intake of a comparable group of nonpregnant women and a group of nonlactating but postpartum women using a 7-day food diary and questionnaire, total daily intakes and meal patterns were not different between body weight-matched lactators and nonlactators. The lactating women, however, consumed a significantly smaller percentage of the recommended dietary allowances (RDAs) per day and were much more calm both before and after meals. The lactating women did not increase their daily intake over their prepregnancy diet.

The total amount of nutrients that the lactating mother secretes in her milk is directly related to the extent and duration of lactation. Furthermore, lactating women who consume a well-balanced diet with adequate calories (2700 kcal/day) meet the RDAs for all nutrients with the exception of calcium and zinc, according to assessments of the average American diet for young women. This is based on nutrient density (nutrient intake per 1000 kcal) of the average woman's diet in the United States. Nutrient densities for proteins, minerals, and vitamins have been determined from nationally representative samples of women aged 19 to 50 years of age. The nutrient values at three different levels of energy are calculated (nutrient density  $\times$  kcal of energy = total intake). The levels of energy used are 2700 kcal, the recommendation for lactating women; 2200 kcal, as reported by lactating women as actual consumption; and 1800 kcal, the minimal level a lactating woman

**Figure 9-3.** Metabolic response to test meal while breastfeeding compared with response of women who bottle feed and nonpregnant control subjects. (From Illingworth PJ, Jung RT, Howie PW, et al: Diminution in energy expenditure during lactation, *Br Med J* 292:437, 1986.)

should consider in a restricted diet. The relative nutrient deficiencies are identified next.

For the lactating woman, a 2700-kcal diet may be deficient in calcium and zinc; the 2200-kcal diet is deficient in calcium, magnesium, zinc, thiamin, vitamin B<sub>6</sub>, and vitamin E; and the 1800-kcal diet is deficient in all the previously mentioned nutrient levels plus riboflavin, folate, phosphorus, and iron unless special attention is paid to intake of these nutrients (Tables 9-4 through 9-7).

Women should be encouraged to follow dietary guidelines, especially in terms of fruits, vegetables, and whole grains; calcium-rich dairy products; and protein-rich foods. Vitamin and mineral supplements are not recommended for lactating women. If, however, dietary review suggests intake is lower than recommended, the woman should be encouraged to consume more foods rich in those nutrients. A woman with serious dietary problems leading to low intake of one or more nutrients should be encouraged by counseling to correct her dietary deficiencies. Nutrient supplements are recommended only as a last resort.

Diets of adolescents have been noted to be low in iron and vitamin A (1500 IU/1000 kcal instead of 1950 IU/1000 kcal). Black women have been observed to consume 30% less calcium, 20% less magnesium, and 20% less vitamin A than white women. Table 9-8 lists measures for improving nutrient intake of women with restrictive eating patterns. Overt signs of deficiency are rare in the United States, even for the nutrients with small safety margins.

## PREBIOTICS AND PROBIOTICS

Human milk contains substantial quantities of prebiotics. Exploration of prebiotics and probiotics has

been motivated by the formula industry in its efforts to try to make infant formulas more like human milk. A probiotic is defined as an oral supplement or a food product containing a sufficient number of viable microorganisms to alter the microflora of the host with the potential for health benefits. A prebiotic, as defined by the AAP, is a nondigestible food ingredient that benefits the most by selectively stimulating the favorite growth and activity of one or more indigenous probiotic bacteria. Synbiotic is a product that contains both probiotics and prebiotics. Postbiotic is a metabolic by-product generated by probiotic microorganisms that influences the host's biologic function. The microorganisms involved are typically *Lactobacillus*, *Bifidobacterium*, and *Streptococcus*, typically producing lactic acid. They dominate the microorganisms in the gastrointestinal tract. Prebiotics commercially are oligosaccharides, which are added to formula, foods, and beverages. The commercialization of these products in formula have yet to be proven to improve infants' defense systems and have yet to be proven as safe. They are promoted as developing the immune system but possibly result in immune dysregulation in susceptible individuals. Breastfed infants are naturally provided the constituents to protect the gastrointestinal tract, encourage the growth of *Lactobacillus*, and suppress pathogens. Breastfed infants who have been given antibiotics will physiologically recolonize their guts given human milk, which also contains a robust supply of *Lactobacillus*.

## VITAMINS

### Water-Soluble Vitamins

Water-soluble vitamins move with ease from serum to milk; thus their dietary fluctuation is more

31-50 yr	<b>1300</b>	120	5*	19	90*	1.4	1.6	17	2	<b>500</b>	2.8	7*	35*	550*

Note: This table (taken from the DRI reports, see [www.nap.edu](http://www.nap.edu)) presents recommended dietary allowances (RDAs) in bold type and adequate intakes (AIs) in ordinary type followed by an asterisk (\*). RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97% to 98%) individuals in a group. For healthy breastfed infants, the AI is the mean intake. The AI for other life stages and gender groups is believed to cover needs of all individuals in the group, but lack of data or uncertainty in the data prevent being able to specify with confidence the percentage of individuals covered by this intake.

<sup>a</sup>As retinol activity equivalents (RAEs). 1 RAE = 1  $\mu\text{g}$  retinol, 12  $\mu\text{g}$   $\beta$ -carotene, 24  $\mu\text{g}$   $\alpha$ -carotene, or 24  $\mu\text{g}$   $\beta$ -cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalents (RE), whereas the RAE for preformed vitamin A is the same as RE.

<sup>b</sup>As cholecalciferol. 1  $\mu\text{g}$  cholecalciferol = 40 IU vitamin D.

<sup>c</sup>In the absence of adequate exposure to sunlight.

<sup>d</sup>As  $\alpha$ -tocopherol.  $\alpha$ -Tocopherol includes *RRR*- $\alpha$ -tocopherol, the only form of  $\alpha$ -tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of  $\alpha$ -tocopherol (*RRR*-, *RSR*-, *RRS*-, and *RSS*- $\alpha$ -tocopherol) that occur in fortified foods and supplements. It does not include the 2*S*-stereoisomeric forms of  $\alpha$ -tocopherol (*SRR*-, *SSR*-, *SRS*-, and *SSS*- $\alpha$ -tocopherol), also found in fortified foods and supplements.

<sup>e</sup>As niacin equivalents (NEs). 1 mg of niacin = 60 mg of tryptophan; 0 to 6 months = preformed niacin (not NE).

<sup>f</sup>As dietary folate equivalents (DFEs). 1 DFE = 1  $\mu\text{g}$  food folate = 0.6  $\mu\text{g}$  of folic acid from fortified food or as a supplement consumed with food = 0.5  $\mu\text{g}$  of a supplement taken on an empty stomach.

<sup>g</sup>Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

**TABLE 9-5** Dietary Reference Intakes: Recommended Intakes for Individuals, Macronutrients (Food and Nutrition Board, Institute of Medicine, National Academies)

apparent. Levels of water-soluble vitamins in milk are raised or lowered by changes in the maternal diet. The body's requirement for vitamin C increases under stress, including lactation. Furthermore, the vitamin C content of human organs at autopsy is much higher in the neonate than at any other time of life. This is true of all the major organs, including the brain.

The influence of maternal intake of vitamin C on the concentration of vitamin C in human milk and on the intake of vitamin C by the infant has been carefully measured in 25 well-nourished lactating women. Supplements ranged from 0 to 1000 mg vitamin C daily (more than 10 times the RDA). Concentrations in milk ranged from 44 to 158 mg/L and were not correlated significantly with maternal intakes, which ranged from 156 (0 mg supplement) to 1123 mg (1000 mg supplement). Dietary vitamin C had no effect on the volume of milk produced. Maternal excretion of vitamin C in urine was correlated with maternal intake. Regardless of the level of maternal intake of vitamin C, the mean vitamin C concentration in breast milk was twice that recommended for infant formula. Vitamin C levels in milk did not increase in response to increasing maternal intake despite tenfold increases, whereas urinary excretion did suggest that mammary tissue becomes saturated.

It is postulated that a regulatory mechanism prevents an elevation in concentration of vitamin C beyond a certain level in milk. Vitamin C levels were at the same or higher levels in exclusively breastfed infants at 6 and 9 months of age compared with levels of supplemented bottle-fed control infants. Levels were dependent on maternal

nutrition and vitamin C levels in milk. Low levels of vitamin C are recorded in 6% of well-nourished healthy mothers. In malnourished women, tissue stores may take time to replenish, which explains why 35 mg/day supplementation failed to increase low plasma levels. Data from multiple studies suggest that there is a level above which further vitamin C supplementation will not affect milk vitamin C levels.

The level of B vitamins, also water soluble, reflects dietary intake. The levels are affected acutely by maternal diet. Infantile beriberi is not unheard of in seemingly normal infants nursed by apparently well-nourished mothers with thiamin-deficient diets. The influence of maternal diet has been pointed out dramatically in reported cases of megaloblastic anemia, methylmalonic aciduria, and homocystinuria in the breastfed infants of strict vegetarians. Vitamin B<sub>12</sub> exists in all animal protein but not in vegetable protein. A strict vegetarian would require vitamin B<sub>12</sub> supplements during pregnancy and lactation.<sup>41,52</sup> Vitamin B<sub>12</sub> deficiency in infants has also been seen in New Delhi, where malnourished mothers produced vitamin B<sub>12</sub>-deficient milk. These infants also had megaloblastic anemia.

Infants of vegetarians who have low vitamin B<sub>12</sub> serum and milk levels have methylmalonic acid in their urine inversely proportional to their vitamin B<sub>12</sub> levels, even though they are asymptomatic.<sup>107</sup> Other authors<sup>41,52</sup> have concluded that the current RDA for infants provides little margin of safety: 0.3 or 0.05 mg/kg body weight is close to the intake below which infant urinary methylmalonic acid measures are elevated.

<sup>a</sup>UL = The maximum level of daily nutrient intake that is likely to pose no risk of adverse effects. Unless otherwise specified, the UL represents total intake from food, water, and supplements. Due to lack of suitable data, ULs could not be established for arsenic, chromium, silicon, potassium, and sulfate. In the absence of ULs, extra caution may be warranted in consuming levels above recommended intakes.

<sup>b</sup>Although the UL was not determined for arsenic, there is no justification for adding arsenic to food or supplements.

<sup>c</sup>The ULs for magnesium represent intake from a pharmacologic agent only and do not include intake from food and water.

<sup>d</sup>Although silicon has not been shown to cause adverse effects in humans, there is no justification for adding silicon to supplements.

<sup>e</sup>Although vanadium in food has not been shown to cause adverse effects in humans, there is no justification for adding vanadium to food and vanadium supplements should be used with caution. The UL is based on adverse effects in laboratory animals and these data could be used to set a UL for adults but not children and adolescents.

<sup>f</sup>ND = Not determinable due to lack of data of adverse effects in this age group and concern with regard to lack of ability to handle excess amounts. Source of intake should be from food only to prevent high levels of intake.

**TABLE 9-8** Suggested Measures for Improving Nutrient Intake of Women with Restrictive Eating Patterns

Type of Restrictive Eating Pattern	Corrective Measures
Excessive restriction of food intake, i.e., ingestion of less than 1800 kcal/day, which ordinarily leads to unsatisfactory intake of nutrients compared with amounts needed by lactating women	Encourage increased intake of nutrient-rich foods to achieve energy intake of at least 1800 kcal/day; if mother insists on curbing food intake sharply, promote substitution of foods rich in vitamins, minerals, and protein for those lower in nutritive value; in individual cases, it may be advisable to recommend a balanced multivitamin-mineral supplement and discourage use of liquid weight-loss diets and appetite suppressants
Complete vegetarianism, i.e., avoidance of all animal foods, including meat, fish, dairy products, and eggs	Advise intake of regular source of vitamin B <sub>12</sub> , such as special vitamin B <sub>12</sub> -containing plant food products or a 2.5-µg vitamin B <sub>12</sub> supplement daily
Avoidance of milk, cheese, or other calcium-rich dairy products	Encourage increased intake of other culturally appropriate dietary calcium sources, such as collard greens for blacks from southeastern United States; provide information on appropriate use of low-lactose dairy products if milk is being avoided because of lactose intolerance; if correction by diet cannot be achieved it may be advisable to recommend 600 mg of elemental calcium per day taken with meals
Avoidance of vitamin D-fortified foods, such as fortified milk or cereal, combined with limited exposure to ultraviolet light	Recommend 10 µg of supplemental vitamin D per day

From the Subcommittee on Nutrition During Lactation, Committee on Nutritional Status During Pregnancy and Lactation, Food and Nutrition Board, et al: *Nutrition During Lactation*, Washington, D.C., 1991, National Academies Press.

Thiamine (vitamin B<sub>1</sub>) has been studied infrequently, but maternal supplementation does not increase milk levels beyond a certain limit. Urinary excretion of thiamine is significantly higher in supplemented compared with unsupplemented women. In malnourished women, evidence indicates that supplementation does increase thiamine levels in milk. It is recommended that thiamine intake be at least 1.3 mg/day (the RDA for non-pregnant, nonlactating women of 1.1 mg/day plus an increment for milk secretion of 0.2 mg/day) when the calorie intake is less than 2200 kcal/day.

Riboflavin (vitamin B<sub>2</sub>) requirements of lactating women in a controlled study in The Gambia showed the minimum to be 2.5 mg/day to maintain normal biochemical status in the mother and adequate levels of vitamin B<sub>2</sub> in her milk.<sup>10</sup> This level is higher than what is recommended in the United States and the United Kingdom.

Niacin (vitamin B<sub>3</sub>) content of human milk has been reported to parallel dietary intake. In unsupplemented diets, low vitamin B<sub>3</sub> levels usually parallel low levels of other B vitamins and low protein intakes.

Pyridoxine (vitamin B<sub>6</sub>) intake and milk levels were studied in healthy lactating women. There were marked diurnal variations of vitamin B<sub>6</sub> levels, with peaks occurring in those mothers taking supplements 3 to 5 hours after a dose. Those taking less than 2.5 mg/day had much lower milk levels. Vitamin B<sub>6</sub> concentrations in human milk change rapidly with maternal intake.<sup>6</sup> When supplemented,

the level in the milk is a direct reflection of amount ingested. Plasma pyridoxal-5'-phosphate levels and birth weight are the strongest predictors of infant growth.<sup>64</sup>

When lactating mothers received supplements of vitamin B<sub>6</sub> ranging from 0 to 20 mg pyridoxine hydrochloride, the levels of vitamin B<sub>6</sub> measurable in the milk paralleled the intake, with levels peaking 5 hours after ingesting the supplement. When maternal intakes of vitamin B<sub>6</sub> approximated 2.0 mg/day, breastfed infants were unlikely to receive the current RDA of 0.3 mg vitamin B<sub>6</sub> per day. The AAP Committee on Nutrition<sup>18</sup> recommends a minimum of 0.35 mg vitamin B<sub>6</sub>/100 kcal milk from birth to 12 months. The RDA for vitamin B<sub>6</sub> for lactating women is 0.5 mg daily. Vitamin B<sub>6</sub> is the vitamin in milk that is most likely to be deficient, because pyridoxine levels in milk are closely influenced by dietary intake.<sup>6,64</sup> Supplementing with an additional 2.5 mg/day results in levels twice as high as in unsupplemented women.<sup>6</sup> The increment in the RDA for vitamin B<sub>6</sub> in lactation is more than five times the estimated secretion of this vitamin in milk,<sup>112</sup> which varies between 0.01 and 0.02 mg/L early in lactation to 0.10 to 0.25 mg/L in mature milk. The recommendation is to advise diets rich in vitamin B<sub>6</sub>, such as poultry, meat, fish, and some legumes, and reserve supplementation for special-risk cases.

Pantothenic acid levels in milk are strongly correlated with maternal intake for the preceding day, although some pantothenic acid is stored in the

body. Studies of malnourished women show increased levels in milk after supplementation. The pantothenic acid content of human milk does not vary appreciably with dietary variations in well-nourished mothers, but the overall intake over time does influence milk levels.<sup>62</sup>

Biotin is reported in few studies, but the findings are consistent that levels range from 5 to 12 mg/L, with supplementation even up to 250 mg/day having little effect except when levels are significantly below this range.

Pregnant and lactating women are at risk for sub-optimal folate status because of the increased dietary requirement to facilitate enhanced anabolic activity. Until megaloblastic anemia develops, no validated, quick, nonintrusive tests exist to assess functional folate status. Milk folate levels are maintained at the expense of maternal reserves, thereby protecting the nursing. O'Connor<sup>88</sup> provides an extensive review of the issues.

Folate supplementation in well-nourished women does not affect the level of folate in the milk, although studies involving women with low folate (less than 60% RDA) show they responded to supplementation with increased levels in their milk. Differences in assay methods have produced inconsistencies among studies. Milk levels normally range between 40 and 70 mg/L and increase slightly in the early weeks of lactation. Daily dose during lactation should be 500 µg/day.

The effect of the stage of lactation on levels of vitamins B<sub>1</sub>, B<sub>2</sub>, B<sub>3</sub>, B<sub>6</sub>, and B<sub>12</sub> and ascorbic acid has been reported. The values remained fairly constant throughout, except for those of vitamin B<sub>3</sub>, which increased slightly over time. The relationship to socioeconomic group showed an increase in vitamin B<sub>3</sub> and B<sub>6</sub> levels with increased status. Vitamin B<sub>1</sub> was higher in poorer mothers. Tables 9-9 and 9-10 summarize the effects of diet on vitamin levels in maternal milk.

## Fat-Soluble Vitamins

Fat-soluble compounds are generally transported into milk via the fat, and levels are less easily improved by dietary change. Because vitamins A and D are stored in tissues, the impact of dietary supplementation is more difficult to measure. Milk levels do not change until a certain level is achieved in the stores. High dietary levels of β-carotene do not appear to result in excessive levels of either vitamin A or β-carotene. An increase in vitamin A in the diet of undernourished women does increase its level in milk.

**Vitamin A.** When malnourished mothers were given a single oral megadose of 209 mmol of vitamin A and the control subjects were given none, serum retinol (vitamin A<sub>1</sub>) levels increased in the supplemented mothers and remained significantly higher for at least 3 months.<sup>104</sup> Breast milk levels were higher (11.3 versus 2.9 mmol/L) and remained so for 6 months. An associated observation was the reduction in the duration of respiratory tract infections and febrile illnesses in the infants of the supplemented mothers. This observation was confirmed by Stoltzfus et al., who did a randomized double-blind study giving women 312 mmol of vitamin A as retinyl palmitate or placebo orally. Maternal levels in the supplemented group were significantly higher at 6 months than in the group given the placebo. Among the infants at 6 months, 36% of the placebo group and 15% of the vitamin A group had low retinol concentrations. Their relative dose response demonstrating low vitamin A stores was 23% in the placebo group and 10% in the treated group. This confirmed the value of high-single-dose vitamin A in lactating women according to the authors.

Maternal postpartum vitamin A supplementation was subjected to a systematic review of randomized controlled trials by Gogla and Sachelev.<sup>43</sup> No evidence of a reduction in mortality or morbidity was

**TABLE 9-9** Water-Soluble Vitamins in Human Milk

Vitamin	Recognizable Clinical Deficiency in Infant	Effect of Maternal Supplements		Effect of Dietary Intake on Milk Content

found; low birth weight was not measured. Policy formulation should be based on improvement of maternal benefits (morbidity and mortality), maternal safety, and cost-effectiveness.

**Vitamin D.** Many women have surprisingly inadequate vitamin D levels.<sup>119</sup> Vitamin D had been considered to be at a stable level in milk that was unaffected by diet. However, studies involving maternal levels and infant levels have demonstrated low milk levels.<sup>53</sup> When mothers were given 0, 500, and 2500 IU ergocalciferol daily, they produced milk with 39, 218, and 3040 mg/mL vitamin D. The effect on levels of 25-hydroxyvitamin D was less dramatic.<sup>53</sup> The physiologic significance to the infant was disputed, because the major source of antirachitic sterols was thought to be sunlight, not milk. The role of water-soluble vitamin D in human milk has not been confirmed. Infants born to mothers with inadequate vitamin D stores need a regular supply of vitamin D through diet, supplements, and exposure to ultraviolet light.<sup>115</sup>

Infant levels of vitamin D have been found to be low. Because of the report of clinical rickets in breastfed infants in a sunny climate, the AAP<sup>4</sup> and the Centers for Disease Control (CDC) have determined that breastfed infants should be supplemented regardless of maternal vitamin D status and exposure to sunlight. This mandate has been supported by dermatologists who have recommended no sun exposure and the use of sunscreen in infancy. The best estimate of adequate exposure to sunlight for white infants was considered to be 30 minutes per week clothed only in a diaper or 2 hours per week fully clothed with head and hands exposed.

Multiple studies have demonstrated that maternal 25-hydroxyvitamin D levels can be raised by supplementation.<sup>42</sup> In women at risk, this supplementation should begin in pregnancy to prevent low cholecalciferol levels and continue through lactation to ensure adequate levels in their milk. Supplementing mothers is preferred to supplementing the breastfed infant because the mother is also in deficit.<sup>106</sup>

Vitamin D deficiency in infants is not breast milk deficiency but the deficiency of sunlight. Societal changes have diminished infant sun exposure including the avoidance of sunlight, the use of sunscreen, the migration to northern latitudes by dark-skinned individuals, and the use of total body clothing for religious reasons by individuals migrating to northern climates. Replacing this natural source of vitamin D has been a challenge, but requires actual supplementation.

While recommending vitamin D supplementation across the board, the AAP<sup>4</sup> and the CDC have not considered maternal supplementation partially because of possible toxicity, although doses of 4000 IU/day for up to 5 months have been shown to be safe in a wide population of adults. To achieve normal vitamin D status in breastfeeding mother-infant pairs, high-dose maternal vitamin D was utilized by Wagner and Greer.<sup>119</sup> A dose of 1600 IU vitamin D per day for 3 months has minimal effect on vitamin D levels in mother or infant; 3600 IU/day provided clinically relevant increases in the nutritional vitamin D<sub>2</sub> status of both mother and her infant. In the absence of sunshine or in dark-skinned individuals, 4000 IU/day appears to be the minimal maternal dose to achieve clinical results. Deficit mothers may need up to 4000 IU/day. Because laboratory vitamin D is easily obtained, doses can be based on individual needs (Table 9-11).

Dark-skinned infants reared in climates where sunlight is minimal may be at significant risk for rickets when breastfed unless attention is given to the possible need for supplements of vitamin D.<sup>10</sup>

**TABLE 9-11** Serum 25-Hydroxyvitamin D Reference Range Recommendations

ng/mL	Interpretation
<b>Serum 25-hydroxyvitamin D</b>	
<20	Moderate risk of deficiency
20-29	Low risk of deficiency
30-60	Adequate
>60	Potentially harmful

Although rickets was considered a disease of the past, the disease has reemerged since the 1980s partially because of the high risk for premature infants, especially micropremature infants, but also because of the increase in breastfeeding, especially by women who avoid dairy products, which are the major food source of vitamin D supplementation.<sup>22</sup> It is just not about rickets anymore, but any signs of vitamin D deficiency, which begins with decreased absorption of intestinal calcium and urinary loss of phosphorus but normal calcium levels in infants. The progression of deficiency shows bone demineralization and elevated alkaline phosphatase followed by hypocalcemia and hypophosphatemia and frank rickets. Vitamin D deficiency has also been associated with significant disease states including autoimmune diseases through vitamin D actions on the immune system (e.g., rheumatoid arthritis, systemic lupus erythematosus; multiple sclerosis; diabetes mellitus type 1; Crohn disease; cancers, such as breast, prostate, colon, and skin; cardiovascular disease; and insulin resistance). Insufficient vitamin D levels in pregnancy have been linked to higher levels of body fat in the child at 6 years of age.<sup>21</sup>

The recommendation is for all breastfed infants and any infant receiving less than 500 mL of fortified formula per day to receive 400 units of vitamin D daily beginning at birth.<sup>4</sup> Preparations of vitamin D only are available because a breastfed infant does not need other vitamins unless the mother is deficient.<sup>42</sup> Just D by Sunlight Vitamins contains 400 units in 1 mL. Bio-D-Mulsion by Biotics Research Laboratory contains 400 units in one drop!

**Vitamin E.** Vitamin E has not been the focus of study of maternal dietary supplements except in the report by Kramer et al.<sup>66</sup> that sunflower oil replacing lard in the diet resulted in a 50% increase in vitamin E levels in the milk. Liberal use of vitamin E creams by health enthusiasts may well expose an infant to large doses by maternal absorption as well as directly when the creams are applied to the breast. Levels of  $\alpha$ -tocopherol are highest in the colostrum when the neonate is most dependent on its physiologic effect as an antioxidant and in the prevention of hemolytic anemia attributed to vitamin E deficiency. Maternal vitamin E intake can influence the levels of vitamin E in the milk. However, no evidence indicates that vitamin E deficiency occurs in individuals with normal fat absorption.<sup>112</sup> To compensate for losses in milk and maintain stores, 4-mg  $\alpha$ -tocopherol equivalents (16 mg) per day are recommended.<sup>36</sup>

**Vitamin K.** The most critical need for vitamin K for the infant is during the birth process and in the first few days of life, when the risk for bleeding, especially intracranial bleeding, is greatest.<sup>48</sup> Maternal dietary intake is most critical during the

last trimester. Transplacental passage of vitamin K is slow. Cord blood levels are almost imperceptible. The synthesis of menaquinones by bacteria in the breastfed infant gut is minimal because lactobacilli do not synthesize them. Studies on supplementation of lactating women have shown that small doses are inadequate to raise the maternal level. Greer et al.<sup>46</sup> have shown that the average woman's intake is now 0.8 to 1.03 mg/kg/day. The content of human milk is 0.1 to 0.2 mg/dL, which does not supply the daily requirement of 1 mg/kg/day. Maternal supplements of 5 mg/day of vitamin K increase breast milk concentration to 4.5 to 6.0 mg/dL, thus increasing serum concentrations in exclusively breastfed infants.

After the intramuscular (IM) injection of 1 mg of vitamin K at birth, no further recommendations for vitamin K supplements are made for healthy breast-feeding infants and their mothers. If the infant receives an oral preparation at birth, the dose of 2 mg should be repeated at 7 and 28 days of age.

Protein induced in vitamin K absence or antagonism (PIVKA) (undercarboxylated prothrombin produced in the absence of vitamin K) levels are a marker of K deficiency. The cord blood of full-term infants often has high PIVKA levels (0.1 AU/mL) correlating with low vitamin K. Levels in the infant are undetectable at 4 weeks after IM vitamin K administration at birth, but in some infants they become elevated by 8 weeks. This has led to the recommendation that mothers be supplemented with 90  $\mu$ g of vitamin K daily through the first 3 months of lactation.<sup>47</sup>

The consensus is that late vitamin K deficiency bleeding should be prevented by prophylaxis (Box 9.1). After a study of different oral schedules

#### BOX 9.1. Administration of Vitamin K to Newborns

Because parenteral vitamin K prevents a life-threatening disease of the newborn and the risks of cancer are unproved and unlikely, the American Academy of Pediatrics recommends the following:

1. Vitamin K<sub>1</sub> should be given to all newborns as a single, intramuscular dose of 0.5 to 1 mg.
2. Further research on the efficacy, safety, and bioavailability of oral formulations of vitamin K is warranted.
3. An oral dosage form is not currently available in the United States but ought to be developed and licensed. If an appropriate oral form is developed and licensed in the United States, it should be given at birth (2.0 mg) and should be administered again at 1 to 2 weeks and at 4 weeks of age to breastfed infants. If diarrhea occurs in an exclusively breastfed infant, the dose should be repeated.

in Australia, Germany, The Netherlands, and Switzerland, it was confirmed that oral doses of 1 mg vitamin K for the infant are less effective than IM dosing. It takes at least 6 hours after an IM dose of vitamin K to improve clotting. The least invasive method would be to increase the milk levels by supplementing the mother. In the 1950s, efforts to increase vitamin K and prothrombin levels at birth by giving mothers a large dose of vitamin K in labor failed to change the incidence of hemorrhagic disease in newborns. However, maternal supplementation during lactation is effective for the mother.

Although the amount of vitamin K available in infant formulas is very high, no toxicity has yet been demonstrated.

## Summary

Although dietary supplements improve the milk quality and quantity in malnourished women, a balanced diet without excessive supplementation is the most physiologic and economic way to ensure good milk. Nutrients, especially vitamins, are excreted in the urine only when taken in excess. The AAP Committee on Nutrition recommends 400 mg vitamin D for breastfeeding infants beginning at birth in the absence of adequate sun exposure. Maternal supplementation is under study. Vitamin K at birth for the infant is essential. The AAP recommends a single dose of vitamin K (0.5 to 1.0 mg intramuscularly) at the time of delivery.<sup>4</sup>

## MINERALS

### Calcium

Calcium has been associated with bone growth, and concern has been expressed because the total calcium in breast milk is low. The available information is inadequate to determine the true requirement for lactation. Studies with radioactive calcium in non-pregnant adults have shown that losses occur into the gut and through the kidney. Absorption and retention also depend on the reserves in the body. Long-term shortage causes economy of utilization, and the apparent requirement is lower.<sup>14</sup> During lactation, the absorption and retention are greater.

Serum calcium and phosphorus concentrations are greater in lactating women compared with non-lactating women.<sup>53</sup> Lactation stimulates increases in fractional calcium absorption and serum calcitriol. This is most apparent after weaning. Alterations in absorption, metabolism, and excretion may conserve calcium during lactation.<sup>49</sup> Women with low calcium intakes have no direct benefit from supplementation as a protective mechanism to maintain breast milk calcium or maternal bone mineral content.<sup>96,98</sup> Urinary calcium was found

to be higher in the supplemented group. Of significance, however, is the presence of risk factors: positive family history of osteoporosis, fair complexion, lower body mass and height, not breastfeeding their infants, smoking, and fat deposits have the greatest predictability for osteoporosis.<sup>63</sup> Scanning transmission techniques showed that lactating women mobilize 2% of their skeletal calcium in 100 days of nursing. The calcium content of milk appears to be maintained despite greatly deficient intake, probably because of skeletal stores. The milk calcium levels are the same in mothers of rachitic and nonrachitic infants. This is most important for women younger than age 25 because the calcium content of bones is expected to increase until age 22. Peak bone mass is achieved during the childbearing years.

Estradiol concentrations are related to bone mineral density because estradiol stimulates osteoblastic proliferation and enhances collagen gene expression. The relatively low estrogen levels during lactation increase bone mobilization. Prolonged amenorrhea is associated with increased mobilization, and the greatest reduction in bone mass occurs early in lactation. Prolactin has a synergistic effect on mobilization. The ratio of dietary calcium to dietary protein has also been identified as important; that is, women with high-protein diets must also have high calcium intake. Recovery after weaning is reported to be negatively affected by parity.

The reference dietary intake (RDI) for calcium is higher for women younger than age 18, even when prepregnant, than for older women (1300 mg calcium compared with 1000 mg recommended for nonpregnant women older than age 18). Calcium status is only one of many possible factors in the etiology of osteoporosis. Dietary guidance during lactation should include recommendations for the replacement of stores. Women who have lactated are not more prone to osteoporosis than nonlactators or nulliparas, and they may be less prone.<sup>14</sup> Postweaning bone regeneration is accelerated for the first 4 to 6 months after lactation ceases. Bone density is then often greater than prepregnancy.

There is no additional requirement for calcium while lactating. The requirement of 1000 mg/day is adequate intake (AI). When dietary calcium intake is greater than the RDA for lactating women, bone mineral content is not diminished during at least the first 6 weeks of lactation.

### Sodium, Potassium, and Chlorine

The concentration of sodium is the most variable of all the minerals, fluctuating as much as tenfold during normal lactation and diurnally, separate from the effects of mastitis, emotional stress, or involution. Maternal sodium or potassium intake has no immediate influence, either high or low,

on postprandial milk sodium or potassium concentrations.<sup>33</sup> Dietary potassium may influence milk potassium more significantly. RDI in lactation is 5.1 g/day. With increasing numbers of women with cardiac and renal disease choosing to lactate, potassium levels in the diet would be of significance, in addition to concerns about necessary medications that are known to deplete potassium levels.

Chlorine level in the breast milk is not thought to be affected by maternal diet. Chlorine deficiency reported in a breastfed infant was associated with normal maternal serum and dietary intake<sup>8</sup> but with deficit levels in the milk (less than 2 mEq/L). Normal is greater than 8 mEq/L. This deficit in the milk was assumed to be a defect of breast function. Daily requirement is 2.3.

The concentration of electrolytes (sodium, potassium, chloride) in milk is determined by an electrical potential gradient in the secretory cell rather than by maternal nutritional status.<sup>112</sup>

## Iron

The iron content of milk is not readily affected by the iron content of the diet or the maternal serum iron level. Increases in dietary iron that increase serum levels do not increase iron in the milk. It is important, however, for the mother to replace her iron stores postpartum.<sup>94</sup> It has not been established that increases in tissue iron are advantageous. Iron that is added to human milk will bind to lactoferrin and may interfere with its function. Infants exclusively breastfed for 7 months or longer were not found to be anemic at 12 or 24 months.<sup>94</sup> Half the infants breastfed for a shorter period were anemic at 12 months because additional dietary iron from solids was not provided.

A large study, however, involving children from Sweden and Honduras examined whether iron supplements affect growth and morbidity.<sup>28</sup> Children were assigned to supplements or a placebo. If the hemoglobin was less than 110 g/L at onset, iron had a therapeutic effect. Growth measurements were significantly lower in length and head circumference in those who received iron. Those who had hemoglobin greater than 110 g/L and received iron had more diarrhea. The authors suggest that iron not be given unless it is needed. In another observational study involving more than 900 children at 8 and 12 months, it was noted that those who combined 6 or more breastfeedings or 600 mL or more cow milk per day had higher levels of anemia. The authors recommend more iron containing solids and less milk for this age group.<sup>54</sup>

The requirement for iron is 1.8 times higher for vegetarians due to the lower bioavailability of iron from vegetarian sources.<sup>90</sup>

Iron supplementation appeared safe according to Friel et al.,<sup>37</sup> who conducted a double-blind, randomized control trial of iron supplementation in early infancy in a total of 77 healthy term breastfed infants using 7.5 mg/day of elemental iron as ferrous sulfate or a placebo from 1 to 6 months of age. Iron supplementation produced higher hemoglobin and mean corpuscular volume at 6 months of age as well as higher visual acuity and psychomotor development index at 13 months of age.

Dietary iron for lactating women is set at 9 mg/day, which is offset by the suppression of menses during lactation.

## Phosphorus, Magnesium, Zinc, and Copper

Phosphorus, magnesium, zinc, and copper levels in milk are not affected by dietary administration of these elements.<sup>67</sup> Again, however, it is important for the mother to replenish her stores.<sup>94</sup>

According to the RDA, many lactating women are receiving marginal amounts of magnesium.<sup>77</sup> The amount recommended for lactation is two to three times the amount estimated to be in the milk or 310 to 320 mg/day.

Zinc has a RDA during lactation of 4 to 13 times higher than the amount estimated to be in the milk on the basis that it is poorly absorbed (20%). Studies done with stable isotopes in lactating women show that absorption was 59% to 84% of intake. Zinc absorption during pregnancy increases dramatically and during lactation decreases slightly but is double the prepregnant rates, presumably in response to the demand by the breast for milk synthesis.<sup>39</sup> Milk levels are unaffected by supplementation and gradually decline over time from 2 mg/day.<sup>68</sup> Supplementation does result in increased maternal absorption and increased plasma levels.

Prolactin is a zinc-binding hormone that is associated with the initiation and maintenance of lactation. Zinc is also thought to be involved with synthesis, storage, and secretion of prolactin. Increasing zinc availability is thought to inhibit formation and secretion of prolactin from the pituitary. The relationships among plasma zinc, prolactin, milk transfer, and milk zinc were studied by O'Brien et al.<sup>87</sup> No differences in milk transfer or prolactin levels were found between those who were zinc supplemented and those who were not. Low zinc levels are seen in those with a history of long-term alcohol ingestion. Their daily requirement is doubled.

Although no major health risks have been associated with low zinc intakes, zinc is known to be important to immune function.<sup>59</sup> RDA for zinc is 12 to 13 mg/day during pregnancy and lactation.

Recommended intake for infants 0 to 6 months of age is 4 mg/day.

Iron supplementation has no significant effect on levels of copper, selenium, and zinc in mother's serum and breast milk.<sup>7</sup>

## Selenium

A correlation exists between selenium in human milk and maternal dietary intake.<sup>72</sup> Maternal plasma levels vary with the form of selenium supplementation (selenomethionine or selenium-enriched yeast).<sup>76</sup> The original source of selenium is the soil, and levels vary geographically. It is transferred to plants and works up the food chain. Breastfed infants are known to have higher intake and utilization than infants fed formula or cow milk because of bioavailability.<sup>2</sup> Many selenoproteins have been identified, but glutathione peroxidase is involved with producing a variety of organic hydroperoxides or reactive oxygen radicals in the liver. Although selenium toxicity is possible, deficiency from low intake is a problem.<sup>74</sup> Two diseases showing selenium deficiency are Keshan disease and Kashin-Beck disease, which are associated with accumulation of lipid peroxides. Dietary studies have shown that intake can affect the mother's plasma and milk levels.<sup>2</sup> RDI is 70 µg daily during lactation, compared with 55 µg for nonlactators.

## Chromium

Breast milk levels of chromium are reported to be  $3.54 \pm 40$  nmol/L (0.18 ng/mL) and independent of dietary intake.<sup>5</sup> Total absorption for lactating women was  $0.79 \pm 0.08$  mmol/dL, which was greater than that of nonlactators. Serum levels were correlated with urinary chromium excretion, a good indicator of serum levels. The estimated RDA for breastfed infants is 10 mg, which is much greater than the levels measured in the study by Anderson et al.<sup>5</sup> The RDA for adults is 45 mg during lactation and 25 mg for nonlactating women of the same age.<sup>36</sup>

## Iodine

Iodine in milk does depend on dietary content. The breast is able to raise the concentration of iodine in the milk above that in the blood, and thus there is an increased danger in giving radioactive iodine to the lactating woman. With iodized salt, bread dough conditioners, and common use of iodine-containing cleansers, excessive iodine intake is a risk.

The question of possible iodine deficiency, however, has been raised in breastfed infants around the globe as well as in the United States. A study of women in Boston found a mean breast milk concentration of 155 µg/L with a mean urinary iodine level of 144 µg/L; 47% of the women had milk insufficient in iodine.<sup>93</sup> Smoking is also recognized to reduce iodine concentrations in breast milk to a mean level of 26 µg/L. The authors suggest that lactating women should take iodine supplements, such as an iodine-containing vitamin preparation with at least 150 µg per dose. The daily requirement is 290 µg; however, more than 450 µg daily is considered excessive.<sup>92</sup> Urinary iodine concentrations optimally are 100 to 199 µg/L with a corresponding intake of 150 to 299 µg/day. Infants need 110 µg/day.

Milk iodine concentrations are higher now than were reported in the 1930s. Mean breast milk iodide levels ranged from 29 to 490 mg/L, averaging 178 mg/L, above the RDA for infants. In a study of pregnant and lactating women in Bangkok, iodine levels were 70.6 and 138.0, respectively, following supplementation with 200 mg iodine daily. Cord blood TSH was reduced with supplementation and in the infants, this demonstrated that maternal supplementation did improve the milk and subsequently the thyroid function of the infants in iodine poor regions.

## Fluorine

Human milk contains  $16 \pm 5$  mg fluoride per liter and reflects, to some degree, the level in the water supply. The risk for excessive fluoride has been pointed out by Walton and Messer,<sup>123</sup> who report dental mottling and milk fluorosis in supplemented breastfed infants. The AAP Committee on Nutrition, therefore, has stated, "It may not be necessary to give fluoride supplements to breastfed infants who are living in an area where water is adequately fluoridated." If the water is not fluoridated or mother drinks fluoride-free bottled water, she should be supplemented.

Fluoride concentrations of infant foods and drinks have been found to vary widely, ranging from 0.01 to 0.72 mg/kg, so that no need exists for supplementation if the diet is well balanced when solid foods are initiated.<sup>120</sup>

## Summary

**Table 9-12** summarizes constituent levels in human milk and changes over time.

**TABLE 9-12** Representative Values for Constituents of Human Milk\*

Constituent (per Liter)*	Early Milk (<28 Days Postpartum)	Mature Milk ( $\geq 28$ Days Postpartum)
<b>Energy (kcal)</b>		<b>650-700</b>

The values are expressed per liter of milk as a percentage on the basis of milk volume or weight of total lipids. Values as mean values or ranges of means.  $\omega$ -3, Omega-3;  $\omega$ -6, omega-6.

\*All nutrient values except for amino acids are modified from Picciano MF: Appendix: representative values for constituents of human milk, *Pediatr Clin North Am* 48:263, 2001.

<sup>†</sup>Modified from George DR, De Francesca BA: Human milk in comparison to cow milk. In Lebenthal E, editor: *Textbook of gastroenterology and nutrition in infancy and childhood*, ed 2, New York, 1989, Raven Press, pp 242-243.

<sup>‡</sup>The cholesterol content of human milk ranges from 100 to 200 mg/L in most samples of human milk after day 21 of lactation.

## *Maternal Nutrition: Immunologic Substances and Leukocyte Activity*

Substances in colostrum and mature milk confer important infection protection on breastfed infants. Maternal malnutrition was associated with lower levels of immunoglobulins G and A (IgG, IgA) in a group of Colombian women studied by Miranda et al.<sup>81</sup> The colostrum contained only one third the normal levels of IgG and less than half the normal albumin. Significant reductions in IgA and complement C4 were observed in colostrum, but lysozyme, C3, and IgM were normal. Titers against respiratory syncytial virus were unaffected by nutritional status. The protective deficiencies improved in mature milk over time and with improvement of nutritional status. The total leukocyte concentrations as well as their bactericidal capacity were similar in well-nourished and undernourished women.<sup>11</sup>

Prentice et al. measured breast milk antimicrobial factors of rural Gambian mothers. The concentrations and daily secretions of all immunoproteins, except lysozyme, decreased during the first year and then remained steady. Compared with those in Western women, levels of IgG, IgM, C3, and C4 were higher in Gambian women; IgA and lactoferrin were similar; and lysozyme was lower. Dietary supplement in Gambian women did not raise the breast milk immunoproteins in this study.

The Subcommittee on Nutrition During Lactation has concluded that the effects of maternal nutritional status on the immunologic system in human milk are controversial.<sup>112</sup> Some studies suggest that malnutrition decreases the production and secretion of some components of the immunologic system, but further investigation clearly is necessary.

## *Recommendations for Nutritional Support During Lactation*

The previous section noted that the quantity, protein content, and calcium content of milk are relatively independent of maternal nutritional status and diet. Amino acids lysine and methionine, certain fatty acids, and water-soluble vitamin contents vary with intake. It is important to point out that stores of calcium, minerals, and fat-soluble vitamins need to be replenished.<sup>124</sup> Much of the data collected have varied, depending on the method used in collection. The daily intakes thought necessary for infants were determined by feeding infants processed human milk in a bottle, which is not a physiologic standard.<sup>24</sup> It is known, for example, that

putting the entire sample in one container removes the natural variation in fat from beginning to end of the feeding.

The Subcommittee on Nutrition During Lactation<sup>39,115</sup> has recommended a balanced diet comparable to one for the nonlactating postpartum mother, with a few additions. Although the calculated caloric cost of producing 1 L of milk is 940 kcal, during pregnancy most women store 2 to 4 kg of extra tissue in the physiologic preparation for lactation.<sup>35</sup> Thus, it is probably necessary to add only 500 kcal to the diet, except in women with known high metabolic rates.

Preparation for lactation begins in pregnancy, if not before. The major daily increases for pregnancy are 300 kcal, 20 g of protein, a 20% increase in all vitamins and minerals except folic acid, which is doubled, and a 33% increase in calcium, phosphorus, and magnesium. In comparing the RDAs for lactating women with those for nonlactating adult women, the increases suggested should provide ample nutrition and replace stores (Table 9-7).

When dietary supplements are suggested, concern arises about increased costs. Cost increases are modest for the standard diet and minimal for the low-budget diet, as demonstrated by Worthington-Roberts. Although one rarely chooses breastfeeding or bottle-feeding on the basis of cost, the price of a few extra maternal kilocalories versus the cost of formula feeding makes a reassuring comparison. Hypoallergenic formulas are even more costly, estimated to be more than \$5 per day.

After the report of the Subcommittee on Nutrition During Lactation,<sup>112</sup> an additional report was prepared, *Nutrition during pregnancy and lactation: an implementation guide*.<sup>113</sup> Its purpose is to offer practical guidance to primary care providers by including a sample nutrition screening questionnaire, indications for supplementation, nutritional assessment guidelines, and how and when to refer patients to registered dietitians.

The subcommittee did not propose a food guide because it recognized that diverse ways are available to meet nutrient needs and that culturally appropriate foods are important, especially in the perinatal period. It did offer the following recommendations<sup>113</sup>:

- Avoid diets and medications that promise rapid weight loss.
- Eat a wide variety of breads and cereal grains, fruits, vegetables, milk products, and meats or meat alternatives each day.
- Consume three or more servings of milk products daily.
- Make a greater effort to eat vitamin A-rich vegetables or fruits often. Examples of foods high in vitamin A include carrots, spinach or other cooked greens, sweet potatoes, and cantaloupe.

- Be sure to drink when thirsty. Lactation requires more fluid than usual.
- If you drink coffee or other caffeinated beverages, such as cola, do so in moderation. Two servings daily are unlikely to harm the infant. Caffeine passes into the milk.

## MALNUTRITION: SPECIAL SUPPLEMENTATION FOR THE LACTATING WOMAN

It has been suggested that supplementing the diet of malnourished mothers with a special formula would be the best way to achieve ideal nourishment for mother and child. Infants will then gain the additional advantages of human milk, such as protection against infection.<sup>65</sup> Such formulas have been devised. Sosa et al.<sup>106</sup> successfully tried this approach in Guatemala. When nutritional supplements are recommended, ideally they are given to the mother. Such studies have been repeated in many geographic areas. The results confirm that the provision of supplemental food improves milk production and the duration of exclusive breastfeeding among undernourished women.<sup>25</sup> In contrast, well-nourished women do not show any benefits from supplementation.<sup>44,124</sup>

With the ready availability of well-balanced nutrition supplements today in the form of stable powders in both supermarkets and drugstores, it should not be difficult to initiate a high-protein, vitamin-enriched diet supplementation that is also palatable for an occasional mother who is at nutritional risk. With the inclusion of breastfeeding as a goal in the Women, Infants, and Children (WIC) program, dietary counseling and supplementation are available for mothers at poverty level to encourage these mothers to breastfeed and to give them nutritional support while doing so. Infants in the WIC programs will receive the greatest benefit from being breastfed. Present WIC supplements focus on improved maternal diet and were improved and expanded in 2009.

Because studies have revealed a negative effect of malnutrition on infection protection properties as well as on galactopoietic hormones (corticosteroids are greatly increased and prolactin decreased), nourishing the mother is the most effective way of benefiting the infant rather than supplementing the infant to meet growth standards.

The impact of dietary supplementation on lactating women with restricted diets has been reported to be inconsistent with respect to lactational amenorrhea.<sup>115</sup> Most recently, a study in Sri Lankan women did not show an effect on menstruation or ovulation with supplementation.<sup>113</sup> However, the study did result in a longer duration of full breastfeeding in supplemented women,

which may have had an effect in suppressing ovulation. No difference was seen between supplemented and unsupplemented women regarding lactational amenorrhea.<sup>115</sup>

## ALLERGY

In families with a strong history of allergy, a hypoallergenic diet avoiding common allergens such as wheat and eggs should be recommended. Interest in the transfer of cow milk proteins to infants via breast milk has increased as case reports appear detailing breastfed infants' reaction to cow protein.  $\beta$ -Lactoglobulin has been identified in breast milk and appears to be related to long-term exposure to cow milk products.<sup>38</sup> Controlling intake has also been reported to reverse the presence of  $\beta$ -lactoglobulin in breast milk. Ovalbumin has been identified in human milk in only a fraction of mothers tested, although average intake was four eggs per week (see Chapter 17).

## VEGETARIAN DIET

The growing interest in vegetarianism has necessitated a better understanding of the several types of diets and their potential for adequate nutrients and growth as well as the motivation for these diets (see Table 9-13). In general, serious vegetarians usually have a greater knowledge of and commitment to good nutrition.<sup>16</sup>

Reports of malnutrition among breastfed infants of vegetarians usually focus on the very strict groups, such as vegans and those on macrobiotic diets. The dietary risks involved are chiefly with the B vitamins because these vitamins are usually associated with protein, which is also proportionally lower from vegetable sources.<sup>101</sup> An additional concern is the availability of various amino acids in specific concentrations to utilize them for protein synthesis. The net protein utilization of a food may be considerably lower than total protein content; therefore, it is important when using vegetable sources of protein to use foods with "complementary protein" at the same meal. Vegetarian cookbooks emphasize this. Throughout history, culturally traditional meals have ensured complementary proteins. Concentrations of polychlorinated biphenyls are lower in the breast milk of vegetarians.

Vitamin B<sub>12</sub> deficiency has been described in vegans because of the absence of animal protein. It is advisable in these cases to supplement the diets of pregnant or lactating women and of infants or growing children with up to 4 mg/day of vitamin B<sub>12</sub>. It has been shown that fermented soybean foods do contain vitamin B<sub>12</sub> as do the single-cell proteins such as yeast because even single-cell

**TABLE 9-13** Vegetarianism and Associated Risks

Type of Vegetarian	Diet Includes	Diet Avoids	Risks
Semivegetarian	Vegetables, milk products, seafood, poultry	Red meat	Minerals*
Ovolactovegetarian	Vegetables, milk products, eggs	Flesh foods (meat, seafood, poultry)	Minerals,* esp. zinc
Lactovegetarian	Vegetables, milk products	Flesh foods, eggs	Minerals,* esp. zinc, protein <sup>†</sup>
Ovovegetarian	Vegetables, eggs	Flesh foods, milk products	Minerals,* esp. iron and zinc, protein, <sup>†</sup> riboflavin, vitamin D, vitamin B <sub>12</sub>
Vegan	Only vegetables	Flesh foods, milk products, eggs	Minerals,* protein, <sup>†</sup> riboflavin, vitamin D, vitamin B <sub>12</sub>
Macrobiotic	Gradual progression to a diet of only cereals		Advanced stage nutritionally inadequate

\*Excessive dietary phytates and dietary fiber inhibit absorption of minerals such as iron, zinc, and calcium. *Phytates* are organic chemicals present in many vegetables and unleavened bread that bind with minerals.

<sup>†</sup>Diets not using complementary proteins may be deficient in net protein because the net protein utilization is low.

animal species contain small amounts of vitamin B<sub>12</sub>. In a study of vegetarian mothers and their infants, a large proportion of the infants had elevated methylmalonic acid levels, indicative of vitamin B<sub>12</sub> deficiency.<sup>107</sup> A significant number of vegetarian women, both lactators and nonlactators, had elevated methylmalonic acid levels and low vitamin B<sub>12</sub> levels.

As noted previously, vegetarians have lower levels of DHA.<sup>103</sup> Comparison of umbilical cord blood of infants born to South Asian vegetarian women showed less DHA in the plasma and cord artery phospholipids than in infants born to omnivores.<sup>103</sup> Early onset of labor, incidence of cesarean delivery, lower birth weight, head circumference, and length, after adjusting for maternal height, duration of gestation, parity, smoking, and sex of infant, were also related to DHA levels.

Reports of growth curves in vegetarian children in the first few years show them to be shorter and leaner than standard, with the greatest effect among those whose mothers were on the most restricted diets.<sup>34</sup> Studies of children from birth to 10 years in The Netherlands reared in a macrobiotic tradition showed the greatest growth retardation with fat and muscle wasting and slower psychomotor development between 6 and 18 months of age.<sup>23</sup> The breast milk of their mothers, who breastfed an average of 13.6 months, contained less vitamin B<sub>12</sub>, calcium, and magnesium compared with matched omnivorous control subjects.<sup>23,32</sup> Breastfed vegetarian infants are usually on the norms for growth, with the exception of those receiving minimal vitamin D and calcium, as reported in dark-skinned mothers in cloudy climates. The mean serum 1,25-dihydroxyvitamin D concentrations were 37% higher in lactating vegetarian women than nonvegetarian women. The serum parathyroid hormone was elevated in all lactators

compared with nonlactators. It is postulated that the low calcium in the vegetarian diet stimulates the elevated 1,25-dihydroxyvitamin D level, and this in turn stimulates the increased absorption of calcium to meet the needs of milk production.<sup>107</sup>

A study of the milk from vegetarian mothers compared with that from nonvegetarian mothers looked at fat and fatty acid composition.<sup>23</sup> Those fats and fatty acids produced de novo by the breast were not different.<sup>108</sup> The precursors of arachidonic acid (AA) were higher in vegetarians, yet the AA level in the milk was lower and continued to decrease the longer the vegetarian diet was maintained. Linoleic acid was greater among vegetarians. The amounts of DHA were not different. Among 34 breastfed infants at 7 months in the Tufts study, 3 were below the 10th percentile for height and weight, 1 had low weight for length, and 3 had high weight for length, whereas of the 51 who were not breastfed, 6 were below the 10th percentile, 2 had low weight for length, and 4 had high weight for length.

Four vegetarian children between 8 and 24 months of age were reported by Hellebostad et al.<sup>51</sup> to have vitamin D-deficient rickets (three with tetany and seizures) and vitamin B<sub>12</sub> deficiency. All the infants were initially breastfed by mothers whose diets were low in vitamin D, high in fiber and phytate (which interferes with enterohepatic circulation of vitamin D), and low in calcium and phosphate.

Cereals are the primary source of dietary zinc in vegetarian diets. The bioavailability of zinc is affected by the presence of phytates, fiber, calcium, or other zinc absorption inhibitors, which results in poor absorption of zinc in vegetarian diets.<sup>90</sup> Vitamins B<sub>6</sub> and B<sub>12</sub>, vitamin A, and calcium, because of a high content of oxalic acid, are poorly absorbed.

Selenium is dependent on the selenium content of the soil, as is zinc. Increased dietary sources or supplementation are required in vegetarians.

General recommendations for lactating vegetarian women are as follows:

1. Supplement with soy flour, molasses, and nuts.
2. Use complementary protein combinations.
3. Avoid excessive phytates and bran.
4. Watch protein and iron intake. Calcium should be supplemented if bone mineralization decreases because the milk levels will be adequate.
5. Supplement with 10 µg vitamin D plus adequate sunshine.
6. Know that vitamins B<sub>12</sub> and B<sub>2</sub> (riboflavin) are low in vegetarian diets and should be supplemented.

If the mother does not supplement herself, the infant must be supplemented.

## SUPPLEMENTATION OF BREASTFED INFANTS' DIETS

For newborn infants, human milk is the ideal food, containing all the necessary nutrients. In establishing dietary norms for infants fed cow milk, many nutrients identified as being needed in the diet were found to exist in greater amounts in cow milk than in human milk. This does not consider the probability that the nutrient may be in a more bioavailable form in human milk. The specific items in question are protein, sodium, iron, vitamin D, and fluorine.

When a breastfed infant must be supplemented with formula, however, it is preferable that a formula low in iron be used to avoid providing excessive iron that will bind with lactoferrin and interfere with its infection protective activity.

The AAP Committee on Nutrition<sup>18</sup> has noted that iron deficiency is rare in breastfed infants and attributes this to increased absorption and the absence of microscopic blood loss into the gastrointestinal tract, which is seen in bottle-fed infants. The Section on Breastfeeding of the AAP recommends a source of iron in solid foods (fortified infant cereal) at 6 months of age for breastfed infants.<sup>4</sup>

The AAP no longer recommends fluoride supplements in all breastfed infants. Many breastfed infants have done without fluorine supplementation and have had no adverse dental problems, but the decision should be based on individual determinants, including family dental history and level of fluoride in the water supply, which is ideally between 0.7 and 1.0 ppm. If the level is less than 0.3 ppm, 0.25 mg of daily fluoride should be given. Maternal supplementation may be the better choice in this case.

The AAP now recommends 400 IU vitamin D daily for all breastfed infants starting at birth unless they are also receiving 500 mL fortified formula daily.<sup>18</sup> Maternal supplementation is a preferred alternative. The Section on Breastfeeding of the AAP, however, tailors the recommendation to the dyad, using supplements of vitamin D to the infant as a last resort.

## EXERCISE WHILE BREASTFEEDING

There are usually no contraindications to exercise in moderation during lactation. The most common obstacle is having sufficient time. The availability of home exercise equipment does offer an option for home programs. Exercise baby carriages, which have large wheels for greater speed and rough terrain, are another option. Because they tip somewhat easily, infants may need a helmet and a safety strap. A safety strap that attaches to the runner's wrist prevents the vehicle from getting away. These carriages are excellent for brisk walks as well.

The impact of programmed exercise on milk volume, milk composition, and ultimately milk acceptability has been studied.<sup>26</sup> Women who exercise excessively, especially those who jog, may have trouble maintaining their milk supply. This difficulty has been attributed to any activity that results in persistent motion of the breasts and excessive friction of clothing against the nipples. A firm athletic brassiere made of cotton will reduce this effect. No data are available on the impact of jogging with or without support on later breast sagging.

The production of lactic acid during exercise has been studied in relation to lactation by Wallace et al., who had mothers report whether their infants refused to nurse or fussed when breastfed after exercise. The study demonstrated that seven healthy lactating women who normally spent more than 30 minutes in aerobic activity (jogging, running, swimming, biking, and aerobics), as well as some who did calisthenics and racket sports, had an increase in their blood lactic acid levels after exercise. When a standardized treadmill exercise was used to maximal voluntary effort, blood lactic acid level increased at 10 minutes compared with that of the at rest sample, but the level at 30 minutes had returned almost to the at rest level. Milk samples at 10 and 30 minutes continued to have elevated lactic acid, although wide variation was seen among subjects.

In a larger sample, when 26 women between 2 and 6 months postpartum who normally exercised during pregnancy and postpartum were exercised on a standardized treadmill to maximal voluntary effort, the levels of lactic acid were correlated to infant acceptance of the milk. The breasts were wiped with a dry towel before milk collection. Milk

samples collected before exercise and at 10 and 30 minutes after exercise revealed an increase in lactic acid levels over baseline at both 10 and 30 minutes. In a double-blind order of samples, the infants were offered milk by dropper and were less likely to accept samples with high lactic acid. The authors noted that the levels of lactic acid were high enough for adults to detect when offered water solutions at the same concentrations (1.6 mmol). Human milk is sweet, but lactic acid is known to be bitter/sour. Infants have been noted to make a puckering facial expression to a sour taste as early as a few hours of age.<sup>110</sup> Studies of sucking in newborns have shown more rapid rates with sweet than sour, with some change in heart rate, respiratory rate, and sucking patterns.<sup>61</sup> The lactic acid level can remain elevated in the milk for as long as 90 minutes, according to Wallace and Rabin.

When exercise studies were undertaken by Wallace et al.,<sup>121,122</sup> comparing the effects of a typical workout and a standard maximal exercise regimen, significant differences were noted. The milk lactate level before exercise was  $0.61 \pm 0.14$  mM and after typical exercise was  $1.06 \pm 33$  mM. After maximal exercise in the same women, the level was  $2.88 \pm 0.80$  mM. Seventeen percent of the subjects had lactate levels above the reported adult taste threshold of 1.5 mM. Milk rejection probably is a function of lactate concentration in the milk and infants' sensitivity to taste. Women who exercised with full breasts developed a peak postexercise lactate concentration at 10 minutes, whereas women who exercised with empty breasts did not peak for 30 minutes.<sup>121</sup> Many of the studies reported may have not measured peak lactate when samples were collected only at 10 minutes.

Mothers have reported that their infants may reject their milk after exercising. Women reported to the Lactation Study Center that their infants were fussy and colicky for as long as 4 to 6 hours after the mother's strenuous exercise. Exercise generates sweat high in sodium and chloride, and lactic acid may change the pH. Although these studies are being expanded, the following precautions might be recommended when breastfeeding after strenuous exercise:

- Shower, or at least wash the breast of perspiration.
- Manually express 3 to 5 mL of milk from each breast and discard.
- If infant displays puckering facial expression, postpone feeding or replace feeding with previously pumped milk.

Levels of prolactin and adrenal activation have been studied in eumenorrheic and amenorrheic women who exercise regularly. Prolactin levels

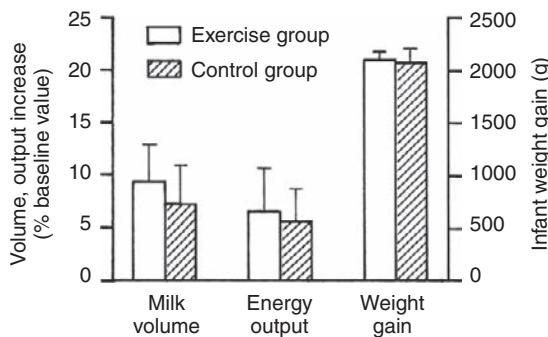

after exercise are elevated for 20 to 40 minutes.<sup>27</sup> The effect appears to be unrelated to anaerobiosis. The hypothalamic-pituitary-adrenal axis is known to be activated under the influence of various forms of stress, including exercise. How this activation might affect milk production or oxytocin-stimulated milk let-down after exercise has yet to be determined.

Serum prolactin and growth hormone increased severalfold during prolonged acute exercise in normal women and runners with and without menses, demonstrating that a threshold of exercise intensity must be reached for this reaction to occur.<sup>17</sup> There was no correlation to menstrual dysfunction.

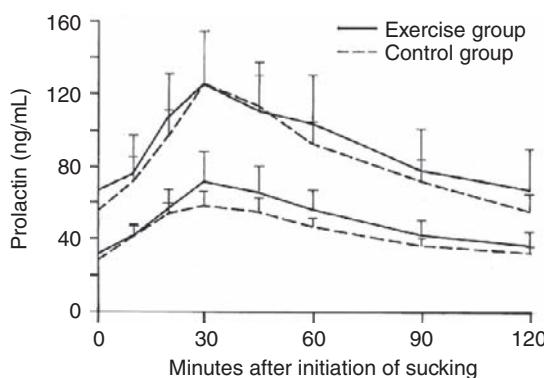

When the lactation performances of eight physically fit, exercising women were compared with those of sedentary control subjects, no significant differences in milk volume or composition were observed despite wide variations in energy intake and expenditure.<sup>73</sup> Exercising women compensated by increasing energy intake; thus no net difference was seen between the groups. It has been reported that lactating women exercising on a regular basis expend an average of 2630 kcal/day exclusive of milk energy output, compared with the 1800 to 1900 kcal/day expenditures of women who did not exercise.<sup>112</sup>

Dewey et al.<sup>30</sup> studied the impact of regular exercise on the volume and composition of breast milk and further confirmed that breastfeeding women can safely exercise. Although previous studies were done on exercising fit women, this study randomly assigned sedentary women to exercise with supervised aerobic exercise to 60% to 70% of the heart rate reserve for 45 minutes per day, 5 days a week for 12 weeks. The control group remained breastfeeding but sedentary. Measurements of energy expended, dietary intake, body composition, and milk volume and composition were collected at 6 to 8 weeks, 12 to 14 weeks, and 18 to 20 weeks postpartum. Maximum oxygen uptake and plasma prolactin response in 2 hours after nursing were measured at the first and last assessment times. No significant differences were seen in maternal weight and fat losses, volume or composition of milk, infant weight gain, or plasma prolactin response between exercising and sedentary women. No women reported difficulty nursing after moderate exercise. The authors<sup>31</sup> did note that the 300 kcal/day mean extra energy expenditure of the exercise group at midpoint in the study decreased toward the end as they cut back on other activities to compensate. This suggests that high levels of energy expenditure<sup>30</sup> may be difficult to sustain while lactating because of fatigue and time limitations (Figures 9-4 and 9-5).

Lovelady et al.<sup>73,74</sup> further evaluated this same study group, randomly assigned to exercise or to remain sedentary. Exercise marginally increased

**Figure 9-4.** Percent increase in breast-milk volume and energy output and absolute increase in infants' weight in exercise and control groups during a 12-week study. Values shown are means  $\pm$  SE. To convert kilocalories to megajoules, multiply by 0.004186. None of the differences between the groups was significant. The 95% confidence intervals were as follows: for the percent change in milk volume, 2% to 17% for the exercise group and -1% to 16% for the control group ( $p=0.66$ ); for the percent change in energy output in breast milk, -2% to 15% for the exercise group and -1% to 12% for the control group ( $p=0.85$ ); and for infant weight gain, 1871 to 2279 g for the exercise group and 1733 to 2355 g for the control group ( $p=0.86$ ). (Modified from Dewey KG, Lovelady CA, Nommsen-Rivers LA, et al: A randomized study of the effects of aerobic exercise by lactating women on breast-milk volume and composition, *N Engl J Med* 330:449, 1994.)

**Figure 9-5.** Plasma prolactin response to nursing in control and exercise groups at beginning and end of study. Values shown are mean  $\pm$  SE. Study began 6 to 8 weeks postpartum and ended 18 to 20 weeks postpartum. Change in the area under the curve from beginning to end of the study was not significantly different between the two groups ( $p=0.38$ ). (Modified from Dewey KG, Lovelady CA, Nommsen-Rivers LA, et al: A randomized study of the effects of aerobic exercise by lactating women on breast-milk volume and composition, *N Engl J Med* 330:449, 1994.)

high-density lipoprotein cholesterol levels but did not affect other lipid concentrations. Further, at rest metabolic rate did not change overtime. Weight and body fat percentage declined similarly in both groups. No difference was found between exercising and sedentary groups regarding insulin, glucose, or thermal response. The authors concluded that

sedentary women can initiate moderate exercise programs during lactation but that exercise does not increase weight loss or fat loss without dietary control, that is, by avoiding compensatory increased intake. In a similar randomized study of 33 women, Potter et al.<sup>95</sup> and Prentice<sup>97</sup> reported that moderate exercise sufficient to improve cardiovascular fitness without marked changes in energy expenditure, dietary intake, and body weight and composition does not jeopardize lactation performance.

Maternal exercise did not alter the mineral content of the milk in a randomized crossover trial measuring phosphorus, calcium, magnesium, sodium, and potassium. Samples were drawn before and during rest periods after 10, 30, and 60 minutes of maximal graded exercise. Thus, with the exception of a temporary rise in milk lactate after prolonged heavy exercise, exercise has no apparent impact on milk composition.<sup>71</sup>

## DIETING WHILE BREASTFEEDING

The Subcommittee on Nutrition During Lactation<sup>112</sup> stated in its report that the average rate of weight loss postpartum while maintaining adequate milk volume is 0.5 to 1.0 kg (1 to 2 lb) per month. In individuals who are significantly overweight, a weight loss of up to 1 to 2 kg (about 4 to 5 lb) per month should not affect milk volume, although weight gain and feeding pattern in the infant should be monitored. The subcommittee<sup>112</sup> considers rapid weight loss, that is, more than 2 kg per month after the first month, ill-advised. In addition, because no data exist about curtailing maternal energy intake during the first 2 to 3 weeks postpartum, dieting immediately postpartum is not recommended and could be associated with poor milk supply. Energy intake must be balanced with the level of physical activity. The subcommittee does not recommend intakes less than 1500 kcal/day; however, brief fasts, perhaps for religious reasons, of less than a day are unlikely to affect milk supply. Liquid diets or weight-loss medications are not recommended. In studies of food-deprived rats, a clear correlation exists between adequate milk production and adequate food intake. This finding was amplified if diet was also restricted during pregnancy.

Studies of weight loss during lactation are scarce. Many women in developed countries experience an appetite surge with lactation and may experience no weight loss in the first months beyond the weight lost in the first weeks. They may not return to prepregnancy weight for 6 months. Women who are prone to gaining weight may be more apt to gain on an unregulated diet. Maternal nutrition status in the United States, as measured by anthropometric indices prenatally

and postpartum, is unrelated to milk volume, according to the studies of Butte et al.<sup>13</sup> and Dewey.<sup>26</sup> Total energy expenditure of sedentary women, including those housebound with a new baby, averages 1800 kcal/day, exclusive of the energy put into the milk produced.<sup>76</sup>

No consistent relationship was reported in a study of 411 postpartum women between mode (i.e., breast or bottle) of feeding and postpartum weight loss.<sup>95</sup> Despite the energy deficiency of breastfeeding women, the trend was to greater weight loss in nonlactators. Women who gained more during pregnancy lost more postpartum regardless of their pregnancy weight. No dietary intake was recorded because the data were collected retrospectively.

The Stockholm Pregnancy and Weight Development Study prospectively investigated trends in eating patterns, physical activity, and sociodemographic factors in relation to postpartum body weight development, following 1423 pregnant women.<sup>88</sup> Weight retention 1 year postpartum was greater in women who increased their energy intake during and after pregnancy. Weight retention also increased in those who not only increased their snacking to three or more times per day but also decreased their lunch frequency. Sedentary lifestyle was correlated with 5 kg or more weight gain over prepregnancy weight. The authors summarized their findings as being related most closely to a change in lifestyle after pregnancy.<sup>88</sup>

The tremendous variability in women's responses to the stress of reproduction and lactation suggests that there is very low stress per unit time. Thus, many different variables exist during the perinatal period to rebalance the energy equation, according to Prentice and Prentice.<sup>99</sup> Some women are energy sparing and some energy profligate. Although generally beneficial, the interaction between exercise and skeletal integrity is influenced by hormonal status and many exercise variables.

During lactation, many women do not need additional dietary supplements as often recommended according to work by Hartmann et al. They reported considerable variation among individual women for the energy output in milk and the energy actually mobilized from maternal stores for milk synthesis, and they recommend that energy should be calculated for each mother depending on her energy stores and milk demands. Even a low-fat diet could be appropriate to maximize the de novo synthesis of fatty acids for milk triacylglycerols, if one were sure there was AI of long-chain PUFAs and basic nutrients. Further, they demonstrated that perceived inability to make milk was usually a function of inappropriate suckling, scheduled feeds, and other

**TABLE 9-14** Dietary Reference Intakes: Additional Macronutrient Recommendations

Macronutrient	Recommendation
Dietary cholesterol	As low as possible while consuming a nutritionally adequate diet
Trans fatty acids	As low as possible while consuming a nutritionally adequate diet
Saturated fatty acids	As low as possible while consuming a nutritionally adequate diet
Added sugars	Limit to no more than 25% of total energy

From Dietary Reference Intakes for Energy, Carbohydrate, Fiber, Fat, Fatty Acids, Cholesterol, Protein, and Amino Acids, Washington, D.C., 2002, Food and Nutrition Board, Institute of Medicine, National Academies.

lactation management issues, not lack of substrate (Table 9-14).

Weight loss during lactation is greatest between 3 and 6 months. Dietary advice for women who choose to diet while lactating should include the following<sup>112</sup>:

- Diet must include balanced, varied foods rich in calcium, zinc, magnesium, vitamin B<sub>6</sub>, and folate.
- Minimum energy intake should be 1800 kcal.
- Calcium and multivitamin-mineral supplements may be necessary to replace stores if diet is marginal.

## Foods to Avoid

The concern about foods causing gas in breastfed babies has no scientific basis. The normal intestinal flora produce gas from the action on fiber in the intestinal tract. Neither the fiber nor the gas is absorbed from the intestinal tract, and they do not enter the milk, even though they may cause the mother some discomfort. The acid content of the maternal diet also does not affect the milk because it does not change the pH of the maternal plasma. Essential oils are present in foods such as garlic and some spices that have characteristic odors and flavors. These oils may pass into the milk, and occasionally an infant objects to their presence.

Twenty-four-hour colic studies by Mennella and Beauchamp<sup>78,80</sup> show that the diet of the lactating woman alters the sensory qualities of her milk. They found that garlic ingestion significantly and consistently increased the intensity of the milk odor as perceived by blinded adult panelists. The odor was not apparent at 1 hour, peaked at 2 hours, and decreased thereafter. Similar observations have been made in other species. Garlic is one of the most potent of the volatile sulfur-containing foods

(onions, broccoli, etc.). Garlic consumption by the mother increased the length of time spent suckling and the rate of suckling of the next feeding.<sup>80</sup> This behavior is usually associated with a tendency of the breast to make more milk. The authors suggest that the mouth movements made during sucking facilitated the retronasal perception of the garlic volatile oils in the milk. This study reports only the first 4 hours postingestion and makes no reference to the period between 4 and 24 hours after ingestion, a time occasionally associated with colic in breastfed infants after ingestion of certain foods by the mothers (often called 24-hour colic).

When these mothers and infants were tested over an 11-day period, those infants who had garlic previously showed no response to reexposure; that is, suckling pattern and volume ingested were unchanged.<sup>79</sup> Garlic odor of amniotic fluid has been noted when the mother consumed garlic before delivery or amniocentesis. These investigators also report that alcohol, mint, and cheese flavors are transmitted to milk. When mothers were fed carrot juice while lactating, the infant subsequently preferred cereal mixed with carrot juice rather than with plain formula or milk.<sup>78</sup>

Animal studies show that odors in utero and early in life are associated with a preference for them after birth. Breastfed infants experience a wide variety of odors and flavors during maternal lactation, which may enhance their weaning to solid foods. This suggests that infants fed standard formulas experience a constant set of flavors, thus missing significant sensory experiences. In experiments with rats, Mennella and Beauchamp<sup>80</sup> found a mother's milk contains gustatory cues reflecting the flavor of the mother's diet and that these cues are sufficient to influence dietary preferences at weaning.

Extensive clinical experience suggests, however, that some infants do not tolerate certain foods in the mother's diet, particularly specific vegetables and fruits. Garlic and onions may cause 24-hour colic in some infants. Cabbage, turnips, broccoli, or beans may bother others, making them colicky for 24 hours. The same has been said of rhubarb, apricots, and prunes. If a mother questions the effect of a food, she should avoid it or document its effect carefully by watching for colic in the 24 hours after ingestion. In the summer, a heavy diet of melon, peaches, and other fresh fruits may cause colic and diarrhea in the infant. Chocolate rarely lives up to its reputation and can be consumed in moderation without causing colic, diarrhea, or constipation in most infants.

Red pepper, which contains capsaicin and related compounds, has been reported to cause dermatitis in breastfed infants within an hour of milk

ingestion.<sup>20</sup> The rash can last 12 to 48 hours and differs from the contact dermatitis known to occur from capsaicin applied directly. When hot peppers are prepared with bare hands, an intensely painful reaction can occur. In countries where red pepper dishes such as kimchi are common (Korea), a perianal rash has long been seen in breastfed infants whose mothers ingested these hot dishes.

## FOOD ADDITIVES

Artificial sweeteners are the most common food additives. Saccharin and cyclamate are not known to be teratogenic, but the remote relationship to cancer in rats has led to the recommendation that they be used in moderation. The same pertains during lactation. Cyclamate is a cyclohexylamine, an indirectly acting sympathomimetic amine that has been banned from use.

Aspartame is a dipeptide sweetener, aspartyl-L-phenylalanine methyl ester, that metabolizes to phenylalanine and aspartic acid. Thus, it poses a risk to those with phenylketonuria. Normal individuals can consume 50 mg/kg/day without adverse effects. In large doses of 75 mg/kg/day, individuals increase their excretion of formate and methanol. When given aspartame, lactating women were noted to have phenylalanine levels four times the normal in their plasma.<sup>108</sup> Milk levels of phenylalanine and tyrosine were only slightly elevated. Aspartame in moderation during lactation is presumed safe unless the infant has phenylketonuria.

## Color of Milk and Maternal Diet

The color of mature human milk is bluish white (foremilk), initially changing to creamy white (hindmilk). The color of colostrum is yellow to yellow-orange. Mothers occasionally report changes in the color of their milk. Most of these changes can be traced to pigments consumed in the diet, medications, or herbal remedies. The infant's urine may also turn color.

## PINK OR PINK-ORANGE MILK

Pink-orange milk was traced to Sunkist orange soda, which contains red and yellow dyes. A case of a breastfed infant with pink to orange urine was reported by Roseman.<sup>104</sup> This combination of food dyes is also used in other brands of soda, fruit drinks, and gelatin desserts. Even fresh beets can change the urine of both mother and infant to a red-pink hue.

## GREEN MILK

Several cases of green milk have been reported to our study center. A careful search of the diet for the offending substance was made in each case. The effect of ingestion of the identified culprit and its avoidance were then tested to confirm the association with the milk's color. Several items have been clearly identified. Gatorade (the green beverage), kelp and other forms of seaweed (especially in tablet form), and natural vitamins from health food sources have been associated with one or more cases of green milk and usually green urine.

## BLACK MILK

Minocycline hydrochloride therapy was associated with black milk galactorrhea in a 24-year-old woman who received the compound for pustulocystic acne for 4 years.<sup>9</sup> Examination of the fluid revealed that the macrophages contained hemosiderin, thus causing the black color. This drug is known to cause black pigmentation of the skin. A second case was reported in a 29-year-old woman who had weaned but could express black milk 3 weeks after beginning oral minocycline therapy. Hunt et al.<sup>56</sup> found iron-staining pigment particles in the macrophages and suggested it was an iron chelate of minocycline.

## SUMMARY

Supplements recommended during lactation for mothers are unnecessary unless the mother's diet is deficient. Finishing the prenatal vitamin supply postpartum is more than adequate. Having adequate vitamin D stores during pregnancy and lactation is important. Continued studies are being conducted to determine the efficacy of large doses of vitamin D for mothers so that supplementing infants can be avoided.

Supplements for breastfeeding infants are ordinarily unnecessary in exclusively breastfed infants unless a deficiency is identified. The AAP does recommend vitamin D 400 mg beginning at birth. Iron needs should be addressed with appropriate solid foods after 6 months of exclusive breastfeeding. Fluoride supplementation is unnecessary if the mother is adequately resourced; if not, the mother should take fluoride.

## CHAPTER 10

# Weaning

### Timing and Techniques

What does *weaning* mean? Textbooks on pediatrics and mothers' manuals imply that it is the process by which one changes from one method of feeding to another. Raphael<sup>47</sup> states that the first introduction of solid foods is the true beginning of weaning. The term *weaning* is derived from the Anglo-Saxon *wenian*, which means "to become accustomed to something different." It does not mean the total cessation of breastfeeding but the addition of other things. If one consults the dictionary, however, one learns that to *wean* is to transfer the young of any animal from dependence on its mother's milk to another form of nourishment or to estrange from former habits or associations. A *weanling* is a child or animal who is newly weaned. If one likens breastfeeding to the continuation of intrauterine life, weaning is a "second birth."

Weaning from a physiologic point of view is a complex process involving nutritional, microbiologic, immunologic, biochemical, and psychologic adjustments. Boys tend to be weaned earlier than girls, possibly because the energy intakes of boys at all ages are greater and male growth rate is more rapid. Psychosocial pressures also trend toward the earlier weaning of male infants.<sup>12</sup>

### Infant's Need

When discussing the process of weaning a human infant, one might say it is the transfer of the infant from dependence on mother's milk to other sources of nourishment. If one were to determine the appropriate time for this to take place, it would be based on nutritional needs and developmental goals. Observations among other mammals suggest

that achievement of a degree of maturity that allows a pup to forage for food is a trigger for initiating weaning by the mother.

The search for the appropriate weaning time for human infants has produced a number of extremes, from the regimen of J.R. Sackett in 1953 of introducing solids on the second day of life to withholding all solid foods until the infant had sufficient teeth to chew thoroughly, a method described by Bartholomaeus Mettinger, a German physician, in 1473.<sup>10</sup> The birth of the infant food industry began with German chemist Justis von Leitbig in 1867. He marketed "the perfect infant food" to the public at the turn of the twentieth century, a mixture of wheat flour, malt flour, and cow milk. Jacobi, the father of modern pediatrics, advised no solids for a year and no vegetables before 2 years of age. Thus the winds of weaning varied by culture, ethnic group, medical intervention, and financial resources.

Acknowledging that humans are primates, Dettwyler<sup>12</sup> recognized that lactation and weaning occur according to certain regular patterns in non-human primates. She searched for a natural age of weaning for human infants uninfluenced by culture and trends. Evaluating various "rules of thumb" for determining weaning age by biologic references, she found them inappropriate. Breastfeeding from an anthropologic point of view is both a biologic process and a culturalized activity. In primitive cultures, the age of weaning from the breast was between 2 and 5 years, averaging 3 to 4 years.

If the definition of weaning is used to mean the cessation of all feedings at the breast, the age at weaning in nonhuman primates and other mammals is a function of genetics and instinct. Primates have a longer gestation, greater infant dependency, longer life spans, and larger brains per unit of body size than other mammals. Dettwyler<sup>12</sup> suggests that a

possible formula for weaning is the ratio of present weight to birth weight as 4 to 1; that is, the offspring weans when four times the birth weight is achieved, usually between 2 and 3 years for well-fed healthy human infants.

If weaning according to attainment of one third the adult weight is used as the rule of thumb, Dettwyler<sup>12</sup> notes the variations in size of human adults by ethnic and cultural groups. The average weight of an adult woman is 54 kg (119 lb); one third is 18 kg (39½ lb), a weight achieved between 4 and 7 years for girls. The average weight of an adult man is 59 kg (130 lb); one third is 19.3 kg (42½ lb). This would mean boys would be nursed longer. The present tendency for obesity in the developed world would accentuate these calculations. The average female weight in the United States is 55 kg (121 lb). The following is an equation for calculation of weaning age:

$$\text{Weaning age (days)} = 2.71 \times \text{adult female weight (kg)}$$

Thus, a modern infant whose mother weighed 55 kg would be weaned at 1228 days, or 3.36 years. Calculating for small, medium, and large women, this period would range from 2.8 to 3.7 years.

When length of gestation is used as the determinant for weaning time, the weaning/gestation ratio can be determined. The ratio across primate species varies from 0.41 in the *Galago demidovii*, a small-bodied primate, to 6.40 in the *Pan troglodytes* (chimpanzee). The former primates nurse less than half the length of pregnancy (11 of 45 days); chimpanzees nurse 1460 days (228-day gestation). Gorillas nurse for 1583 days (256-day gestation). Because the human is closest to the chimpanzee and gorilla, six times the gestation period might be a more physiologic norm: 54 months, or 4½ years.

When the eruption of the first permanent molar is used as the indicator for complete weaning, it estimates weaning at 5½ to 6 years in humans.<sup>12</sup> Tooth eruption is genetically controlled and comparatively unaffected by diet or disease. Six years is also identified as the time of achieving adult level of immunocompetence in humans.

The range of calculated ages for weaning derived from these formulations ranges from 2.3 years to 6 or 7 years. Before the widespread availability of foods suitable for infants and of artificial formulas, infants were traditionally breastfed for 3 to 4 years (Figure 10-1).

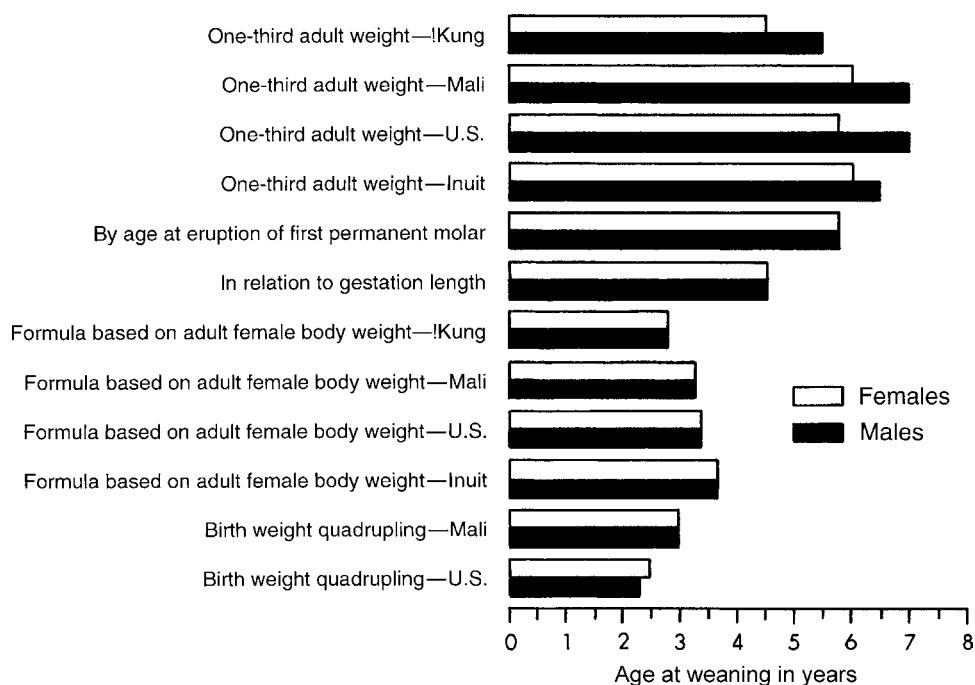

Other species gradually introduce other foods and teach their offspring how to obtain them on their own. Usually the mothers in most species make the determination for final termination and no longer permit the young to nurse. There seems to be a close correlation between age of weaning

and age of reproductive maturity measured either as first ovulation (menarche) or average age of first breeding. Dettwyler<sup>13</sup> notes that these markers are also related to body size, with larger-bodied species breastfeeding longer. Gorillas, she notes, breastfeed 4 to 5 years, chimpanzees breastfeed for 4.5 to 7 years, with average age of breeding being at 10 years of age and 11 to 12 years, respectively. When a similar calculation is made for humans, assuming breeding at 16 years of age, duration of breastfeeding would be 3 years. Studies on the milkborne factors that might cue the initiation of weaning in other species have not shown any cause and effect. The rat undergoes a "weaning crisis" during which the anatomy of the gut changes; some enzymes appear and others disappear. Chapter 3 discusses the enzymatic adaptations of human infants.

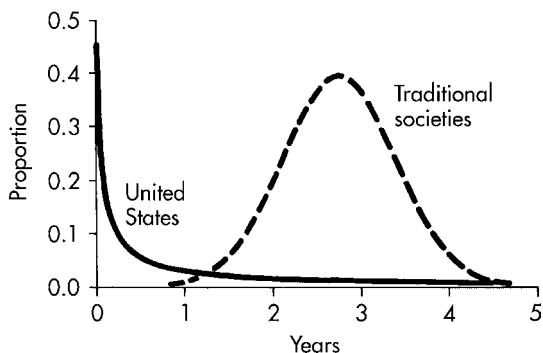

Among humans, many cultural influences mandate weaning time and process. Public and social pressures have influenced weaning for some families in industrialized society. Few traditional societies wean before 1 year of age, and some do not begin until 2 years of age (Figure 10-2). In ancient Hebrew tradition (c. 536 BC), breastfeeding duration according to the Talmud was at least 3 years. Aristotle had suggested that women should breastfeed while no menstruation was occurring, failing to recognize that one influences the other (lactation suppresses menstruation). The Romans recommended breastfeeding at least to the age of 3 years. In the Muslim world, especially Africa and the Sudan, however, weaning of children is by the Islamic teaching of the Koran, which advises breastfeeding until at least 2 years of age, with many breastfeeding to age 4 or 5. Before 1979 the average time of complete cessation worldwide was 4.2 years. Hervada and Newman<sup>25</sup> provide a historic review of weaning that also presents recent concerns about iron deficiency and other problems more common to formula-fed infants.

Breastfeeding benefits for an older infant have also been evaluated. In the developing world, breastfeeding continues for at least 1 to 2 years after introduction of solid foods. Major benefits include not only the nutrients but also protective, digestive, and trophic agents that extend the period of infertility in the mother and reduce the incidence and severity of infectious diseases for the infant. A review of middle-class breastfed infants between the ages of 16 and 30 months in the United States revealed a decrease in the number of infections and improved overall health compared with those children no longer breastfed.

Nutritionally, it is appropriate to begin iron-containing foods at 6 months, the time the stores from birth are diminishing. The requirement at this age exceeds that supplied by human milk. An

**Figure 10-1.** Natural age at weaning according to technique used. (Modified from Dettwyler KA: *A time to wean*. In Stuart-MacAdam P, Dettwyler KA, editors: *Breastfeeding: biocultural perspectives*, New York, 1995, Aldine de Gruyter.)

**Figure 10-2.** Comparison of age at weaning in United States and 64 traditional societies. (Modified from Dettwyler KA: *A time to wean*. In Stuart-MacAdam P, Dettwyler KA, editors: *Breastfeeding: biocultural perspectives*, New York, 1995, Aldine de Gruyter.)

additional source of protein becomes necessary toward the end of the first year of life because the grams of protein needed per kilogram of body weight can no longer be supplied by milk alone as the infant grows heavier. The content of protein in the milk begins to drop slightly after 9 months of lactation. A human infant also needs bulk, or roughage, in the diet. The exact time this need becomes apparent is not known, but it may well be by the end of the first year (**Table 10-1**).

Developmentally, an infant is ready to learn to chew solids instead of suckle liquids at about 6 months. It has been suggested that there is a

"critical period of development" during which infants can and must learn to chew. Chewing is an entirely different motion of the tongue and mouth from sucking. The sucking fat pads in the cheeks begin to disappear at the end of the first year. The rooting reflex has been lost. Even though all the teeth are not in, the development of good dentition requires chewing exercise.

### Role of Development in Initiation of Weaning

Although the developmental milestones of infant behavior are noted to influence the introduction of weaning foods, the development of the gastrointestinal tract plays an equal role. Even the taste buds, which can be identified at the seventh week of fetal life as collections of elongated cells on the dorsal surface of the tongue, are fully innervated over the next weeks. The fetus is known to suck and swallow in utero; sucking is discussed in **Chapters 3 and 8**.

When taste becomes a factor in feeding is not known, although a lack of discrimination has been noted in the first weeks of life: infants have consumed formula with high salt or absence of chloride with morbid results. As more women are pumping and storing their milk, a notable number of women have their infants reject the stored milk, which is

<b>TABLE 10-1</b> Recommendations on Duration of Breastfeeding		
WHO	Exclusive for 6 months	Continue 2 years and beyond
AAP	Exclusive for 6 months	Continue 1 year and as long as mother/infant wish
AAFP	About 6 months exclusive	Continue 1 year/mutually desired
ACOG	About 6 months exclusive	As long as possible
Healthy People 2010	75% at birth	25% at 6 months
Healthy People 2020	Exclusive for 6 months	Continue for 1 year

Modified from Dettwyler KA: A time to wean: the hominid blueprint for the natural age of weaning in modern human populations. In Stuart-MacAdam P, Dettwyler KA, editors: *Breastfeeding: biocultural perspectives*, New York, 1995, Aldine de Gruyter.

noted to smell sour. The cause remains unknown. See discussion of lipase and sour milk. Because of the variation in the composition of mother's milk over a feeding, over a day, and from time to time according to maternal dietary intake, a breastfed infant has a richer range of experience in tasting than a formula-fed infant. Breastfed infants are, therefore, more accustomed to new taste experiences. Similarly, feeding problems in infants are rare in breastfed infants.

Both sucking and chewing are complex movements, having reflexive as well as learned components. The development of the chew-swallow reflex is necessary for the successful introduction of solids. This skill develops sequentially with neuronal development and then is a learned behavior conditioned by oral stimulation. Before this point, when a spoon is introduced, the infant purses the lips and pushes the tongue against the spoon. By 4 to 6 months, the tongue is depressed in response to the spoon and the food accepted, and by 7 to 9 months, rhythmic biting movements occur regardless of the presence of teeth. Biting and masticatory strength and efficiency progress throughout infancy. If a stimulus is not applied when the neural development is taking place, the chewing reflex will not develop and the infant will always be a poor chewer. There is a relationship between prolonged sucking without solids and poor eating. The clinical model for this is a child sustained on

parenteral feedings or gastrostomy beyond a year who has tremendous difficulty accepting solids.

For a human infant, nursing also plays a role as a comfort and emotional support, a mechanism often referred to as "comfort nursing." Inadequate nipple contact may lead to thumb sucking or the substitute use of a pacifier. Young monkeys and apes in the wild do not suck their thumbs, but they do in captivity when bottle fed. Infants of the !Kung tribes in Africa do not suck their thumbs.<sup>12</sup> They are carried by the mother and breastfed in frequent short bursts.

In summary, an infant is ready to explore new feeding experiences at approximately 6 months. Feeding is an important social as well as nutritional encounter. Eating solids and learning to drink from a cup are important social achievements as well. This readiness does not mean the infant is taken from the breast, but that the diet is expanded and now includes solid foods, other liquids, and breast milk. Although a range of qualitative, quantitative, and temporal practices are known, the optimal approach matches the needs and requirements of a given child with the functions and capacities of the body.

## Introduction of Solids

The World Health Organization (WHO), the Canadian Pediatric Society, the Paediatric Society of New Zealand, and similar groups in England and Scotland<sup>55</sup> emphasize that weaning is not the termination of breastfeeding but the addition of solids while continuing breastfeeding. The key recommendation on length of exclusive breastfeeding reads as follows:

...to strengthen activities and develop new approaches to protect, promote and support exclusive breastfeeding for six months as a global public health recommendation, taking into account the findings of the WHO expert consultation on optimal duration of exclusive breastfeeding, and to provide safe and appropriate complementary foods, with continued breastfeeding for up to two years of age or beyond, emphasizing channels of social dissemination of these concepts in order to lead communities to adhere to these practices.

The intake of supplementary foods may add nutrients in a less bioavailable form, and it decreases the bioavailability of nutrients in human milk and the intake of other important factors in human milk. Investigators have shown that when solid foods are introduced in the diet of breastfed infants, energy intake per kilogram of body weight does not increase.<sup>43</sup> Solid foods displaced energy intake from

human milk in 6-month-old infants even though they were breastfed on demand.<sup>35</sup>

In information collected by Dewey et al.<sup>14</sup> in 1994 on well-nourished breastfed infants, no "faltering" in growth pattern could be identified. In a review of protein and energy during weaning, Axelson and Räihä<sup>3</sup> conclude that 1.65 g/kg/day from 5 to 9 months and 1.48 g/kg/day from 9 to 12 months are appropriate. The growth of exclusively breastfed infants from 4 to 6 months of age matched or exceeded that of randomly selected breastfed infants given 20% added protein. The exclusively breastfed group received 0.98 g/kg/day, whereas the supplemented group received 1.18 g/kg/day. Thus, protein intake is not a limiting factor with respect to growth that would mandate weaning from the breast. On review of protein requirements for infants and children established by WHO, they were higher than necessary for breastfed infants. Formula-fed infants require more protein because of comparatively poor utilization.<sup>9</sup>

Recommendations for the optimal time to introduce complementary foods to the breastfed infant remain controversial. The Section on Breastfeeding of the American Academy of Pediatrics (AAP) supports the introduction of solids at 6 months in concert with the WHO and UNICEF.<sup>49</sup> This choice was in response to a systematic review of published reports in developed and underdeveloped countries conducted by Kramer and Kakuma<sup>33</sup> that included controlled clinical trials and observational studies in many languages. From 2668 reports, only 36 citations met criteria of an internal comparison group. Rigorous assessment of health outcomes included growth, iron and zinc status, infectious morbidity, atopic disease, neuromotor development, rate of maternal weight loss, and duration of lactational amenorrhea.<sup>35</sup>

This discussion of the weanling's dilemma (i.e., the choice between the known protective effects of exclusive breastfeeding against infectious morbidity and the theoretical insufficiency of breast milk alone as nutrition) was confirmed again by a Cochrane Review in 2009; 6 months of exclusive breastfeeding is optimal.<sup>54</sup>

In summary, exclusive breastfeeding for 6 months supported appropriate gain in weight and length and adequate iron and zinc status when mother is well nourished, reduced infection rates, provided some reduction in atopy, and had a significant advantage in achieving some developmental milestones. The important conclusion reached by WHO-UNICEF is the recommendation of exclusive breastfeeding for 6 months. In a report published in *Pediatrics* in 2010, the Section on Breastfeeding of the AAP recommends 6 months.<sup>49</sup>

The challenge of meeting nutrient needs of infants and young children when complementary

foods are added is great. It is a period of high nutrient density requirement, especially iron and zinc. In countries where cereal-based porridges with low nutrient density are the weaning foods, deficiencies are common. Iron and zinc need to be accounted for (Figure 10-1).

The duration for which the iron endowment at birth remains adequate varies, so some infants will benefit from additional iron at 4 to 6 months.<sup>15</sup> The data on zinc are meager. The concentrations of zinc in milk decline after the first few months of lactation and are independent of maternal zinc intake.<sup>34</sup> Hepatic stores will sustain levels in the infant, but exogenous zinc will be required and is most readily obtained from meat.

In an effort to teach adolescent mothers to delay introduction of solid foods and weaning from breastfeeding, investigators used home visitations every other week for a year using food frequency questionnaires at 3 months for a subset of mothers.<sup>23</sup> Mothers who only used breast milk (or formula) but no solids were considered optimal feeders. The mothers were exposed to counseling and instructional videos to help them read their infants' cues, utilize nonfood strategies for managing behavior, and to develop techniques for negotiating with an interfering grandmother. The authors thought these efforts helped these mothers follow the national guidelines and instructions for infant feeding by Women, Infants, and Children (WIC).

Breastfed infants self-regulate their total energy intake when other foods are introduced. No advantage to introducing complementary foods before 6 months has been seen. A review by Foote and Marriott<sup>18</sup> expresses the concern that some infants might need additional nutrients. They point out that the energy density of the food should exceed that of breast milk (4.2 kJ/g or 0.55 to 0.80 kcal/g). They also warn that foods with high phytate levels can interfere with mineral absorption and recommend the avoidance of juices and other drinks. Giving infants solids by 4 months is associated with less positive health outcomes such as increased body fat, higher body mass index, and a greater incidence of wheezing and respiratory illness in childhood, according to Fewtrell et al.<sup>17</sup>

When iron was added to the diet at 4 months by giving iron-rich solids to infants who did not have iron deficiency anemia, the length growth was less than in unsupplemented control infants. Head growth was also slower in iron-supplemented infants. No improvement in weight gain was observed, and the treated infants had more occurrences of diarrhea if their hemoglobin levels were normal.<sup>15</sup> More boys than girls had iron deficiency anemia at 9 months according to Dewey et al.<sup>15</sup>

In the study of nutrient intakes and food choices of 3000 infants and toddlers participating in the

Feeding Infants and Toddlers Study (FITS), there were 450 participants in the WIC nutrition program.<sup>6</sup> It was observed that infants in the WIC program were less likely to have ever been breastfed and were more likely to be taking formula.<sup>45</sup> The mean usual intake of nutrients exceeded adequate intakes. Mean energy intake was excessive with little consumption of fruits and vegetables. In the entire study of 3000 infants, 76% were fully or partially breastfed at birth, dropping to 30% at 6 months and to 16% at 1 year. Average duration of breastfeeding was 5.5 months. From 4 to 6 months, more than 65% had been given solids, not all of which were nutrient dense. Sweetened juices, French fries, hot dogs, potato chips, popcorn, pizza, and candy were reported in up to 9% of infants aged 7 to 8 months old.

An infant's first flavor experiences probably occur in utero. When garlic was ingested by mothers before amniocentesis or delivery, the amniotic fluid smelled of garlic.<sup>40</sup> The normal fetus ingests amniotic fluid in utero and thus experiences those flavors. When breastfed, the infant continues to experience those flavors as a bridging experience to solid foods.<sup>39</sup> Not surprisingly, breastfed infants consume cereal prepared with their mother's milk more eagerly and in greater volume than when it is prepared with water. In a carefully controlled experiment, infants were fed the cereals by their mothers, who wore facial masks but no perfume to avoid affecting the infant's interest in the food.<sup>40</sup> The infant's interest was reflected in opening of the mouth sooner, fewer negative facial expressions, and greater intake. Mennella and Beauchamp<sup>40</sup> suggest that from the perspective of flavors, weaning means "to accustom," which actually describes what occurs with breastfeeding: the flavors in the milk accustom the infant to new flavors in the transition to solid foods. Putting mother's milk in the bland cereal is part of the bridging. Infants whose mothers have a more varied diet during pregnancy and lactation tend to adapt to solid foods more readily, according to these investigations.

Weaning to a cup is a natural transfer because infants learn to drink from a cup by 7 to 9 months. The use of fruit juice in the cup was originally encouraged for its vitamin C content. Fruit juice may be replacing milk, however, in the diets of young children.<sup>11</sup> This is a concern because milk is an important source of protein and calcium, whereas nutrients in fruit juices are limited predominantly to carbohydrates, calories, and varying amounts of vitamin C. Juices are also replacing fruit in the diet. Excessive fruit juice consumption reportedly leads to short stature and failure to thrive in some infants, chronic diarrhea in some, and obesity in others.<sup>38</sup> The trend often begins when fruit juice is put in a nursing bottle. The

pediatrician should be alert to the exact content of the weaning foods, ensuring adequate protein, calcium, vitamins, and fiber, and to the development of feeding skills, including feeding from a cup and from a spoon.

## *Mothers' Rights*

---

In practice, human mothers are often the determinants of weaning time, as is true for other species. Some mothers want to nurse for a few weeks and wean to a bottle to go to work. Other mothers wean at 3 months to be free again.<sup>41,42</sup> Certainly any time spent breastfeeding is to an infant's advantage. The critical point in weaning is to make it a gradual adjustment for both mother and infant. The year 2010 health goals for the United States recommend that mothers nurse exclusively for at least 6 months,<sup>54</sup> continuing while adding weaning foods until 1 year and then for as long thereafter as mother and child wish.

A study of the psychosocial factors influencing weaning time in primigravidae was conducted when the 81 participants were 8 months postpartum.<sup>28</sup> Maternal worries about the demands of breastfeeding had a negative effect on the duration. If mothers worried about the demands of breastfeeding, they were more likely to perceive problems with scheduling breastfeeding when they returned to work. Mothers who worried about lack of family support to breastfeed were more apt to worry about the demands of breastfeeding. Those women who saw the practical advantages of breastfeeding did not perceive returning to work as presenting a problem and nursed longer. Medical illness, sore nipples, fatigue, or breast infections were not influential in weaning. Work and scheduling have a larger role in most mothers' decision to wean.<sup>25</sup>

## *Weaning Process*

---

Gradually replacing one feeding at a time with solids or a bottle or cup, depending on an infant's age and stage of development, is usually preferable.<sup>5</sup> After the adjustment has been made to one substitute feeding, a second feeding is replaced with a substitute, usually at the opposite time of day. This process is continued until only the morning and night feedings remain. Then these two are gradually stopped. The morning and night feedings can be maintained for some months, and often an infant is nursed well beyond the second year, especially at these times. Mothers who wish to wean partially as early as 3 months may continue the morning and night nursing. This schedule is especially suited to the working mother. The decline

in lactation and the regression of the mammary gland occur slowly with gradual weaning.

When an infant is fully breastfeeding and solids are initiated, a feeding of solids is given during the day and breastfeeding continues on demand. As solids are increased and a three-meals-per-day schedule is reached, breastfeeding still continues on demand, although nursings may be fewer or briefer. No nursings need be intentionally omitted in this scheme, although it is important to give the scheduled solids before breastfeeding the infant.

The study of the composition of milk during abrupt weaning revealed that the secretory capability of the mammary gland of women changed dramatically after complete cessation of breastfeeding but that the involuting gland remained partially functional for 45 days. After termination that occurred in 1 day, sample collections were attempted for each breast by manual expression at the same time on days 1, 2, 4, 8, 16, 21, 31, 42, and 45. The concentrations of lactose and potassium decreased, while sodium, chloride, fat, and total protein increased progressively over 42 days. The milk becomes notably salty, but the infants continue to drink the salty fluid. The increase in protein was related to increases in the concentrations of lactoferrin, IgA, IgG, IgM, albumin, lactalbumin, and casein. Concentrations from each breast were similar throughout.

The involution in other species is rapid. For example, complete reabsorption occurs in 7 days in cows. The threshold dose of oxytocin required to elicit milk ejection increased progressively for at least 30 days after termination of breastfeeding. It is thought that a psychological nursing stimulus contributes to this effect in humans because they continue contact with their infants, whereas other species are separated. Experimental animals given oxytocin after weaning also show a delay in involution.

Weaning ages and techniques in a sample of American women who practiced extended breastfeeding were reported by Sugarman and Kendall-Tackett.<sup>51</sup> Women were recruited from La Leche League meetings in the area and nationally, utilizing survey forms (closed-end, self-administered, 96-item questionnaires). Based on 134 mothers and 211 children, the weaning age ranged from 1 month to 7 years 4 months. For those who weaned three children, as well as the entire sample, the tendency was to nurse the youngest the longest, perhaps because it was not supplanted by a sibling.

Reasons for weaning were predominantly child-led for about 60% of children, but weaning was the mother's decision in up to 15.8% in the youngest child (Tables 10-2 and 10-3). Those who were still nursing responded to the question, "Have you thought about weaning this child?" predominantly with a "no" (Table 10-4).<sup>51</sup>

A normal, well-adjusted mother may experience some depression and sadness at the reality of the last feeding.<sup>48</sup> It may be difficult to deal with this experience. It is important to recognize this as a physiologic phenomenon as well as an emotional one. If a mother is forced by circumstances beyond her control to wean early, she may need understanding and encouragement to cope with the disappointment. If she had pressure from friends or relatives to breastfeed, she may need to face what she considers failure and recognize that one can bottle feed and still mother very well.

**TABLE 10-2** Reasons for Weaning and Types of Methods

Reasons for Weaning or Not Weaning (Have You Thought about Weaning This Child?)

Response	Frequency (%)
No, weaning should be child-led	75.9
No, enjoy the nursing relationship	72.3
Yes, for a specific reason (pregnancy, returning to work)	4.8
Yes, child is ready/child is biting	7.8
Yes, due to social pressure	3.6
Yes, child is nursing too frequently for age	3.6

From Sugarman M, Kendall-Tackett KA: Weaning ages in a sample of American women who practice extended breastfeeding, *Clin Pediatr* 34:642, 1995.

Historically, weaning has varied from strict to permissive schedules depending upon cultural norms.<sup>10</sup> Rigid feeding schedules were associated with early weaning.<sup>7</sup> Weaning has varied from early strict denial to slow and gentle withdrawal. In the twentieth century, the time considered proper for weaning gradually shortened from 2 or 3 or 4 years to as soon as 6 to 8 months or less for some mothers and infants. Public opinion has overlooked an infant's needs in favor of what are considered the mother's rights. It is not necessary to have a specific plan for weaning in the early weeks of nursing unless constraints on the mother's time are an issue. Weaning should be done with an infant's needs as a guide. If an infant younger than 1 year of age rejects the breast, it is unusual but not abnormal and should not be considered by the mother as a personal rejection. Some bottle-fed infants throw down the bottle at 9 months as well.

Studies of weaning practices are few. In a study of primigravidae, the women introduced solids because their infants seemed hungry and less satisfied and woke more frequently. The average time to introduce nonmilk food in bottle-fed infants was 3 months and in breastfed infants, 5 months. Most observations are done on duration of feeding when the success rate is low.

The reasons given why women in Dunedin, New Zealand, elected to wean their infants early included concern about their milk supply and other maternal problems.<sup>25</sup> One of the most significant factors in lactation termination was mismanagement of breastfeeding by health professionals. A similar study in Sweden reported that 66% of the mothers weaned because they thought their milk was drying up.

Brazil had also experienced a decline in breastfeeding. The study was undertaken to understand the causes of early weaning to develop better means of encouraging longer breastfeeding and delaying

**TABLE 10-5**

Main Reasons for Premature Weaning

Reason	N	%
Not enough, inadequate, or "weak" milk	307	30.9
Child refused breast	177	17.8
Illness of child	159	16.0
Mother needed to go to work	149	15.0
Correct age for bottle-feeding	139	14.0

weaning. The bottle was introduced at birth by 24% of women, at 2 months by 72.6%, and at 6 months by 88.0%.

**Table 10-5** lists the main reasons given for weaning. A third of the mothers believed their milk was weak. In general, most studies of weaning practices indicated that most weaning is mother initiated, often because she thinks her milk is no longer adequate. The primary cause of failing milk supply reported by most investigators is inadequate help or instructions about milk production from medical personnel. In a study of 750 mother-baby dyads, Howard et al.<sup>26</sup> showed a clear relationship to early weaning, decreased exclusive breastfeeding, and the early introduction of a pacifier. In most studies, those who breastfeed longer tend to be older than 25 years, well-educated, middle class, self-educated about lactation, and enjoy breastfeeding.<sup>21</sup>

The problem of recall bias when reporting breastfeeding duration was investigated by Huttly et al.,<sup>28</sup> who compared responses given at 11, 23, and 47 months postpartum by the mothers of 1000 children; 24% misclassified weaning time at 23 months and 30% at 4 years. Those in the better-educated, higher socioeconomic group were more apt to report longer breastfeeding.

In worldwide epidemiologic studies, the interruption of breastfeeding because of pregnancy may play a significant role. The mean monthly bias introduced was to reduce breastfeeding by 2 months. In Third World countries, infant death also lowers the duration of breastfeeding inversely to the mother's education; that is, the less educated the mother, the greater the risk for infant death from infection and accident.

## Why Women Wean

In 2001 using the National Survey of Family Growth to analyze breastfeeding behaviors of a national probability sample of 6733 first-time

mothers in the United States from 15 to 44 years of age, Taylor et al. found 3267 women who breastfed.<sup>52</sup> Among these women, 46%, 68%, 78%, and 85% had weaned by 3, 6, 9, and 12 months, respectively. The reason 1091 women stopped was because their infant was "old enough to wean." This reason was claimed by 15%, 34%, and 78% at the same 3-month intervals. White and Hispanic women had similar weaning patterns. For black women who stopped because their child was "old enough to wean," greater numbers weaned sooner (22%, 46%, 68%, and 86% stopped at 3, 6, 9, and 12 months, respectively).<sup>29</sup>

Physical and medical problems were the next most common reasons (26.9%), followed with "job or schedule" (only 17.9%), and "preferred to bottle feed" (15.3%) (Table 10-6). Differences by race revealed black women stopped because they "preferred to bottle feed." Hispanic women had a few more infants who refused the breast (3.7%) compared to black women (0.5%) and white women (2.1%).

In 2006 to 2007, the Infant Feeding Practices Study II (IFPS II), a mail survey supported by the Division of Nutrition of the Centers for Disease Control and Prevention, was focused on why women stop breastfeeding, and the reasons were not significantly different.<sup>36</sup> In a forced answer questionnaire the statements were slightly different but the three top explanations were that infant was not satisfied, the child was old enough to wean, and concern about nutritional issues. In the first 2 months, mothers were concerned that the milk was inadequate; after 2 months, however, mothers were concerned that infants' activities were meant to self-wean, and later weaning took place for social reasons such as work or maternal freedom. When infants were approximately 1 year old, the misconception that it was the age to wean was a factor. Clearly, each of these issues could be addressed through adequate counseling. When data were extracted from the Pregnancy Risk Assessment Monitoring System (PRAMS) to examine breastfeeding behaviors, periods of vulnerability for breastfeeding cessation, predelivery intentions, and breastfeeding behaviors, it was clear that younger women with limited economic resources stopped early.<sup>1</sup> Those who planned to breastfeed were more likely to continue than those who did not plan ahead to breastfeed. Early postpartum cessation was due to physical discomforts of breastfeeding and the uncertainty about milk supply. Professional intervention early might well change these figures.

A longitudinal observational study involving appropriate controls and mothers who delivered healthy term infants at Yale-New Haven Hospital and planned to take them to the clinic showed that

a mother's knowledge and problems with lactation were not associated with early stopping of breastfeeding.<sup>16</sup> Those who lacked confidence in their success and those who believed the baby preferred formula were most likely to stop in 2 weeks. The rates of discontinuation were 27%, 37%, 70%, and 89% by 1, 2, 8, and 16 weeks, respectively. In this population of minority women, 91% of whom were already enrolled in WIC, the authors<sup>32</sup> recommended that the focus needs to shift from increasing knowledge and problem management to enhancing a mother's confidence and correcting misconceptions about an infant's preferences. The probability of early weaning is increased by the occurrence of stressful life events during pregnancy such as separation, divorce, financial stresses, and residential moves. This was independent of hospital care and delivery issues.<sup>37</sup>

Reasons why mothers wean sooner than they had planned were analyzed from 1177 mothers over 18 years of age who responded to monthly surveys from the IFPS II conducted by the Food and Drug Administration (FDA) and the Centers for Disease Control (CDC).<sup>44</sup> Sixty percent of these mothers stopped sooner than they had planned. The major reasons given were (1) difficulties breastfeeding, (2) concern for infant nutrition and weight gain, (3) maternal illness or need to take medicine, and (4) the time and effort associated with pumping. Continued professional intervention is suggested as a possible solution (Table 10-7).

In a subsequent study from the IFPS II that included 1334 mothers who reported a 7-day food frequency questionnaire monthly, determination was made of the exact time mothers were introducing solids. Of those in the study, 24.3% of breastfed, 52.7% of formula-fed, and 50.2% of mixed-fed infants started before 4 months.<sup>9</sup> The mean age of introduction was 11.8 weeks, and 9.1% of mothers who were formula feeding started before 4 weeks. It was claimed that a doctor suggested it for 55.5% of mothers and 46.4% of mothers were told that solids would help the baby sleep. The odds of these behaviors were higher for formula-fed infants (Table 10-8). Breastfeeding mothers tend to feel more satisfied with the infant feeding experience.

Mother-infant dyads with unlimited access to lactation consultants had slower introduction of solid foods at the initial complementary feeding period, compared to dyads followed in the well-baby clinic at the University of Iceland.

## *Infant-Initiated Weaning*

Infant-initiated weaning in the first year of life was investigated by Clarke and Harmon,<sup>8</sup> who studied

*CI*, Confidence interval; *NSFG*, National Survey of Family Growth; *OR*, odds ratio.

\*The 90 women who were still breastfeeding at the time of the interview and the 131 women who categorized their race as "other" (211 total; 10 women were in both groups) were not included in the analyses. The 25 women (0.8%) who answered "other" as a reason for not breastfeeding (including the baby's father or someone else discouraged breastfeeding, fears about breastfeeding, and other) were not included in the analyses. The reference group is women who stopped breastfeeding because the baby was "old enough to wean" (final  $n=3000$ ).

<sup>†</sup>NSFG sampling weights applied.

<sup>‡</sup>Adjusted for maternal demographics (age, race, marital status, education, poverty level).

50 healthy breastfed infants who were totally weaned, 46% of the group of infants initiated the weaning. This is often mistakenly referred to as "self-weaning." The onset was usually between 5 and 9 months of age, with a median age of 6 months. Mothers described the behavior as an increased interest in exploring the environment and in other foods and a decreased interest in breastfeeding.

The duration of infant-initiated weaning is approximately 1 month and is an interactive process that requires "at a minimum maternal complicity." It can lead to relatively easy mutual weaning. It can usually be reversed, however, by a mother's efforts to continue breastfeeding.

## Emergency Weaning

Occasionally, sudden weaning is necessary because of severe illness in the mother or some prolonged separation of mother and infant. (Sudden illness in the infant does not require weaning, and, in fact, weaning is contraindicated.) This is difficult for both. After abrupt weaning the mammary glands remain partially functional for more than a month.

Changes in the composition of the mammary secretion of women after abrupt termination of breastfeeding have been investigated in seven women before and after termination. The concentrations of lactose and potassium decreased while sodium, chloride, fat, and total protein increased progressively for 42 days. The increase in protein

represents an increase in the concentration of lactoferrin, IgA, IgG, IgM, albumin,  $\alpha$ -lactalbumin, and casein. This represents dramatic change in secretion with abrupt weaning.

Depending on an infant's age and flexibility, because the nursing mother will be unsuccessful, a patient "surrogate mother" may need to provide a feeding or two by bottle to switch an infant to a bottle in abrupt weaning. In other cases an infant may take only solids and refuse other liquids for days.

## Milk Fever

The mother in the meantime may have considerable discomfort. Engorgement may be significant if it is only 4 to 6 weeks postpartum. The mother may experience milk fever at any time in abrupt weaning. This illness is characterized by fever, chills, and malaise, resembling a flu-like syndrome. It is thought to be caused by the sudden reabsorption of milk products into the system. Milk fever usually lasts 3 to 4 days and should not be confused with more serious illnesses.

The hormonal change resulting from sudden weaning early in lactation is more definitive because the prolactin levels from suckling are higher immediately postpartum (see Chapter 3). The hormone-withdrawal syndrome may be more marked with early weaning. Prolactin has been associated with a feeling of well-being; thus its decrease may be associated with

<b>TABLE 10-7</b>		Sociodemographic Characteristics of Mothers Who Met and Did Not Meet Their Intention for Breastfeeding Duration

relative depression. Patients with psychiatric disorders have been observed to cope postpartum until they wean the infant from the breast. It is important to provide an adequate social and medical support system during weaning for the mother who is prone to depression or psychiatric problems. Maternal suicide and injury to the infant by the mother have been reported.

## *Refusal to Breastfeed: "Nursing Strike"*

Sudden onset of refusal to nurse can occur at any time and often is taken by the mother as a personal rejection, who promptly follows through by weaning completely.<sup>18</sup> Often these mothers consider the refusal to mean that they do not have enough milk or that something is wrong with their milk. This behavior has been called "nursing strike" and has been noted to be temporary.<sup>44</sup> The various causes associated with this abrupt behavior include the following:

1. Onset of menses in the mother
2. Dietary indiscretion by the mother
3. Change in maternal soap, perfume, or deodorant
4. Stress in the mother
5. Earache or nasal obstruction in the infant
6. Teething
7. Episode of biting with startle and pain reaction by the mother

If a reason is identified that is possibly associated and can be changed, nursing should resume. It may take extra effort to reestablish the relationship. Suggestions that may be made to the mother include the following:

1. Make feeding special and quiet, with no distractions and no other people in the room.
2. Increase amount of cuddling, stroking, and soothing the baby. Walk with the infant cradled in the arms or an infant sling.
3. Offer the breast when the infant is sleepy.
4. Do not starve the child into submission.
5. If simple remedial steps do not result in a return to nursing, the physician should see the child to rule out otitis media, fever, infection, thrush, and so on.
6. If biting was the associated event, keep finger ready to break suction should it occur again to avoid startling the infant.

## *Are Growth Parameters and Illness Influenced by Weaning?*

Most writings on weaning refer to the problems in underdeveloped countries when infants are weaned

early to overdiluted cow milk or to artificial formulas that do not contain the antiinfective properties of human milk for human infants. Weanling diarrhea is a clinical syndrome (weanling diarrhea is a collection of diseases) associated with weaning from the breast. In 1900 in New York City, the death rate from dysentery, diarrhea, and enteritis in children in the first year of life was 5603 in 100,000 infants. This was largely attributed to weaning from the breast. Diarrheas are strongly associated with weaning not only because of the introduction of other foods but also because of the loss of the protective properties of human milk.

Diarrheas contribute to the malnutrition seen in underdeveloped countries because of the resultant lack of appetite and increased metabolic losses. In Third World countries, morbidity and mortality rates in infancy rise sharply at the time of weaning from human milk because of the rapid onset of infections. Malnutrition is also a major threat to the weanling in the developing world. Rickets, iron deficiency, and protein energy malnutrition are the three major threats. Second to these are the risks of zinc deficiency, allergy, and obesity, which affect a wider group of children.

In well-nourished mothers and their infants, diarrhea does not occur from controlled gradual weaning unless the infant has a cow milk allergy or metabolic disorder.

Data from over 1600 infants from five prospective randomized trials concluded in the UK were utilized to determine the influence of weaning at <12 weeks on growth and health outcomes (diarrhea, vomiting, chest infections, atopy, and sleep). The infants included term Appropriate Gestational Age (AGA), term Small for Gestational Age (SGA), and preterm infants. Early weaned infants were larger at 12 weeks but the growth trajectories of the two groups were equal at 18 months. Health outcomes were not different in those weaned before and after 12 weeks. Larger infants were fed solids sooner.

It has been shown that pacifier use shortens breastfeeding duration. In a study of over 500 infants, it was shown that early cessation of breastfeeding and/or pacifier use predispose the infant to long-term persistent finger sucking. Cessation of breastfeeding before 12 months or pacifier use before 14 months is associated with persistent finger sucking according to Fukumoto and colleagues.<sup>20</sup>

## *Changes in Milk Composition During Gradual Weaning*

Changes in the nutrient composition of human milk during gradual weaning were studied by Garza et al.<sup>21</sup> in six fully lactating women recruited at 5 to

**TABLE 10-9** Nutrient Density (mg/100 kcal) of Milk During Weaning

	Week							PTM*	R†
	0	2	4	6	8	10	12

\*Nutrient densities of milk from women who deliver premature infants.

†Nutrient densities calculated to achieve intrauterine growth rates assuming that the caloric requirement of low-birth-weight infants is 130 kcal/kg.

From Garza C, Johnson CA, Smith E, et al: Changes in the nutrient composition of human milk during gradual weaning, *Am J Clin Nutr* 37:61, 1983.

7 months postpartum (Table 10-9). The weaning consisted of decreasing the frequency and duration of breastfeeding by one third each month for a period of 3 months. Milk was collected at 2-week intervals. Volume decreased to 67%, 40%, and 20% of baseline each month. The concentrations of protein and sodium were increased to 142% and 220% of baseline, respectively, by the twelfth week of weaning. Changes in fat composition were linear through the tenth week but at the twelfth week were similar to baseline. Iron was increased 172%, calcium was unchanged, and zinc fell to 58%. Similar observations have been made in bovine milk. Milk produced during either rapid or gradual weaning is characterized by a decreasing concentration of lactose. Fat accounts for an increasing percentage of calories (up 80%), and protein remains stable at 6% of calories.

The immunologic components in human milk were also measured, and the concentrations of certain components of the immunologic system are maintained during gradual weaning.<sup>22</sup> The effect of gradual weaning differs from that of abrupt weaning, in which the concentrations of all components rise dramatically. Measurements at 4, 8, and 12 weeks showed a decrease in the milk volume of 67%, 40%, and 20% as the levels of IgA and secretory IgA rose slightly. Lysozyme and lactoferrin rose slightly. The total intake of protective factors is stable temporarily (increased concentration in spite of decreased volume).

Lipase activities in human milk during weaning were studied by Freed et al.<sup>19</sup> Bile salt-stimulated lipase slowly decreased throughout weaning, whereas lipoprotein lipase became substantially lower or absent compared with colostrum. Lipase activity continues but decreases with the decrease in milk volume.

Studies in other species suggest that gut maturation observed at normal weaning time is not dependent on components in the milk but is triggered by thyroxine and corticosterone in the plasma of the offspring.<sup>24</sup> The anatomic changes in the breast during weaning are discussed in Chapter 2.

The caloric needs for infants have been overestimated in the past. Continued growth occurs on lower volumes of human milk than formula, with breastfed infants refusing additional milk even when a woman increases her volume by pumping.<sup>46</sup> The energy requirement is 115 kcal/kg/day in the first 2 months of life, after which requirements decline rapidly, reaching a low of 85 kcal/kg/day at 6 months. Between 6 and 12 months of age, requirements gradually increase with increased activity to 100 kcal/kg/day. These figures are a radical departure from those recommended in the past. Most studies of energy intakes show, at all ages, that boys have greater intake and greater rates of growth than girls and are usually weaned sooner.<sup>53</sup> Further, the effects of infection and social deprivation are important to consider; children in supportive, loving environments have been noted to grow on fewer calories than the deprived child.

## Physician's Role

A physician's responsibility in weaning is to advise the mother concerning the initiation of the appropriate solid foods, which probably should begin at 6 months of age and usually not before. Introduction of a cup as a developmental step should usually begin by 7 months. Eating finger foods and learning self-feeding are the next steps for the child.

None of the above means termination of breastfeeding, but rather the gradual developmental progression of feeding. Breastfeeding continues "on demand." As other foods are introduced and feeding begins to cluster into three meals and some "snacks," breastfeedings will be decreased eventually to two or three per day in the second year.

The nourishment value is not a key issue of continued nursing after 1 year if other foods are adequate, although very valuable nutrition and immunoprotection continue to be provided. A physician's role is to ensure adequate nutrition

and to be available for advice for as long as breastfeeding continues.

No detriment to nursing is known, and there is some indication that nursing a few times per day or during times of stress is beneficial to the mother-infant relationship when the child is older than 1 year of age. The objections raised are usually based on custom or personal taste. It is important for a clinician to avoid judgmental counseling based only on personal biases. Lay publications on the subject may help guide a mother who is nursing a toddler.<sup>27</sup>

A physician may need to help the mother work through her own feelings about nursing her infant beyond the first year. Many women have been overwhelmed by friendly advice from lay experts about infants who nurse for several years. Beyond a year, weaning is rarely child initiated until age 4. The child may not lose interest, so the final steps in termination may require maternal intervention if weaning is desired sooner. A mother is not a poor parent if she begins to feel resentful toward nursing. Planning appropriate alternatives to breastfeeding sessions that are to be eliminated is helpful in turning a child's attention toward the new event instead of toward the loss of an old and cherished one, a feeding at the breast. A mother may need to be helped to see how to avoid situations that easily predispose to nursing. She needs to know that it is acceptable to set some rules and to have some limitations and control over the breastfeeding.

If the mother becomes pregnant, she should decide when she wants to wean or whether she will continue to nurse through pregnancy and then tandem-nurse the new baby (see Chapter 20). For the child, it is important to avoid abrupt weaning or weaning to make room for the new baby, who will now take the child's place. Weaning well before delivery is usually less traumatic for the child than at delivery time. At delivery, however, a new infant is fed first to ensure that the newborn receives adequate colostrum.

## Motivation to Wean

The motivation to wean an infant may be multifactorial and often is suggested by the father, grandmother, or members of the mother's social circle. The physician should not initiate the plan to wean except for medical reasons but may initiate discussion about it to ensure that the mother has given it some thought.

Reasons for weaning have been analyzed by a number of investigators. Factor analysis of a longitudinal database was done by Kirkland and Fein.<sup>31</sup> Mother's concerns about her milk supply, wanting to leave the infant, and wanting someone else to feed the infant were the major reasons for weaning

in this group from 6 to 12 months postpartum. Concern about the appropriate age for breastfeeding cessation was a prominent concern toward the later months. Parents may find nursing an older baby or a toddler distasteful. Mothers are encouraged to anticipate and plan for weaning; it can be gradual, taking advantage of developmental progress and new interests of the toddler. It is wise to avoid associating sleeping with a feeding as the time to wean approaches because it may be more difficult to make the break. The father can play a vital role in nonnutritive cuddling, beginning from birth, and can be especially helpful in easing an infant through weaning, particularly when night feedings have become the custom. Not all parents perceive weaning, night feedings, and taking an infant to the parents' bed in the same light. The AAP Committee on sudden infant death syndrome (SIDS) has banned co-sleeping. Not all physicians view these matters equally, but they should avoid imposing personal views on patients and share the AAP SIDS statement. The family bed and co-sleeping practices are discussed in Chapter 6.

Regarding weaning in developing countries, the decision was thought to be made on the basis of traditional beliefs, nutritional status of the child, or similar reasons. When the reasons for termination were studied in West Africa, however, illness in the child, a new pregnancy, and illness in the mother were found to be the most common precipitating events. Health workers should be aware of this to be able to counsel mothers appropriately.

## Closet Nursing

A physician should be fully informed about breastfeeding physiologically and psychologically. A trusted physician communicates well with patients and is kept informed by the parents. Unfortunately, many mothers are driven to "closet nursing" by insensitive, uninformed relatives and friends and even health care providers. Closet nursing is nursing privately at home in secret. The practice propagates ignorance about breastfeeding duration and influences not only other mothers but also physicians who are unaware and custody court judges who are led to believe extended nursing is abnormal. Thousands of normal, healthy children are breastfed until they are 3 or 4 years old. The benefits of human milk continue. Research documents health protection and improved development for at least 2 years. It has not been evaluated beyond that except for the positive emotional and bonding experience associated with long-term nursing.<sup>51,48,30</sup>

Because breastfeeding surveys are not carried out much beyond a child reaching 1 year old, data

are scarce. Dettwyler<sup>13</sup> set up a voluntary survey of children who had been breastfed more than 3 years, amassing 1280 children in 5 years between 1995 and 2000. The average age of weaning in this special group was 4.24 years (range 3 to 9.17 years). Half the children were weaned between 3 and 4 years. Child-led weaning occurred at 4.39 years and mother-led weaning at 3.83 years. Those who voluntarily participated were middle- to upper-class women who worked outside the home, were highly educated, and were of European-American ethnicity. Two thirds of the mothers became pregnant while nursing and then tandem nursed the two. The average length of tandem nursing was 1.62 years.

Although not necessarily common in the United States, worldwide, breastfeeding a child more than 2 years is in no way abnormal.

## *Working Mothers*

Some mothers return to work. Whether the reason is money, career, or personal satisfaction is not relevant to management. It takes tremendous commitment to work and breastfeed, but it can be done, it has been done, and it will be done. Usually the biggest problem a mother faces is coping with people who do not understand why she bothers. An understanding physician who provides the reassurance and support necessary to manage is a great asset. A mother may go home for a feeding in the middle of the day, pump milk to leave for the infant to have from a bottle, or give a substitute bottle. If there are occasional bottles of formula, the powder preparations are more economical and require only warming of the water before adding the powder to ensure rapid solution. Chapter 21 offers suggestions for collecting milk.

Some infants quickly learn the mother's schedule and will sleep while she is away and feed more frequently during the evening and night to make up for it. It takes some personal adjustment to plan ahead and a babysitter who is patient and cooperative. Many infants are tended in daycare centers, which requires packing up and transporting the infant to other surroundings.

A mother needs to be alert to the infant's needs as well and can plan to leave feedings ready when she is away, even if she had hoped the infant would sleep through the day. If a mother works long hours or has an inflexible schedule, it may be necessary to wean the infant to morning and night feedings at the breast. This arrangement still provides the special benefits of human milk as well as the closeness that an infant needs; thus, it is worth the effort. Chapter 18 discusses maternal employment.

## *Legal Issues*

In the present turmoil of family life in which parents are separating when the children are still young, several custody cases have been based on weaning times or, more accurately, on the time breastfeeding is totally terminated. A number of cases in the United States have come to the attention of the Study Center in which the father has sought custody on the basis of prolonged breastfeeding, when the child nursed for comfort to about age 4. In most cases the judge found in favor of the mother. In one case in Rochester, New York, the judge found in favor of the father when an expert witness, a local psychologist, declared that "you have to be crazy to nurse that long." No amount of scientific evidence could counter this inappropriate remark (personal communication).

No evidence shows that breastfeeding a child beyond infancy is harmful. In fact breastfeeding benefits toddlers and young children both nutritionally and psychologically. Breastfeeding is neither child abuse nor neglect and no reported legal decisions made to date claim that it is.<sup>4</sup> Our society is not knowledgeable about, or supportive of, extended breastfeeding. Breastfeeding past infancy is as old as mankind and was common in Western cultures until 100 years ago with the advent of artificial feeding and commercialization of the field.

Other issues of parental rights have surfaced in cases of child custody and visitation rights when the child is younger than 2 years of age and breastfeeding. Usually the argument over separation of the mother from her breastfeeding infant is part of a larger problem. Physicians called on to give expert testimony need to review carefully all the issues because rarely is the breastfeeding question the only problem. Right and wrong have not been established for all circumstances. It would seem appropriate also that judges review the entire case and qualifications of the respective parents and refrain from basing their decision on personal biases and emotional testimony. It is also advisable for expert witnesses to be fully informed on a subject about which they will testify and to avoid extending their comments beyond their area of expertise.

Developmental psychologist Ainsworth<sup>2</sup> has studied the maturation of the child and summarized the literature, which shows that infants with a strong attachment to their mothers through breastfeeding are psychologically independent at 2 years of age. These children have more mastery of themselves at age 5 and less anxiety entering school than bottle-fed children.

## Why Do Some Women Not Breastfeed?

Given the tremendous benefits to mother and infant of breastfeeding, why do some women choose not to breastfeed? Studies in our laboratory in the 1990s among young women in the WIC program prenatally indicated that although they knew that mother's milk was best and why, they did not plan to breastfeed because there were too many rules. Prenatal classes about infant feeding given at WIC made formula feeding look easy and breastfeeding complicated. These complications began with dietary restrictions, moved to hand grips and body positions, and ended with all the limitations about alcohol, caffeine, and medications. They found it overwhelming and certainly not physiologic or natural.

Using the data from the National Survey of Family Growth to analyze the breastfeeding behaviors of a national probability sample of 6733 first-time mothers aged 15 to 44 years, Taylor et al.<sup>52</sup> measured the reasons for never breastfeeding. The most common reason mothers gave was "preferred to bottle feed" (66.3%). The next most common reason was a "physical or medical problem" (14.9%). For women giving physical or medical problem as the reason, no one problem stood out, and most were probably surmountable. Job or schedule was a distant third as a reason (9.8%). "Did not know how to breastfeed" was given by 4.7% of women even though more than 97% had received prenatal care. According to the survey, 1.8% of the babies refused the breast. The authors stated that provider encouragement increased breastfeeding initiation among women of all social and ethnic backgrounds. They found that most women have decided about breastfeeding by the third trimester; thus providers of prenatal care should have a significant role in breastfeeding promotion. "Preferred to bottle feed" was interpreted by Taylor et al.<sup>52</sup> as representing an intrinsic decision on the part of the mother or an amalgam of many indistinct social and cultural pressures.

## CHAPTER 11

# *Normal Growth, Failure to Thrive, and Obesity in Breastfed Infants*

### *Normal Growth*

The focus on growth evaluations in childhood have relied on averages: averages of the fat, the thin, the tall, the short, the sick, and the well. The real science is looking at ideal growth in ideally fed children anywhere in the world.

The growth of exclusively breastfed infants has become the focus of much interest among pediatricians, researchers, and nutritionists.<sup>12</sup> Historically, the Boyd-Orr cohort study in the 1920s and 1930s showed that breastfed children were taller in childhood and adulthood.<sup>80</sup> Stature was associated with health and life expectancy. Adult leg length is very sensitive to environment factors and diet in early childhood because this is the time of most rapid leg growth. After infancy, chest growth is rapid before puberty and is sensitive to stress and illness. Cross-sectional association between cardiovascular risk factors and components of stature (total height, leg length, and trunk length) was demonstrated. The risk of coronary heart disease was inversely related to leg length but not trunk length in the Caerphilly study in South Wales.<sup>110</sup>

A number of long-range follow-up studies have been initiated to address the issues of growth during the critical first year of life, when brain growth is greater than it ever will be again in postnatal life. An interest in height and weight increments and ratios is only part of the concern about obesity and the long-range issues of adiposity. Does breastfeeding protect against adult obesity? Does human

milk protect against cholesterol "intolerance" in adult life? The questions are clear, but the answers are not unless one assumes the teleological approach: human milk is ideal for human infants, with its low protein, controlled calories, and persistent unchangeable cholesterol.

The questions are actually, "Is it safe to overfeed an infant with formula?"; "Is it safe to deprive an infant of cholesterol during a period of critical brain growth when brain growth depends on cholesterol?"; and "When infants are deprived of cholesterol in early infancy, are they less able to tolerate it later?"

Antiquated data and anthropometric standards have led to the belief that the growth curves and tables of normal height and weight do not reflect the growth of most healthy, well-fed breastfeeding infants.<sup>83</sup> Reliability of weight gain as a measure of growth has developed because it is a measurement easily obtained.<sup>83</sup> Measurement of length, however, is considered a better standard.<sup>93</sup> Weight gain and linear growth are not always correlated. Furthermore, during infancy and childhood, the lower leg grows at a higher rate than the rest of the body. Knee-heel length can be expressed as a percentage of total length and increases with age: 25% at birth, 27% at 12 months, and 31% in adult life. During several decades of formula feeding, "normal" growth curves were developed based only on formula-fed infants. Furthermore, whole cow milk is fortunately almost totally abandoned, and the recommendations for introduction of solid food at 6 months and older have been universally

adopted by nutrition-conscious physicians and parents. World Health Organization (WHO) and United Nations International Children Education Fund (UNICEF) have reconfirmed that breastfeeding should be exclusive for the first 6 months. Growth curves have been developed based on breastfed infants on delayed solids.

Bottle-fed infants gain more rapidly in weight and length during the first months of life than do breastfed infants.<sup>26</sup> Therefore, evaluating an infant's physical growth by standards set by bottle-fed infants predisposes one to the diagnosis of failure to thrive.

Forman et al.<sup>35</sup> reported a longitudinal study of breastfed and bottle-fed infants during the first few months of life that demonstrated the 10th and 90th percentile values for weight and length of the two groups were similar at birth, and the 10th percentile values of the two groups were similar at age 112 days. The significant difference was in the values for the 90th percentile. Bottle-fed infants were above this percentile in substantially greater numbers. These differences were attributed to caloric intake rather than the difference in composition of the diet. Fomon et al. showed that the bottle-fed infant not only gains more in weight and length, but also gains more weight for a unit of length. This gain reflects the overfeeding of the bottle-fed infants.<sup>34</sup>

Most studies of growth in breastfed infants have been plagued with the problem of variation in supplementation and the occurrence of partial weaning.

The effects on growth of specific protein and energy intake in 4- to 6-month-old infants who were either breastfed or formula fed with high and low protein were measured by Axelsson et al.<sup>3</sup> No significant differences were found in the growth rate of crown-heel length and head circumference or weight gain. The authors concluded that the differences in protein intake between breastfed and formula-fed infants without differences in growth indicate that the formulas may provide a protein intake in excess of the needs. When milk intake and growth in exclusively breastfed infants were carefully documented in the first 4 months by Butte et al.,<sup>11</sup> energy and protein intakes were substantially less than current nutrient allowances. Infant growth progressed satisfactorily when compared with National Center for Health Statistics (NCHS) standards, despite that energy dropped from  $110 \pm 24$  kcal/kg/day at 1 month to  $71 \pm 17$  kcal/kg/day at 4 months.<sup>11</sup> Similarly, protein intake decreased from  $1.6 \pm 0.3$  g/kg/day at 1 month to  $0.9 \pm 0.2$  g/kg/day at 4 months. Reevaluation of protein and energy requirements is essential.

Weight-for-length and weight gain were significantly correlated with total energy intake but not with activity level during the first 6 months of life in breastfed infants studied by Dewey et al.<sup>24,22</sup>

Energy intake was considerably lower than recommended—85 to 89 kcal/kg/day—when compared with the 115 kcal/kg/day recommended dietary allowances of the National Academy of Sciences in 1980.<sup>17</sup> Presently energy recommendations suggested by the Institute of Medicine (IOM) are expressed as:  $(89 \times \text{wt}[\text{kg}] - 100) + 175$  kcal.

Those infants who consumed the most breast milk became the fattest. A 4-kg infant would require 105 kcal/kg/day.

When patterns of growth are examined in the infants of marginally nourished mothers, weight gain is comparable to a reference population but does not permit recovery of weight differential at birth, which was significantly small for gestational age (SGA).<sup>7</sup> The intakes of energy and protein by individual infants were reflected in their weight gain but were below internationally recommended norms.<sup>30</sup> Maternal milk alone, when produced in sufficient amounts, can maintain normal growth up to the sixth month of life. Exclusive breastfeeding in Chilean infants of low-middle and low socio-economic families produced the highest weight gain and practically no illness or hospitalization.<sup>59</sup>

In the Copenhagen Cohort Study in 1994, exclusively breastfed term infants had a mean intake of 781 and 855 mL/24 hours at 2 and 4 months, respectively.<sup>82</sup> The median fat concentration of human milk was 39.2 g/L and was positively associated with maternal weight gain during pregnancy. This supports the concept that maternal fat stores laid down during pregnancy are easier to mobilize during lactation than other fat stores. This may limit milk fat when pregnancy fat stores are exhausted.

The effect of prolonged breastfeeding on growth has been an issue of concern, especially in developing countries.<sup>35</sup> In a review of 13 studies, Grummer-Strawn<sup>42</sup> pointed out in 1993 that eight reported a negative relationship, two had a positive relationship, and three had mixed results. Grummer-Strawn identified the flaws in study design and suggested that until better information is available, women should nurse as long as possible because the benefits to infant health exceed the risks in these geographic areas.

In addition to recognizing the importance of genetic, metabolic, and environmental influences in producing significant differences in growth patterns, Barness<sup>5</sup> suggests that recommendations for nutrition of healthy neonates may be too high for some and too low for others. However, the benchmark for nutritional requirements of the full-term infant remains milk from the infant's healthy, well-nourished mother.

Gain in physical growth is not as critical as gain in brain growth, but measurements of brain growth are only indirectly implied from growth of the head. In evaluating any infant's progress, head circumference

is an important consideration, especially in the first year of life. Deceleration in the rate of increase in head circumference occurs over the first year. The head circumference increases about 7.5 cm (3 inches) in the first year of life and another 7.5 cm in the next 16 years of life. When growth failure includes failure of head growth, the failure is severe. However, many other factors independent of body growth influence head growth.

A weight loss of 5% is usually accepted as the norm for bottle-fed infants in the first week of life, although information in pediatric textbooks is meager. A loss of 7% is average for breastfed infants, but when this occurs in the first 72 hours of life, a clinician should be alert to breastfeeding problems and should review the process. A loss of 10% is the maximum for breastfed infants. Clinicians should confirm that positioning and latch-on are correct and that the breasts have responded with some engorgement and milk production. The mother-infant dyad with this problem will need close observation and support. Referral to a licensed certified lactation consultant may be appropriate if the pediatric office does not have a trained staff member available (nurse practitioner with lactation training).

Initially after birth, a normal infant loses 5% of body weight before starting to gain, whether breastfed or bottle fed. Breastfed infants who are given added water or added formula to force fluids in the first few days of life lose more weight and are less likely to start gaining by the fourth day than infants who are exclusively breastfed or who were bottle fed.

The time at which an infant regains birth weight is equally unclear. In their extensive study of 1139 breastfed and formula-fed infants, Nelson et al.<sup>91</sup> summarize weight at 8 days by stating, "Most formula-fed but not most breastfed infants have exceeded their birth weights by age 8 days." They also report that gains in weight and length were greater for boys than for girls in the age intervals of 8 to 42 days, 42 to 112 days, and 8 to 112 days. These authors provided weights and lengths for the critical first 112 days. Birth weight is doubled between the 50th and 75th percentiles at 4 months of age and tripled at 12 months. Obese infants with higher weight/length ratios tripled their weight sooner, suggesting that rapid tripling time may be an indicator of obesity. Black infants in general doubled and tripled their weights sooner, but more black infants were bottle fed.

## GROWTH OF BREASTFED INFANTS

Dewey et al.<sup>24,25,21</sup> have suggested that new, separate growth charts are needed for breastfed infants.

The DARLING (Davis Area Research on Lactation, Infant Nutrition, and Growth) Study collected data prospectively on growth patterns, nutrient intake, morbidity, and activity levels of matched cohorts of infants who were either exclusively breastfed or bottle fed during the first 12 months of life. Measurements were followed beyond 12 months to 18, 21, 24, and 36 months as well. Growth in length and head circumference did not differ significantly between the two groups; however, weight gain was slower among breastfed infants after about 3 months of age. These weight gain differences continued even after solid foods were added at 6 months in both groups. Breastfed infants were leaner than their counterparts. The slower growth rates and lower energy intake of the breastfed infants were associated with normal or accelerated development and less morbidity from infectious illnesses. The authors<sup>21</sup> concluded that it is normal for breastfed infants to gain at this pace, which is less rapid than that indicated by the scales developed for bottle-fed infants.

When the growth patterns of a large sample of breastfed infants were pooled from the United States, Canada, and Europe, Dewey et al.<sup>24,25,21</sup> reported that results were consistent across studies. Breastfed infants grew more rapidly in weight during the first 2 months and less rapidly during 3 to 12 months. Head circumference was well above the WHO/Centers for Disease Control and Prevention (CDC) median throughout the first year. Length-for-age did not decline nor did the weight-for-age and weight-for-length scores as breastfeeding increased in duration.

Garza et al.<sup>37</sup> reviewed growth patterns of breastfed infants. Breastfed infants clearly consumed less energy than recommended by WHO in the second 3-month period by choice and not because the mother could not produce more milk. Dewey et al.<sup>22,23</sup> first pointed this out when they had mothers pump to increase their production and found the infants self-regulated to the original intake measured before the pumping program in spite of the fact that the mother was producing more milk.<sup>22</sup>

## INTERNATIONAL GROWTH CHARTS

It became clear that growth curves developed by the CDC were averages taken from bottle-fed infants, mostly overfed, fat and thin, tall and short, sick and well. They reflected how children grew on the average. The WHO developed an international committee of experts to develop a model for how children should grow. Data were collected from six countries of widely divergent populations from stable families who breastfed exclusively for

6 months and continued for a minimum of a year and longer. The infants had access to health care and good housing. This multicenter growth reference study involved 8440 children zero to 5 years of age from Brazil, Ghana, India, Norway, Oman, and the United States (Sacramento, California).<sup>114,117</sup>

The sample had ethnic or genetic variability in addition to cultural variation in how the children were nurtured, strengthening the standard's universal applicability. The remarkable observation was that all the children grew at the same pace; curves could be superimposed, regardless of racial background. The observations confirmed the thought that children in a healthy environment can achieve their genetic growth potential regardless of poverty, ethnicity, or culture. The charts differ from the CDC growth charts, especially for the first 2 years of life, in which formula-fed infants show greater weight gain that averages 600 to 650 g heavier at 12 months of age. Differences in length are minimal and, therefore, breastfed infants are lower in weight-for-length measurements and other indices of fatness. Breastfed individuals are not shorter in adult life but less likely to be obese. Assessment of sex differences and heterogeneity in motor milestone attainment among populations in the multicenter study support the appropriateness of pooling data from all sites and both sexes for the purpose of an international standard. Six gross motor milestones were used: sitting without support, hands-and-knees crawling, standing with assistance, walking with assistance, standing alone, and walking alone. The WHO child growth standards depict normal growth under optimal environmental conditions and can be used to assess children everywhere, regardless of ethnicity, socio-economic status, and type of feeding. They represent how children should grow globally.<sup>113,116</sup>

The recommendation for use of the WHO charts by the CDC states the following for infants under 24 months: use the WHO growth charts recognizing the values 2 standard deviations above and below the median, or the 2.3rd and 97.7th percentiles (labeled) as the 2nd and 98th percentile. The rationale for this use is recognition that breastfeeding is the recommended standard for infant feeding and, unlike the CDC charts, the WHO growth charts reflect patterns of breastfed infants for 4 months and still breastfeeding at 2 months, all based on a high-quality study.

The continued use of CDC charts from 24 to 59 months is recommended because they extend for 20 years, whereas WHO charts cover 0-59 months. Switching at 24 months is explained because of the transition at 24 months from measuring recumbent length to standing height. The WHO charts reflect optimal growth while the CDC charts reflect population averages.

## IMPACT OF WEANING FOODS ON GROWTH

Weaning foods is a term used by breastfeeding practitioners, but the infant nutrition community uses the term *complementary foods*, foods that complement breast milk. As an infant approaches 6 months of age, the stores of iron are diminishing, and iron in human milk is not sufficient to meet needs; likewise, the once high-levels of stored zinc are diminishing, and the levels of zinc in human milk are decreasing. Thus, complementary foods need to contain iron and zinc, as most meats and fortified cereals do.<sup>103</sup> Krebs et al.<sup>63</sup> found low measurements of iron and zinc levels in breastfeeding infants at 6 months; when meat was added as a weaning food, levels increased toward normal. Routine assessment of iron and zinc levels increased toward normal. Routine assessment of iron and zinc levels is not practical; therefore, the Committee on Nutrition recommends fortified cereal or infant style meats as weaning food.<sup>9</sup>

The timing of initiation of weaning foods before 6 months of age has shown that as energy intake increases from solid foods, energy intake from breast milk decreases. The downward trend of weight/age and weight/length ratios continues with the addition of solids, which would not be expected if growth faltering were the basis for the decline.<sup>37</sup> Breastfed infants apparently self-regulate when offered solids and also leave some solids uneaten. When breastfed infants were given solids between 4 and 7 months, their weight-for-age and weight-for-length were consistently lower than those for infants introduced to solids at 8 months or older. Length-for-age was similar between the two groups.

Does the growth rate of exclusively breastfed infants reflect a need for higher protein?<sup>50</sup> This question has challenged the wisdom of exclusive breastfeeding. A group of exclusively breastfed infants were matched with a second group who received prepared solid foods, including egg yolk, beginning at 4 months of age.<sup>23</sup> Neither weight gain nor length gain from 4 to 6 months differed between the groups. The solid-food group received 20% higher protein intake as well as higher intakes of iron, zinc, calcium, vitamin A, and riboflavin. The authors concluded that protein intake is not a limiting factor in the growth of breastfed infants.<sup>23,50</sup>

Similarly, Cohen et al.<sup>16</sup> demonstrated that breastfed infants given solids at 4 months self-regulated so that the energy intake and protein intake were the same in both the supplemented group and the unsupplemented group. When Motil et al.<sup>86</sup> calculated the gross efficiency of nutrient utilization for each infant in a longitudinal study of breastfed and bottle-fed infants, length and weight

gains and lean body mass and body fat accretion during the first 24 weeks of life were similar. The formula-fed infants had received significantly higher nitrogen and energy. The gross efficiency of dietary energy utilization for lean body mass deposition was two times greater in breastfed than bottle-fed infants. No association was found between lean body mass deposition and dietary protein intake. This confirms previous studies that human milk protein does not limit growth.<sup>86</sup> Breastfed infants self-regulate their energy intake at lower levels than formulated. Body temperature and metabolic rates are lower in breastfed infants.<sup>18</sup>

Recommendations for optimal duration of exclusive breastfeeding have been controversial.<sup>18</sup> The WHO has revised its recommendation for both developed and developing countries to promote exclusive breastfeeding for 6 months.<sup>117</sup> Kramer and Kakuman<sup>61</sup> provided a comprehensive review of the literature, including both controlled clinical trials and observational studies in any language comparing exclusive breastfeeding to exclusive breastfeeding for less time with mixed feeding for at least 6 months. The health outcomes reported included growth, iron and zinc status, infectious morbidity, atopic disease, neuromotor development, rate of postpartum maternal weight loss, and duration of lactational amenorrhea. The conclusions were exclusive breastfeeding for 6 months resulted in lower risk for gastrointestinal infection and no growth deficits. In concert with the WHO, the section on breastfeeding of the AAP promotes exclusive breastfeeding for 6 months. The WHO recommends the need for animal source foods as well as fruits and vegetables in the initial period of 6 to 9 months of age as demonstrated in the Multicenter Growth Reference Study.<sup>114,113,116</sup>

## PROLONGED BREASTFEEDING

Considerable controversy surrounds the question of prolonged breastfeeding. Although the value of prolonged breastfeeding has not been challenged in industrialized countries, it has in developing countries. When the fat and energy content were measured in 34 mothers of healthy term infants who had been lactating for more than a year (12 to 39 months) and compared with the milk of control mothers who had been lactating for 2 to 6 months, levels were significantly increased in fat and energy content. The elevated levels did not correlate with maternal age, diet, body mass index (BMI), or number of daily feedings.<sup>77</sup> Some studies showed that small, undergrown infants are breastfed longer.<sup>14,57</sup> Careful assessments reveal that larger infants are weaned earlier. A cautious review of available studies suggests that prolonged breastfeeding does not cause malnutrition; rather, the small and

undergrown infants are kept at the breast longer. Child size appears to be related to the decision to wean so that, in general, large healthy infants are weaned completely from the breast earlier.<sup>15</sup> Thus, smaller infants being breastfed longer is not the cause of the undergrowth.

## CATCH-UP GROWTH IN SMALL-FOR-GESTATIONAL-AGE INFANTS

SGA infants have been identified as being at risk for continued growth failure in extrauterine life, learning difficulties, and behavioral problems. Lucas et al.<sup>73</sup> explored the influence of early nutrition on growth in the first year of life in full-term SGA infants, comparing those receiving breast milk with those receiving formula. This was a subset of a study on early carnitine supplementation. An equal number of breastfed and formula-fed infants received carnitine. Additional demographic, social, clinical, and anthropometric data were collected. Breastfeeding was associated with a greater increase in weight at 2 weeks and 3 months of age, which persisted beyond the actual breastfeeding period. The authors reported greater catch-up growth in head measurement and a greater increase in body length in the breastfed infant. They suggest that breastfeeding promotes faster catch-up growth, and breastfed infants have the potential for improved catch-up growth in developmental parameters as well.<sup>73</sup>

In a study designed to examine the role of zinc supplementation in catch-up growth in SGA infants, Castillo-Duran et al.<sup>13</sup> reported that infants who were exclusively breastfed had increased growth compared with those who were formula fed and supplemented with zinc.

## COGNITIVE AND MOTOR DEVELOPMENT

Cognitive development in the first 7 years of life was related to breastfeeding practices of a birth cohort in New Zealand.<sup>31</sup> The researchers took into account maternal intelligence, maternal education, maternal training in child rearing, childhood experiences, family socioeconomic status, birth weight, and gestational age. The breastfed children had slightly higher test scores on the Peabody Picture Vocabulary Test, the 5-year measure on the Stanford Binet Intelligence Scale, and the 7-year measure on the Wechsler Child Intelligence Scale. Measures of language development were equally influenced. This very small improvement in scores persisted when all variables were taken into account. The scores were also influenced by length of breastfeeding less than and longer than 4 months.

An additional study on the same birth cohort was done to assess breastfeeding and subsequent social adjustment in 6- to 8-year-old children. Fergusson et al.<sup>32</sup> studied prospectively 1024 children who were part of the Christ Church Child Development Study. They used the maternal and teacher ratings of childhood conduct disorders. A statistically significant tendency for conduct disorder scores declined with increasing duration of breastfeeding; that is, breastfed children were less prone to conduct disorders than bottle-fed children. Breastfed children, however, tended to come from slightly more socially advantaged, economically privileged homes that were more stable. The analysis failed to examine early mother-infant interaction patterns.

This cohort of 1000 individuals has now been reported as an 18-year longitudinal study by Horwood and Fergusson.<sup>55</sup> A small but detectable increase in child cognitive and educational achievement in the children who had been breastfed as infants was still seen. The results were confirmed in standardized tests, teacher ratings, and academic outcomes in high school and young adulthood.

De Andraca and Uauy<sup>20</sup> reviewed the factors in human milk and the breastfeeding process that affect optimal mental and visual development. The complex relationships point to a clear advantage to breastfeeding.

The relationship of infant-feeding practices and dependent variables to the subsequent cognitive abilities were reported by the WHO Growth Reference Study Group<sup>113</sup> from the Yale Harvard Research Project in Tunisia. Within the underprivileged group, they found that breastfeeding promoted not only physical growth but also sensor motor development as assessed by Bayley motor and mental scales. No great differences were found in the ability to sit alone or to take first steps, but especially among boys in the lower socioeconomic group, significant superiority of breastfed infants at 8, 14, and 16 months of age was observed in the Bayley mental scales. In this study, all infants were from the same social and intellectual strata.

The question of whether breastfeeding influences a child's developmental outcome has appeared in modern literature since Hoefer and Hardy<sup>53</sup> first reported in 1929 that breastfed infants were more active and achieved motor milestones earlier than bottle-fed infants. These authors described enhanced learning ability and higher intelligence quotient (IQ) scores at 7 to 13 years of age in children exclusively breastfed for 4 to 9 months. Although socioeconomic status and mothers' education were not reported, it is an interesting historic note that it was the well-educated, higher socioeconomic mothers who could afford to bottle feed in the 1920s and 1930s and into the 1940s. In an attempt to

clarify the relationship to maternal status, Taylor and Wadsworth<sup>106</sup> took the negative hypothesis but were unable to eliminate the possibility that breastfeeding had a positive effect on intellectual development at 5 years of age.

In a national study of 13,135 children in England, Scotland, and Wales, a positive correlation between duration of breastfeeding and performance in tests of vocabulary and visuomotor coordination was found; these behavior scores remained steady when tested against intervening social and biologic variables. This British 1946 cohort study has continued. In 2002, Richards et al.<sup>98</sup> used a meta-analysis to show that breastfeeding conferred a 3.2-point increment in cognitive function through adolescence. They showed that breastfeeding was significantly and positively associated with educational attainment and cognition at age 15 years and with adult social class. Breastfeeding did not affect verbal memory independently at 53 years of age. Breastfeeding clearly has long-term potential impact across life's course according to the authors.<sup>98</sup>

The advantage of human milk for at-risk infants has been investigated by Lucas et al.,<sup>75,74</sup> who raised public awareness when their results were reported in newspapers internationally in 1992. The initial cohort of 771 infants whose birth weights were less than 1850 g were given their mothers' milk; these infants had a mean eight-point advantage on the Bayley Mental Developmental Index compared with infants who did not receive their mothers' milk.<sup>75</sup> Both groups received nutrition by feeding tube for the first month of life. A 4.3-point advantage remained when outcome was adjusted for demographic and perinatal factors. The same advantage was found using an IQ equivalent test, which is a fundamentally different test. The same group of infants was tested regularly, and results at age 7½ to 8 years showed a 10-point advantage in IQ testing even when controlled for maternal social class and education.

This report precipitated a torrent of responses from other investigators,<sup>56–95</sup> who provided support for and against the conclusion that breast milk is effective in improving the outcome of high-risk infants.

To determine the effect of breastfeeding on optimal visual development, Birch et al.<sup>6</sup> studied term and preterm infants fed human milk or corn oil-based formula with no added omega-3 essential fatty acids. Visual testing using visual-evoked potential and forced-choice preferential looking activity was performed at 4 months' adjusted age; infants given human milk scored better. This was confirmed at 36 months using random dot stereo acuity and letter-matching ability. Results correlated with a measure of dietary omega-3 sufficiency index from the infants' red blood cells at 4 months.

## Failure to Thrive

### DEFINITION

Failure to thrive is an imprecise, archaic term. Failure to thrive is a symptom and not a diagnosis. The causes of failure to thrive in children have been associated with malfunctions of many organ systems as well as with nutritional, environmental, social, and psychological factors. Failure to thrive while breastfeeding has often been inappropriately considered in the same terms as failure associated with other sources of nourishment and involving other age groups. Failure to thrive while breastfeeding is a phenomenon associated with the first year of life and more likely younger than 6 months. Exclusive breastfeeding is appropriate for the first 6 months, and then solids should be added. Therefore, the symptom is no longer exclusively associated with lactation, except in rare cases in which the infant is breastfed beyond 9 months with no solids added.

The term failure to thrive has been loosely used to describe all infants who show some degree of growth failure. It is a syndromic classification that has been used to describe infants whose gain in weight or length or both fails to occur in a normal progressive fashion. For the breastfed infant, it may be a matter of comparing a slower gainer to the excessive weight-gain patterns of the bottle-fed infant.

The current diagnosis and treatment of failure to thrive emphasizes the assessment of, and therapy for, malnutrition and its complications and the contexts in which they occur according to the AAP.<sup>18</sup> The AAP suggests that the needs of each child who is not thriving should be evaluated according to four parameters: medical, nutritional, developmental, and social. The entire family should be included. The ecologic context in which such a situation occurs in the land of plenty suggests the source is poverty and food insecurity. This approach is appropriate for children beyond infancy but not for the newborn and early months of life when the child is breastfed.

The disorder for an infant is defined as failure to thrive when the infant continues to lose weight after 10 days of life, does not regain birth weight by 3 weeks of age, or gains at a rate below the 10th percentile for weight gain beyond 1 month of age. Unlike a bottle-fed infant, who can be placed in a hospital where professionals can feed him or her, a breastfed infant needs to be evaluated in the home setting and nursing at the breast unless it is an emergency. If the infant requires hospitalization, then the breastfeeding mother is part of the work up, including examination of the breasts for signs of milk production and response to pumping.

A more serviceable measure of failure to thrive than percentiles is proposed by Frank et al.,<sup>36</sup>

who suggest the use of a percentage of the median values for the age on the growth chart. Thus, normal is greater than 90% of median weight, mild malnutrition is 75% to 90% of median, moderate is 60% to 74% of median, and severe is less than 60% of median weight. Similar percentages are applied to height and weight-for-height. Thus a 1-month-old infant whose median weight-for-age would be 5000 g and who is only 3800 g is 75% of median, or mildly malnourished (Table 11-1).

Human growth has been considered a continuous process, characterized by changing velocity with age. Lampl et al.<sup>65</sup> made serial measurements of normal infants weekly, semiweekly, and daily during the infants' first 21 months. They show clearly that growth in length occurs by discontinuous, periodic, saltatory spurts. Furthermore, these bursts were 0.5 to 2.5 cm (0.2 to 1 inch) during intervals separated by no measurable change (2 to 63 days' duration). The authors suggest that 90% to 95% of normal development during infancy is growth free.<sup>65</sup> Length accretion is distinctly a salutatory process of incremental bursts punctuating background stasis. Thus, evaluation of length requires more than one measurement and the careful consideration of an experienced physician familiar with growth parameters. In standard text books, the term failure to thrive has been replaced with malnourished or suffering from protein-energy malnutrition but is used for children older than a year and not breastfed.

As more and more women breastfeed, increasing numbers of cases of failure to thrive appear in the literature, although it is a rare phenomenon. No statistical data on incidence rates are available because no large prospective study has been done.<sup>67</sup> Only in extreme cases are infants hospitalized, but the number of these cases is increasing as well, partly because of a failure to recognize the disorder and refer the infant to medical care promptly.

With the introduction of the WHO growth charts based on normal healthy breastfed infants instead of on overfed formula-fed infants, the diagnosis of failure to thrive is less frequent. An occasional child is clearly not gaining nor growing

**TABLE 11-1** Daily Weight Gain and Recommended Allowances

Age (mo)	Median Daily Weight Gain (g)	Recommended Daily Allowance (kcal/kg/day)
0-3	26-31	108
3-6	17-18	108
6-9	12-13	98
9-12	9	98

due to lack of sufficient breast milk or more likely because of an underlying metabolic disorder causing lack of metabolism of nutrients or lack of absorption. Children with congenital anomalies of the first arch, such as cleft lip and/or cleft palate, are at risk but should be identified before hospital discharge and scheduled to receive close follow-up. Children with developmental delay may present after a month or so when they cannot maintain adequate suckling and the mothers' milk supply dwindles. It is appropriate to evaluate an infant for lead intoxication when there is insufficient growth or developmental delay. Psychosocial risk factors include unusual health and nutrition beliefs of the family. Fear of obesity or other diseases have been associated with rigid and restricted feeding patterns. Allergic families may actually breastfeed to avoid the use of soy milk and other substitutes.

#### **BOX 11-1. Parameters for Evaluation of Breastfed Infants**

<b>Infant Who Is Slow to Gain Weight</b>	<b>Infant with Failure to Thrive</b>
Alert healthy appearance	Apathetic or crying
Good muscle tone	Poor tone
Good skin turgor	Poor turgor
At least six wet diapers/day	Few wet diapers
Pale, dilute urine	"Strong" urine
Stools frequent, seedy (or if infrequent, large and soft)	Stools infrequent, scanty
Eight or more feedings/day, lasting 15 to 20 minutes	Fewer than eight feedings, often brief
Well-established let-down reflex	No signs of functioning let-down reflex
Weight gain consistent but slow	Weight erratic, may lose

### **Diagnosis**

The problem of slow or inadequate weight gain has confounded even the physicians most committed to breastfeeding. It should be approached with the same orderly diagnostic process used to attack any medical problem. Thus, a complete history, including the details of the breastfeeds, a physical examination of the infant, an examination of the maternal breast, observation of the feeding, and appropriate laboratory work are indicated. Organizing the data collected by this process will help to identify the facts that appear under maternal and infant causes separately.

### **Slow Gaining Versus Failure to Thrive**

Some helpful distinctions exist between a breastfed infant who is slow to gain weight and the infant who is failing to thrive while breastfeeding.<sup>68</sup> These parameters should be included in the routine "well baby" evaluation of all breastfed infants, beginning with the first visit (Box 11-1). With early discharge often occurring less than 48 hours after birth, the first visit may need to be within 48 hours of discharge from the hospital, depending on an infant's gestational age, weight loss before discharge, history of jaundice, and the mother's experience. The pediatric office or clinic should have a failsafe system of follow-up for all newborns that includes access by telephone. The pediatric office should also be alert to the close follow-up of primiparas, especially those mothers who are older and well educated. A study of delayed lactogenesis and excess neonatal weight loss by Dewey et al.<sup>23</sup> revealed the high correlation not to ethnic groups, but to age and advanced education, noting increased problems with early breastfeeding. In the absence of a telephone in the home, visiting

nurse involvement may be appropriate. Although many hospitals provide breastfeeding warm lines that mothers can call for information and help, the family must make the transition from the birthplace to the primary care provider promptly, especially for parents of a first baby who have no previous office contact. New parents often do not recognize when there is a problem.

The feeding pattern of an infant with slow weight gain is usually frequent feedings with evidence of a good suck. The mother's breasts are full before feeding, and she can describe a let-down during the feeding. At least six diapers per day are wet, urine is pale and dilute, and stools are loose and seedy. Weight gain is slow but consistent. If the infant is gaining extremely slowly but is alert, bright, and responsive and developing along the appropriate level, the infant is a "slow gainer." In contrast, the infant with true failure to thrive is usually apathetic or weakly crying with poor tone and poor turgor. Few diapers are wet (none is ever soaked) and urine is "strong." Stools are infrequent and scanty. Feedings are often by schedule but always fewer than eight per day and brief. No signs of a good let-down reflex are found. True failure to thrive is potentially serious; early recognition is essential if the integrity of both brain growth and breastfeeding is to be safely preserved.

Although slow gaining may be familial or genetic (small parents), it is always appropriate to be sure the process of breastfeeding is optimized.<sup>9</sup> Attention to adequate fat in the milk is important, especially because mothers have often been encouraged to "switch nurse," that is, switch back and forth between breasts in each feeding to build up an adequate milk supply. The switch-nursing process interrupts the release of fat and the production of fat-rich

hind milk. If the mother is interrupting the feeding to go to the other side, a period of feeding exclusively on one breast during each feeding may change the gaining pattern. If necessary, the level of fat in the milk can be checked by doing a "creamatocrit," comparing milk before and after the timing change (see Chapter 21). By weighing the infant before and after a feeding with a digital readout scale, an accurate measurement of breast milk intake can be recorded. A gainer will have good intake.

In a schema for classifying failure to thrive at the breast, the causes associated with infant behavior and problems are distinguished from those related to maternal problems (Figure 11-1). The causes in the infant can be further evaluated by looking at net intake, which may be associated with poor feeding, poor net intake from additional losses, or high energy needs. The maternal causes can be divided into poor production of milk and poor release of milk. When a poor let-down reflex continues long enough, it will eventually cause a decrease in milk production. Several factors may affect the outcome, and more than one management change may be indicated.

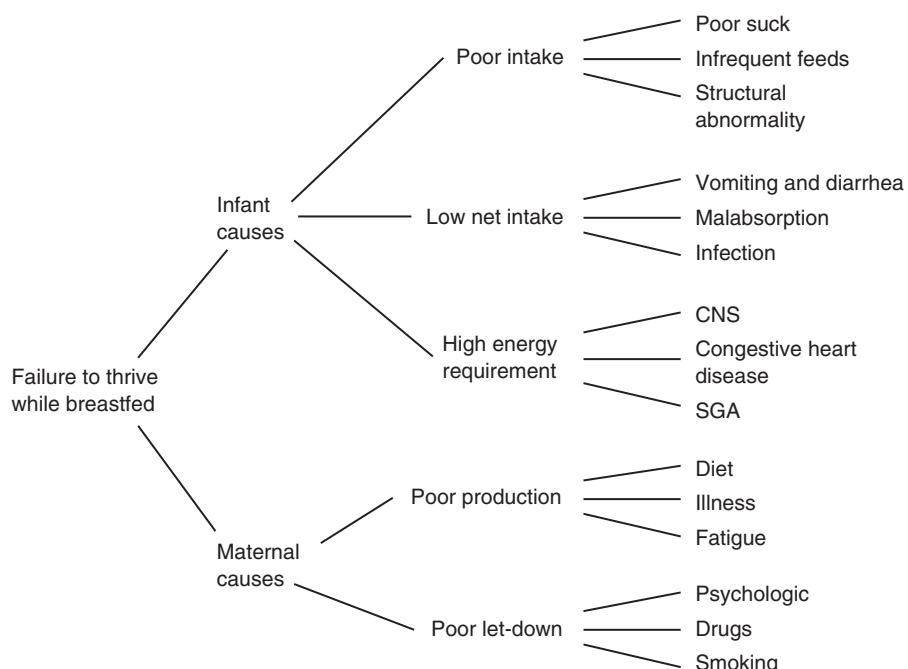

## Evaluation of Infant

Examination of the infant should suggest any underlying physical problems, such as hypothyroidism, congenital heart disease, mechanical abnormalities of the mouth (e.g., cleft palate), or major neurologic disturbances.<sup>6</sup> An infant's ability to root, suck, and coordinate swallowing should

be observed. Today, a greater risk for missing subtle structural problems exists because infants spend much of their hospital life out of the newborn nursery away from the eyes of experienced nurses and are discharged before problems become manifest.

The routine observation of a feeding by an infant's physician should be part of the discharge examination from the hospital. If this is not practical, such an examination should be incorporated into the first office or clinic visit within the first week of life. The mother should be asked to let you see how the baby feeds. The focus, however, should be to watch the positioning of the mother and the infant, placement of the mother's hands, and initiation of latch-on (see Chapter 8). A small number of infants will be identified with physical abnormalities that need medical attention (Box 11-2).

Lukefahr<sup>76</sup> identified 38 infants younger than 6 months of age in a suburban pediatric practice as having failure to thrive while breastfeeding. Only 2 of 28 infants (7.1%) who presented in the first 4 weeks had underlying illnesses (salt-losing adrenogenital syndrome and congenital hypotonia); 5 of the 10 presenting between 1 and 6 months had underlying disease (all of whom actually presented with a problem by 4 months). This report stresses the importance of ruling out underlying disease and the urgency of having a pediatrician evaluate a child when the symptom of poor weight gain is first suspected, thus avoiding the serious complications of dehydration and metabolic disorders that may result when "home remedies" for lactation problems are used.

**Figure 11-1.** Diagnostic flowchart for failure to thrive. CNS, Central nervous system; SGA, small for gestational age.

**BOX 11-2. Conditions Associated with or Causing Disorders of Sucking and Swallowing**

Absent or Diminished Suck	Mechanical Factors Interfering with Sucking	Disorders of Swallowing Mechanism (Not Including Esophageal Abnormalities)
Maternal anesthesia or analgesia	Macroglossia	Choanal atresia
Anoxia or hypoxia	Cleft lip	Cleft palate
Prematurity	Fusion of gums	Micrognathia
Trisomy 21	Tumors of mouth or gums	Postintubation dysphagia
Trisomy 13-15	Temporomandibular ankylosis or hypoplasia	Palatal paralysis
Hypothyroidism		Pharyngeal tumors
Neuromuscular abnormalities		Pharyngeal diverticula
Kernicterus		Familial dysautonomia
Werdnig-Hoffmann disease		
Neonatal myasthenia gravis		
Congenital muscular dystrophy		
Central nervous system infections		
Toxoplasmosis		
Cytomegalovirus infection		
Bacterial meningitis		

**Oral Motor Problems: Feeding Skills Disorder.**

Growth failure secondary to feeding skills disorder is the terminology proposed by Ramsay et al.<sup>97</sup> to replace nonorganic failure to thrive. The authors describe a series of children who were referred for nonorganic failure to thrive who had displayed subtle problems since birth. The criteria include early abnormal feeding-related symptoms present shortly after birth, such as impaired oral function, suggesting the infants are minimally neurologically abnormal, sometimes associated with borderline low Apgar scores. Difficulties during earlier stages of feeding development not only may interfere with the development of more mature feeding skills, but also may contribute eventually to difficulties in mother-infant interaction. The common finding among all infants with failure to thrive was underlying feeding-related symptoms that were neurophysiologic but manifested in different degrees of oral sensorimotor (and pharyngeal) impairment. The neurologic impairment may vary from obvious cerebral palsy to symptoms that are not apparent on casual observation but lead to abnormal feeding-related symptoms in early life. When the mother copes and adapts, the disorder goes unnoticed until solid foods are added. Diagnosis requires oral sensorimotor assessments and a neurologic examination sensitive enough to measure minimal neurologic impairment in an apparently healthy child who is failing to gain. Early history is also critically important.

**Small-for-Gestational-Age Infant.** A SGA infant will be identified if gestational age and birth weight are scrutinized. This infant is small at birth despite full gestation time in utero. An SGA infant has a large nutritional deficit from intrauterine failure to grow. The cause of the intrauterine problem should be assessed: placental insufficiency,

maternal disease, toxemia, heavy smoking, or intrauterine infection, such as toxoplasmosis.

SGA infants are difficult to feed initially by any method and often require tube feedings for a few days. Their caloric needs parallel the needs of an infant of appropriate weight for gestation rather than their actual low weight. SGA infants should be placed on frequent feedings, every 2 to 3 hours by day and every 4 hours at night. They should be awakened for feedings if they sleep long periods. If they have not been nursing well, the breast may not have been stimulated to produce to its full capability. The mother may need to express milk manually or mechanically pump milk to enhance her production. Her milk may then be given by a passive means such as a tube, a small cup, or the lactation supplementing device, which provides additional stimulus to the breast while providing the extra calories needed (see Chapter 19).

An infant who is sufficiently starved in utero may have a degree of inanition that prevents active sucking at first, predisposing to further starvation. The successful nursing of an SGA infant may require extended efforts by the mother to ensure adequate growth. Such efforts are well worth the trouble if one considers the impact of intrauterine growth failure on the central nervous system. It is to the infant's advantage to have the critical amino acids, such as taurine and the lipids of human milk, with which to "catch up" brain growth. As noted earlier, SGA infants are more likely to close the growth gap more rapidly if breastfed.<sup>12</sup>

**Jaundice.** An infant with an elevated bilirubin level from any cause may be neurologically depressed and lethargic and, therefore, may not nurse well. If the infant appears jaundiced, laboratory evaluation to determine the cause and its appropriate treatment

should be undertaken. Visible jaundice under 24 hours of age requires a full evaluation and is not related to breastfeeding. When an infant is taken from the breast at 2 or 3 days of age because of jaundice, this interferes with the establishment of lactation at a critical time, especially for a primipara. Management of the jaundiced infant depends on adequate calories and the active passage of stools, which is the means by which the body excretes the bilirubin in meconium and stools.

"Breastfeeding jaundice," which is related to underfeeding or starvation, does not develop until the infant is 3 or more days old, so other causes must be sought. In addition, care must be taken to help the mother continue to stimulate production with manual expression or pumping to avoid inducing iatrogenic lactation failure. (See [Chapter 14](#) for discussion of hyperbilirubinemia.)

**Metabolic Screen.** Most hospitals provide, often because the law mandates it, screening for metabolic disorders, including galactosemia, phenylketonuria, maple syrup urine disease, and disorders of metabolism of other amino acids. If these simple screening tests were not performed or their validity is in doubt, they should be done again. Usually the service is available in the state or county laboratory. Thyroid screening for abnormal thyroxine ( $T_4$ ) or thyroid-stimulating hormone should also be performed. Mass screening programs for neonatal thyroid disease have identified cases of deficiency that, even in retrospect, were not in evidence; the infant showed none of the characteristic findings of hypothyroidism, such as thick coarse features, hoarse cry, slow pulse, macroglossia, umbilical hernia, and jaundice. In the neonate, hypothyroidism is often associated with failure to thrive if undiagnosed and untreated.

**Galactosemia.** Galactosemia, which is a hereditary disorder of the metabolism of galactose-1-phosphate, is manifest by renal disease and liver dysfunction after ingestion of lactose. The lack of galactose-1-phosphate uridyltransferase activity may be relative or partial. The clinical symptoms may be fulminating, with severe jaundice, hepatosplenomegaly, weight loss, vomiting, and diarrhea, or may be more subtle. Cataracts are not invariably present. In mild cases, failure to thrive may be the presenting symptom. A urine screen for reducing substances (by Clinitest and not Dextrostix, which will only identify glucose) should be done on all infants who fail to thrive, especially if there is hepatomegaly or jaundice.

The definitive diagnosis is the identification of absence or near absence of galactose-1-phosphate uridyltransferase activity in red blood cell hemolysates. Even though a routine initial metabolic screen for galactosemia was done on the second

or third day of life, a urine screen should be considered. The treatment is a lactose-free diet, which would mandate prompt weaning from breast milk to prevent further insult to the liver, kidneys, and brain. This is one of the few indications for prompt weaning from human milk. A formula free of lactose (e.g., Isomil, Nutramigen) is indicated. No medical indications exist, however, to use a lactose-free formula for a normal breastfeeding infant either to supplement or to wean from breast milk, which contains lactose. (Refer to pediatric texts on neonatal metabolic disorders for a full description of galactosemia; see also [Chapter 14](#).)

**Vomiting and Diarrhea.** Vomiting and diarrhea are unusual in a breastfed infant. Spitting up small amounts of milk after feedings is sometimes observed in otherwise normal infants and is of no consequence if it does not affect overall weight gain. Although pyloric stenosis is reportedly less common in breastfed infants, this phenomenon should be ruled out in any infant who vomits consistently after feeding, has diminished urine and stools, shows no weight gain or actually loses weight, and has reverse peristalsis. Usually these infants do well initially and then the vomiting becomes progressive.

Vomiting may be a presenting symptom for various metabolic disorders. Thus, metabolic disorders should be considered in the differential diagnosis. All possible metabolic disorders, such as congenital adrenal hyperplasia, are not routinely screened. These infants may present with vomiting and weight loss in the first week or two of life or with an acute episode of sepsis. The usual causes of vomiting, as well as the causes peculiar to breast milk, should be considered. Maternal diet should be checked for unusual foods. In families at high risk for allergy, intake by the mother of known family food allergens may cause symptoms in the infant. Diarrhea may be caused by foods in the mother's diet or her use of cathartics, such as phenolphthalein.

**Chronic Infections.** Chronic fetal infection in utero, which predisposes a SGA infant to intrauterine growth failure, may continue to cause growth problems in the presence of adequate kilocalories. Chronic viral infections include cytomegalovirus, hepatitis, acquired immunodeficiency syndrome (AIDS), or other less common viruses (see [Chapter 13](#)).

**Acute Infections.** An infant who is not growing well may have an infection in the gastrointestinal tract; therefore, the nature of the stools is important. The urinary tract may be another site of infection not readily identified. If, however, the initial evaluation includes a urinalysis with microscopic evaluation and a white blood cell count and differential count, this can usually be ruled out (see [Chapter 13](#)).

**High Energy Requirements.** When the metabolic rate of an infant is increased, weight gain will be diminished or absent. When the infant is hyperactive with a strong startle reflex and sleeps poorly, consideration should be given to stimulants present in the milk as well as to neurologic disorders. When a mother drinks coffee, tea (including herbal teas), cola, or other carbonated beverages with added caffeine, the accumulated caffeine may be sufficient to make the infant irritable and hyperactive. The best treatment is to replace the caffeine-containing beverages (see Chapter 12). Some disorders of the central nervous system are associated with hyperactivity. Infants with severe congenital heart disease are constantly exercising to breathe and oxygenate and have greatly increased metabolic rates. For management of these special infants at the breast, see Chapter 14.

## Observation of Nursing Process

In addition to establishing that no obvious physical or metabolic reasons exist for the failure to gain weight, an infant should be observed suckling at the breast. Does the infant get a good grasp and suck vigorously? If not, what interferes? A receding chin, a weak suck, lack of coordination, the breast obstructing breathing, and mouthing of the nipple or other ineffectual sucking motions are some of the possibilities. If the problem is the suckling process, the infant may need assistance. This cause is more common with infants who have had some experience with bottles or rubber nipples or who use a pacifier. Small or slightly premature infants who were started on bottle feedings have trouble relearning the proper sucking motion with the tongue (see Chapter 8).

Bottle-feedings and pacifiers may have to be discontinued until the infant is more experienced at the breast. This will require a program of manually expressing milk to soften the areola, having milk at the nipple to entice the infant, and gently offering the nipple and areola well compressed between two fingers. If the infant has a receding chin or a relaxed jaw, it may help to have the mother hold the lower jaw forward by supporting the angle of the jaw with her thumb. The physician should examine the infant carefully to be sure the jaw is not dislocated, especially if a vertex delivery was done in the posterior position (sunny side up). The physician can easily move the jaw forward to relocate it.

Positioning the infant for the breast so the child directly faces the breast, straddling the mother's leg in a semiupright position, may work best. This is the position twins may assume when nursing simultaneously when they are 3 to 4 months old. Although it is not recommended routinely, for an infant with a receding chin or a cleft, having the mother lean slightly forward for latch-on may help. She should

then bring the infant upward as she sits back for the feeding.

It may be necessary to assist both mother and baby. If the infant by 2 weeks of age cannot maintain the breast in the mouth without the mother holding it, it is an indication of improper suckling. In that situation, the infant may need to be repositioned with the ventral surface squarely facing the mother's chest wall—that is, tummy to tummy—and the breast presented by the mother with her hand positioned with thumb on top and fingers below the breast. (See discussion in Chapter 8.) The mother may have to maintain support throughout the feeding. Failure to maintain the breast in the mouth has neurologic implications for long-term follow-up.

When infants have trouble maintaining the latch when the flow of milk is excessive and causes choking, the mother may try lying flat on her back holding the infant over the breast, which she supports with her hand. The flow becomes manageable and the infant's mouth relaxes and draws the breast in.

A good check of adequate let-down is to observe the opposite breast as the baby nurses to see if milk flows. It can also be tested by seeing if milk is flowing when nursing is interrupted abruptly. If let-down was good, milk will continue to flow, at least drop by drop, for a few moments from the breast that had been suckled. A mother can be trained to listen for the infant's swallowing. During proper suckling, the masseter muscle in the jaw is in full view and is contracting visibly and rhythmically. Swallowing can be seen and heard. The ratio of suck to swallow is 1:1 or 2:1. Occasionally, infants do not suck vigorously at the breast but occasionally use rapid shallow sucks called "flutter sucking" with little or no swallowing. These infants can be gradually taught to suck effectively. Correct positioning of the breast directly in the infant's mouth and holding the breast firmly in position with all the fingers under the breast and only the thumb above allow the infant to grasp properly without sucking the tongue or lower lip. Nipple shields usually make the situation worse.

The most productive part of the diagnostic work up is often observation of the baby at the breast. For this reason, this critical responsibility should not be passed on to others but should be performed personally by the physician as well as an international board certified lactation consultant.

The five general types of nursing patterns described in Chapter 8 should be kept in mind. If the mother understands that it is acceptable for the infant to drop off to sleep and snack later, she may not hesitate to follow this lead, thus providing a more adequate feeding.

Some infants will not settle down and nurse well if there is too much activity or noise in the room. Some need to be tightly swaddled; others fall asleep and

need to be unwrapped and stimulated to provide adequate suckling time. Frequent feedings, using both breasts, may be the answer in some cases. In others, there may be too many ineffective feedings, which are wearing the mother out; a change that lengthens the time between feedings but also lengthens the time at the breast may help, especially if it is quiet and the chair allows mother to nap while feeding. Concentrating on using one breast at a feeding to increase the fat content may be the most effective change.

### **PSYCHOSOCIAL FAILURE TO THRIVE**

In the study of undernutrition in bottle-fed infants and infants beyond the suckling age, terminology has received more attention than the underlying issues. Thus, the emphasis has been on "organic" versus "nonorganic" failure to thrive. A disorder of maternal/infant bonding has become synonymous with maternal deprivation. *Reactive attachment disorder* has been the term substituted for psychosocial failure to thrive. When an infant does not have an organic disorder that explains the growth failure, the patient is diagnosed as having psychosocial failure to thrive. The typical psychosocial and nutritional pattern reported in psychosocial failure to thrive includes evidence of a chaotic family life, emotional deprivation, and inadequate nutrition.

### **Prolonged Exclusive Breastfeeding**

Prolonged exclusive breastfeeding may occasionally result in a unique deficit in the developmental process of eating. Exclusive breastfeeding is not nutritionally adequate in the second half of the first year, especially beyond 12 months, although nursing can safely continue for several years when combined with adequate solids that provide protein, iron, and zinc.

The syndrome of the breastfed infant in the second 6 months of life with frequent breastfeedings, poor intake of complementary foods, and poor growth has been labeled a manifestation of "vulnerable child syndrome" by O'Connor and Szekely.<sup>92</sup> These children are described to have good weight gain for 5 to 6 months, but by 8 months their weight/height score has decreased dramatically. The intake of solid foods is minimal. These infants refuse solids, aggressively spitting food out. The breastfeeding pattern is usually every 1 to 2 hours during the day and frequently at night. Further investigation revealed numerous household stressors and usually the mother's need to maintain control by breastfeeding.

The growth of predominantly breastfed infants who live in underprivileged populations in developing countries falters between 4 and 6 months of age, but the reason has never been well understood. In developed countries, energy intake declines between 4 and 6 months but growth does not falter.

To determine whether growth faltering in this age-group was due to inadequate intake of human milk, the nutrient intakes of 30 Otami Indian infants from farms in Capulhuac, Mexico, were studied from 4 to 6 months. Growth velocities were not correlated with nutrient intakes. The children's growth faltered despite energy intakes comparable with those of children in more supportive and protected environments. The energy requirements of these children were significantly higher. Some infants in developed countries may live in equally challenging environments.

Parental misconception and health beliefs concerning what constitutes a normal diet for infants have been reported by Pugliese et al.<sup>96</sup> as a cause for failure to thrive as well. They reported seven infants from 7 to 22 months of age with poor weight gain and linear growth who received only 60% to 90% of minimum caloric intake for their age and sex. The parents explained that they wanted to avoid obesity, atherosclerosis, or junk food habits. It has also been shown that parental health beliefs and expectations have led to short stature and delayed puberty in older children.

### **Fruit Juice Excess**

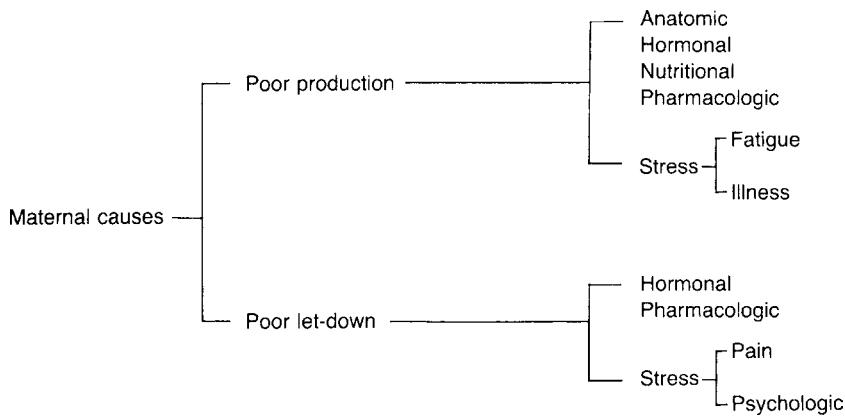

The custom of excessive use of fruit juices in recent decades has replaced the use of water for additional fluids after 6 months of life when the infant is learning to drink from a cup or a straw. The attractive packaging has contributed to this trend. Excessive fruit juice diminishes appetite, resulting in decreased dietary intake of nutrient-dense foods and a decrease in weight gain and ultimately in linear growth. An excess of fruit juice may be a cause of failure to thrive in older infants. Decrease in total high-energy intake is combined with malabsorption of fructose and diarrhea from sorbitol, thus compounding the problem.<sup>101</sup> Excessive fruit juice intake in infancy is a major nutrition problem because juice has low nutrient value but high calories. The AAP has developed a guideline with restrictions on the use of fruit juices. For older children, their high caloric content may be a contributor to obesity.

### **Maternal Causes**

Questions about a mother's health, dietary habits, sleep pattern, smoking habits, medication intake, the events that occur during nursing, and the psychosocial atmosphere in the home are an important part of the history (Figure 11-2).

### **Anatomic Causes**

Lactation failure from insufficient glandular development of the breast has been described by Neifert

**Figure 11-2.** Maternal causes of failure to thrive.

and Seacat<sup>90</sup> and Neifert et al.,<sup>89</sup> who report three cases in which the breast tissue was asymmetric. Transillumination confirmed a minimally active gland. One family showed a history of similar failure. All three women benefited psychologically from the diagnosis and chose to continue to breastfeed and supplement. The authors have since identified 14 more women who had anatomic deficiency but normal prolactin levels and failed to respond to a thorough team approach to lactation support.<sup>82</sup> Retained placenta is also a cause of early lactation failure that is quickly identified by a complete history of postpartum breast change and patterns of lochia that an obstetrician associates with retained tissue (see Chapter 16). If prolactin response to stimulus is adequate, ultrasonography can determine the presence of adequate mammary tissue and ductal arborization.

### One-Breast Versus Two-Breast Feeding

An infant whose failure to thrive was traced to inadequate fat intake associated with using both breasts, each feed resulting in low fat (and relatively high lactose by comparison), caused the debate regarding using one or two breasts during each feeding to be rekindled. When this infant was fed at one breast per feeding, the low-density feeding changed to high-fat feeding, resulting in decreased stooling and increased weight gain. Some women require more time to release fat into the milk, and limiting the feeding to one breast enhances fat content. In some cases this is true, and it is further verified by an infant fed at both breasts having many loose stools because of the high lactose and considerable gassy discomfort that also resolves with the change to single-breast feeds.

In early lactation, when milk supply is being established, mothers may be encouraged to nurse on both breasts at each feed to provide frequent

stimulus. A clinician, however, should obtain a thorough history of feeding frequency and distribution between breasts, especially when the infant is well hydrated, has many stools, and may or may not be fussy but fails to gain weight, remaining less than birth weight for several weeks. The need for higher fat content in the feeding may be a consideration in the slow-gaining baby as well. An adjustment in feeding to enhance the fat content should be tried. Usually limiting each feeding to one breast will do that (see Chapter 8). However, some women have smaller storage capacity than others, as demonstrated with ultrasound imagery by Hartmann et al.<sup>49</sup> These women need to feed from both breasts at each feed. Storage capacity ranges from 100 to more than 250 mL per breast.<sup>49</sup>

### Poor Milk Production

**Diets.** Although it has been demonstrated that malnourished mothers can produce milk for their infants, marginal diets in Western cultures do affect some mothers' ability to nourish an infant. A case of failure to thrive in a breastfed infant associated with maternal dietary protein and energy restriction was reported.<sup>85</sup> The mother, at 8 months postpartum, independently reduced her dietary energy to 20 kcal/kg/day and her protein to 0.7 g/kg/day to treat cholecystitis medically and avoid surgery. At 12 months, her infant's growth curves had fallen below the 5th percentile in both weight and length, although the infant had been receiving solid foods since 24 weeks of age. The authors concluded the failure to thrive was directly related to severe maternal restriction.<sup>85</sup>

Dietary analysis and maternal anthropometry showed that women who gained adequate weight and skin thickness during pregnancy had increased milk production and weight gain in their infants for the first 6 months of life.<sup>30</sup>

If a mother is restricting intake deliberately or inadvertently, she should be instructed to meet the dietary requirement for lactating women (a minimum of 1800 kcal/day for adequate nutrient intake) (see Chapter 9). She does not have to drink milk, but the necessary dietary constituents should be in the diet through cheese, eggs, ice cream, or other sources of calcium and protein. It may not be the nutrition itself but the calming effect of a nourishing beverage while breastfeeding that facilitates nursing. Studies of hormones triggered while eating have shown that more milk is produced if a mother eats just before or during breastfeeding. Prescribing brewer's yeast as a dietary supplement has been observed to provide improvement in milk production beyond that accounted for by mere addition of the same nutrients. Some mothers report a feeling of well-being from taking yeast that they do not obtain from taking daily vitamins. Concern has been expressed regarding the effect of increased vitamin B<sub>6</sub> on prolactin production, but doses that suppress lactation are 60 times the therapeutic dose.

**Maternal Illness.** The presence of infection or other illness in a mother may affect milk production, and the cause of the illness should be identified and treated. Urinary tract infection, endometritis, or upper respiratory infection may need treatment with antibiotics. The antibiotic prescribed should be appropriate for the infant as well because it will pass into the milk. Metabolic disorders such as thyroid disease should also be considered. Postpartum hypothyroid disease is increasingly being recognized as screening tests of T<sub>4</sub> and thyroid-stimulating hormone are being done when a mother complains of severe "baby blues" or fatigue. Adequate treatment with thyroid hormone will result in increased milk supply.

**Fatigue.** The most common cause of inadequate milk supply is fatigue. Fatigue may be caused by lack of sleep because the infant demands considerable attention at night, but generally it is more subtle. The pressures of the rest of the family for meals or services or the self-inflicted demands of a job, career, or social commitments may be the cause. The mother must be placed on a medically mandated strict rest regimen that is respected by family and friends. In the first month, while lactation is being established, fatigue is devastating to milk production. The infant then becomes hungry more often, cries, and demands more frequent feeding; thus the vicious circle is established. In later months of lactation, a mother becomes quickly aware of the impact of protracted fatigue on the nursing experience and usually will take steps to increase her rest.

**Poor Release of Milk.** Interference with the let-down reflex may cause a well-nourished lactating mother to fail to satisfy her infant. The collecting ducts may be full, but if the let-down or ejection

reflex is not triggered, the process will be at a standstill. The infant becomes frustrated and pulls away crying or screaming. Interference with the ejection reflex, such as pain, fatigue, stress, smoking, and general environmental chaos, is predominantly iatrogenic and rarely hormonal (see Chapter 8).

Smoking may interfere with the let-down reflex. Mothers should be discouraged from ever smoking in the same room with the infant because of the occurrence of second-hand smoke predisposing to the early and frequent respiratory infections in infants of smokers. Smokers are less likely to breastfeed, and if they do choose to breastfeed, they tend to wean earlier because of insufficient milk. Trouble with milk production may be related to the nicotine itself. Extensive studies of smoking mothers have demonstrated a clear relationship between smoking and the amount of milk produced.<sup>54</sup> The infants of these mothers grow more slowly. Avoiding smoking for 2 hours before a feeding will improve the let-down reflex and minimize the amount of nicotine in the milk. Given the value of breastfeeding to the infant, especially in reducing the risk for sudden infant death syndrome, it is important that smokers try to reduce the smoke exposure but still breastfeed (see Chapter 16).

Experimentally, alcohol has been shown to interfere with oxytocin release in laboratory animals, but the dosage used correlates with moderate to heavy drinking in humans. Studies following the offspring of women who drink heavily have shown some delay in gross motor activity at 1 year using the Bayley developmental scales.<sup>72</sup> Other studies have suggested that alcohol changes the flavor of the milk and that infants nurse less well at a feeding immediately after the mother has had a drink.<sup>69,81</sup> This is contrary to observations over the years in countries where wine and beer are common beverages and are considered galactagogues (see Chapter 12).

The clinician should consider the impact of smoking or alcohol use in the context of reviewing inadequate milk production.

Medications that the mother may be taking should be evaluated. Although l-dopa and ergot preparations are known to inhibit prolactin release, other medications less well identified may have the same effect (see Chapter 12).

The most common cause for the failure of the ejection reflex is psychologic inhibition. In a few cases the cause of the psychologic stress may be obvious, such as a husband or mother who openly disapproves of breastfeeding, but in most cases the nursing mother has already considered this possibility and reassures the physician that she is relaxed and calm. It will require carefully assessing the mother's history to "tease out" the source of stress. This is the time when a home visit by the nurse practitioner from the physician's office or an experienced public health nurse will be valuable. The

nurse may observe what is overlooked by the mother: construction of a new building next door, incessant barking from the neighbor's dog, or marital discord. Home observation may lead to the source of the problem.

### No Obvious Cause

Even though no obvious cause for failure to thrive is identified, the treatment may have to include establishing a positive attitude. Jelliffe and Jelliffe<sup>58</sup> have often referred to nursing as a "confidence game." It becomes necessary to instill confidence rather than fear in the mother. Threatening a mother with stopping breastfeeding and switching to formula does not instill confidence. A physician should prescribe a positive plan for the number and length of feedings, suggest diet and rest for the mother, and set reachable goals for infant growth.

If the let-down reflex is the crux of the problem and simple adjustments have not changed the ejection quality, oxytocin as a nasal spray (Pitocin) can be prescribed (see Chapters 8 and 19). It is available only by prescription and should be used under the physician's guidance because of possible side effects in some women (e.g., headache, vasoconstriction), although it is not dangerous. Oxytocin nasal spray does not affect the milk or the infant. It is contraindicated only in pregnancy or hypersensitivity. Nasal spray Syntocinon is no longer available commercially; it can be prepared by a pharmacist placing Pitocin in a nasal dropper.

Seven mothers whose breastfed infants were contented but starving were given metoclopramide (or chlorpromazine in one) in various dosages.<sup>45</sup> Only one mother thought it was not helpful. The authors did not describe how effective appropriate supportive breastfeeding management was and when the medication was started or how long it was maintained. All the infants gained weight, and breastfeeding was continued for 2 to 12 months.

Other authors have also reported the recovery from lactation failure by mothers taking metoclopramide (10 mg three times per day).<sup>8</sup> Gupta and Gupta<sup>44</sup> report a 67% success rate in those with no milk and 100% recovery in those with an inadequate supply. The effect continued after the drug was discontinued. Such a medication is useful only when accompanied by appropriate instructions for proper breastfeeding and assistance in using a breast pump for additional stimulus to increase the supply of milk mechanically. A medication should be prescribed only when routine methods fail. Effect of the drug may dissipate if the infant is still unable to go to the breast. Domperidone (Motilium), a peripheral dopamine antagonist, is known to enhance milk production, although clinical experience in blinded controlled studies is absent. Available internationally but not in the United States, it

has to be ordered by prescription. It is antidotedly reported to enhance milk production with a dosage of 10 to 20 mg orally three to four times per day.<sup>46</sup>

Measurement of prolactin levels is readily available in most laboratories, but the appropriate clinical protocol has not been confirmed by controlled study. Given the information about baseline and response to stimuli (see Chapter 3), it would be advisable to obtain a baseline level, which should be above normal for the laboratory, and a second value after 10 minutes of breastfeeding. Using a heparin lock with venous line placed well before the baseline specimen is drawn and before feeding ensures the least disturbance to lactation. The intrafeeding value should show a significant increase over baseline (twice baseline).

A group of women diagnosed with lactation insufficiency by history were given thyrotropin-releasing hormone (TRH).<sup>46</sup> Four received 5 mg every 12 hours for 5 days. A consistent 50% increase in prolactin concentrations was seen. Both milk production and let-down were increased. Nine women received 20 mg twice per day, and baseline prolactin was significantly elevated. The women reported subjective and objective increases in breast engorgement and milk let-down, and all returned to full nursing. Two women were given 40 mg TRH daily for 5 days and developed clinical signs of thyrotoxicosis by the seventh day, which disappeared by the tenth day. The investigators<sup>46</sup> had previously given TRH to fully lactating women in a controlled study to demonstrate prolactin response, which occurred within 60 minutes. No change in milk volume or quality in these fully lactating women and no side effects were observed. When Hall and Kay<sup>47</sup> gave 200 mg TRH and followed prolactin and milk production for 6 hours, no dramatic changes in milk production were observed, although the prolactin levels rose. There is no indication that the mothers received more than 1 day's dose. Such therapy has not become clinically available.

A rare infant who does not respond to management adjustment may have a malabsorption or metabolic disease as yet undiagnosed that will not become overt until the child is exposed to formula or cow milk. Infants with a strong family history of cystic fibrosis, milk allergy, or malabsorption should have a careful diagnostic work up before abandoning human milk, which may be the most physiologic feeding available for the infant. Neonatal metabolic screening tests should be repeated.

### Dehydration, Hypernatremia, or Hypochloremia

A few cases of severe disease have been reported in the literature. These infants were hospitalized because of dehydration and evidence of more severe metabolic disturbance. They serve to illustrate the

outcome if anticipatory care or palliative home management is unsuccessful. The mothers are usually but not always primiparas, new at breastfeeding and child rearing. When the record is reviewed, one often sees that the early danger signs were present at discharge from the hospital. The mother may have a history of difficult delivery or be taking medication for pain that leads to a less vigorous baby and, secondarily, inadequate stimulus for lactation. Supplementary bottles of water or milk were initiated in the hospital instead of directing attention toward the lactation process.<sup>15,2</sup>

As a precautionary measure, a physician should see all breastfeeding dyads promptly. At this visit, review of the weight, feeding history, number of wet diapers, stool pattern, and physical findings should alert the physician to impending difficulties. Observation of the infant at the breast should be part of the assessment. A problem in monitoring breastfed infants is the use of ultraabsorbent diapers, which makes it impossible to detect the number of voidings or volume of urine passed. No specimen can be wrung from the diaper for specific gravity or other analysis. It is recommended that parents of infants younger than 2 months not use ultraabsorbent diapers, especially when the infant is breastfed, until a better monitoring device is developed or until breastfeeding is well established. If, on the other hand, the patient is not seen in the office until there is significant dehydration, it is urgent that laboratory studies, including those for sodium, chloride, potassium, pH, blood urea nitrogen, and hematocrit (bilirubin when indicated), be obtained. An assessment of the degree of dehydration should be made based on skin and tissue turgor and tone and urinary findings.<sup>38,51</sup>

When a breastfed infant has abnormal electrolyte levels, the physician should also obtain levels of sodium, chloride, and potassium from the mother's milk, being certain to sample each breast separately.<sup>15,2</sup> Collecting a few milliliters at the beginning and the end of the feeding and mixing the two samples from a single breast is a good technique. The infant may have occult loss of electrolytes, such as that seen in abnormal renal wasting or retention, cystic fibrosis, hyperaldosteronism, or pseudohyperaldosteronism. The simplest approach is to measure milk electrolytes and infant urine levels to rule out high milk sodium as a cause of the infant's hypernatremia. Weaning milk has elevated sodium or it occurs when lactation is failing.

In reported cases, infants with hypernatremic failure to thrive are no different at initial presentation from infants with normal sodium levels.<sup>15,68</sup> They may even have a negative neonatal history. At home they develop a poor suck, sleep for long intervals, cry infrequently, and feed infrequently. When observed at the breast, they may be labeled

as having a sucking disorder. On examination, however, the lethargy, dehydration, and malnutrition are obvious to a skilled clinician. In the extreme, the infant may have cardiovascular collapse with hypothermia and hypoglycemia. Elevated serum blood urea nitrogen, creatinine, and hematocrit and urinary specific gravity confirm the diagnosis. Hypernatremia has been observed in approximately half the reported cases of severe dehydration in breastfed infants.<sup>15,38</sup> Although milk sodium levels were not reported in all cases, several cases of elevated milk sodium are reported. Sodium, chloride, and lactose are the prime constituents that control the osmolarity of the milk. Because the sodium, chloride, and lactose have a reciprocal relationship, inadequate lactose production ultimately results in elevated sodium level (see Chapter 4).<sup>15,51</sup>

Elevated sodium in the milk may be a cause or an effect of insufficient milk. When the breast is inadequately stimulated, it begins to involute and produces "weaning milk," which is high in sodium. Milk pumped from nonlactators in the postpartum period has high sodium. Maternal sodium intake excesses do not result in elevated sodium levels in the milk, however.<sup>28</sup> Sodium enters the milk by a controlled mechanism independent of maternal levels in normal women. Milk sodium is much lower than serum sodium, whereas milk potassium is much higher than serum levels.

Hypernatremic dehydration is an emergency that requires hospitalization.<sup>68</sup> The mother should room-in if at all possible. Most pediatric units provide this option. It is preferable to maintain lactation in most cases. The treatment of the illness after the dehydration has been treated with intravenous fluids depends on the etiology of the hypernatremia. The sodium of an infant's serum and mother's milk should be followed until normal. Increasing maternal milk output with appropriate lactation counseling, including mechanical pumping between feedings to increase volume, usually normalizes the sodium. The oral feedings for the infant should be limited to breastfeeding after milk sodium is normal while the intravenous fluids are tapered. To provide increased caloric resources to the infant and an appropriate sodium load, the Lact-Aid supplementer (see Chapter 19) may also be used to stimulate the breast and to avoid bottle feeding and inadequate intake until the breast increases production.

Chloride deficiency has received attention because of a highly publicized formula-manufacturing error. This syndrome is characterized by failure to thrive with anorexia, hypochloremia, and hypokalemic metabolic alkalosis. Chloride deficiency syndrome has also been reported in an infant whose mother had only 2 mEq/L chloride in her milk (normal 8 mEq/L).<sup>51</sup> The mother had successfully

nourished her previous five infants. The infant had done well until 3 months of age and then had gradually slipped below the 3rd percentile for weight at 6 months. The infant was severely dehydrated and hypotonic with plasma sodium of 123 mEq/L, chloride of 72 mEq/L, potassium of 2.9 mEq/L, and blood pH of 7.61. There were no abnormal urinary losses. When the breastfeeding infant has clinical dehydration, it is important to check not only the sodium but also the chloride content of the infant's serum and urine and the mother's milk.

Human infants younger than 3 weeks of age do not respond to inappropriate solutions by not sucking. This finding is also observed in studies in other species in which pups continue to suck when the solution is unphysiologic. A natural experiment occurred in a newborn nursery in the 1960s, when six infants died of hypernatremia after receiving many feedings of formula made from salt rather than sugar.<sup>33</sup> The infants who were less than 1 week old did not reject the feedings.

### Lactation Failure

Occasionally, failure to thrive is actually caused by lactation failure. Historically, sudden complete cessation of lactation was described in the late 1800s after horse-drawn carriage accidents and other great trauma. Advocates of breastfeeding have tended to dismiss this as a possibility and struggle frantically to reverse the situation. Some women who cannot make milk have primary hypoprolactinemia, and others have secondary hypoprolactinemia, as in Sheehan syndrome (see Chapter 16). Because it is now possible to identify these women by obtaining prolactin levels that confirm the diagnosis,<sup>111</sup> when reasonable efforts at stimulation are ineffective and the mother is unable to do without the Lact-Aid providing almost a full feeding volume, evaluation of the mother is appropriate. Some mothers prefer to discontinue efforts to breastfeed before they have been completely stripped of their self-esteem by total failure.

If one explores the animal literature, one finds no similar situations in other species. Lactation failure in nursing animals is rare—it is not a trait that is transmitted from generation to generation because the offspring do not survive. Interferences with milk ejection can be identified and treated in some mammals. A syndrome in sows involves agalactia associated with mastitis and metritis.<sup>19</sup> Mammalian lactation failure is attributed to nutritional, pharmacologic, and "emotional stress" causes in animals. Aside from gross dietary deficiency, there is depression or inhibition of the anterior pituitary gland, which is responsible for synthesis in the alveolar cells, and inhibition of transport and discharge of synthesized products from alveolar cells to the

lumen. Certain plant alkaloids have been noted in other species to inhibit lactation. Ergot derivatives are best known, but colchicine, vincristine, and vinblastine are also causative. Some plant lectins such as concanavalin interfere with transport and discharge phases of milk production.

Understanding lactation failure is increasing among clinicians as the diagnostic resources expand.<sup>111</sup> Some herbs may inadvertently suppress lactation. A thorough history of herbal use is always appropriate in any clinical assessment.

### *Maternal and Infant Obesity and Breastfeeding*

It is generally recognized that women who breastfeed return to their prepregnancy weight more quickly and in greater numbers than do bottle feeding mothers.<sup>104</sup> When lactation performance was examined, Hilson et al.<sup>52</sup> reported that overweight or obese women had less success initiating breastfeeding than their normal-weight counterparts. The rates of discontinuance of exclusive breastfeeding in overweight and obese women were also higher, even when socioeconomic status and maternal education were controlled. The population was predominantly white. When the study was conducted on a minority population in Rochester, New York, the Hispanic obese women were poor lactators, but black women's lactation was not affected by obesity.<sup>64</sup> The authors conclude that excessive fatness in the reproductive period may inhibit lactational performance.

Discussion of the impact of adiposity is rarely undertaken without including a discussion of cholesterol levels. Obesity and atherosclerosis in developed societies constitute a major public health issue. Does breastfeeding in infancy protect against obesity and atherosclerosis in adult life? This remains an open question. Energy requirements for infants receiving formula have been overestimated.<sup>10</sup> Breastfed infants require and receive 110 kcal/kg/day at 1 month and 70 kcal/kg/day at 4 months. The low energy intakes are not caused by limitations in maternal milk production as previously assumed but represent physiologically regulated intakes. Breastfed infants deposit less fat than formula-fed infants despite the fact that the two diets appear similar on paper. Although the breastfed infant appears protected against obesity in infancy, the effect appeared to be lost after 3 years of age according to Hamosh.<sup>48</sup>

A prospective cohort study of 462 healthy full-term infants observed from birth to 12 months was done by Kramer et al.<sup>62</sup> Their goal was to overcome methodological defects in previous studies of the

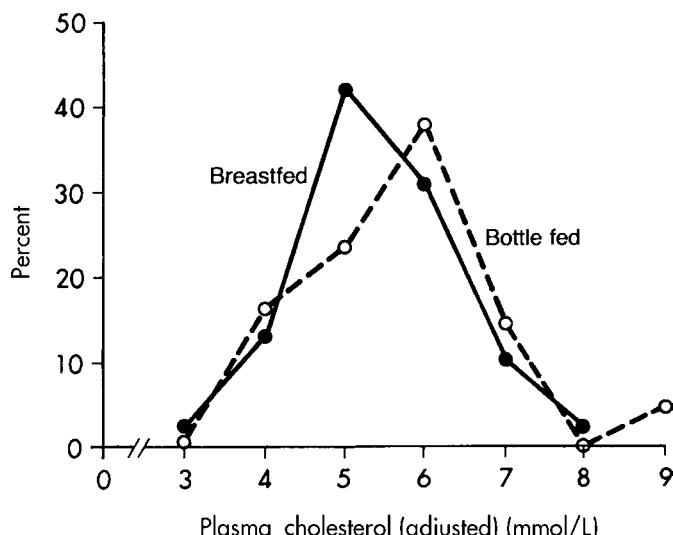

etiological determinants of childhood obesity that failed to control for confounding factors. At 6 and 12 months, measurements of height, weight, BMI (weight/height<sup>1</sup>), and skinfold were taken and correlated with duration of breastfeeding, introduction of solids, and parental heights and weights. Significant determinants of BMI were birth weight, duration of breastfeeding, and introduction of solid foods. Breastfeeding and delayed introduction of solid foods offered some protective effect against obesity at 1 year in this study.

The effect of breastfeeding on plasma cholesterol and weight in young adults was studied longitudinally by Marmot et al.<sup>78</sup> in a sample of people born in 1946. The infant-feeding history was obtained. At age 32, women who had been breastfed had significantly lower mean plasma cholesterol than women who had been bottle fed (Figure 11-3). The difference for men was smaller, and men who had been breastfed had higher mean weight and skinfold thickness. Multiple studies, both short- and long-range, with small populations and conflicting results have been reported in humans, although animal studies strongly suggest that species-specific milk reduces the risk for obesity and elevated cholesterol.

Indices of fatness and serum cholesterol at age 8 years in relation to feeding and growth during early infancy were reported by Fomon et al.<sup>34</sup> from their detailed longitudinal nutrition project involving 469 children born between 1966 and 1971. In infancy, the formula-fed children had more rapid gains in height and weight, which were attributed to greater food intake. At age 8, there were no differences in indices of fatness related to mode of feeding during infancy and no significant differences

in serum cholesterol concentrations. Breastfeeding in infancy has been associated with decreased coronary heart disease mortality, but the mechanisms are unclear. In a prospective study of 7276 singleton term infants born between 1991 and 1992 and followed to 7.5 years, the systolic and diastolic blood pressures of the breastfed infants were lower compared with those never breastfed (1.2 mm and 0.9 mm, respectively). Even partial breastfeeding had an effect. A further reduction in systolic pressure (0.2 mm) was seen for each 3 months of breastfeeding. Outcome was adjusted for social and economic parameters.<sup>87,108</sup>

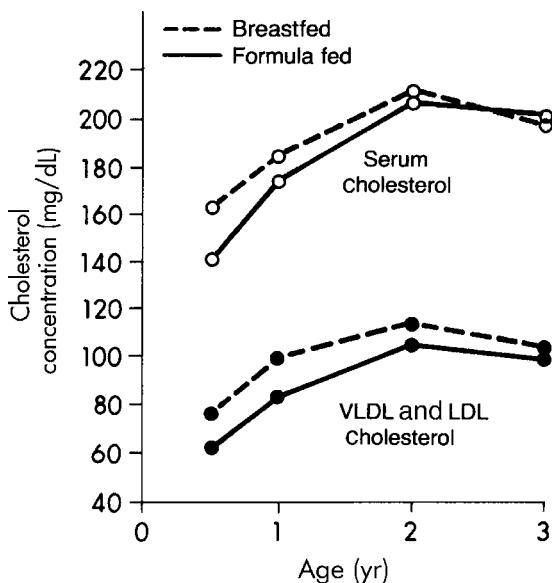

Serum cholesterol may be too insensitive a quantitation to detect early changes and classify lipoprotein classes, and apoprotein concentrations may be necessary.<sup>48</sup> The effects of breastfeeding versus formula feeding are not attributable to differences in cholesterol intake. According to Mott et al.,<sup>87</sup> varying the cholesterol content of infant formulas, which normally contain no cholesterol, has not reduced long-lasting differences in serum cholesterol or lipoprotein concentrations or in cholesterol metabolism. Lack of control of genetic differences and sampling under uncontrolled dietary conditions have limited the interpretation of many human studies. Mott et al.<sup>87,88</sup> performed a long-term study with 83 baboons to determine the effects of infant diet (breastfeeding versus formula feeding and the level of cholesterol in the formula). The type of dietary fat and level of dietary cholesterol as well as sex and heredity were reviewed. The progeny of 6 sires and 83 dams were randomly assigned to diet groups of breastfeeding or formula with 2, 30, or 60 mg/dL, respectively, of cholesterol. The 30 mg/dL milk resembled baboon milk. They

**Figure 11-3.** Plasma cholesterol in adults according to type of infant feeding. (From Marmot MG, Page CM, Atkins E, et al: Effect of breastfeeding on plasma cholesterol and weight in young adults, *J Epidemiol Community Health* 34:164, 1980.)

were weaned to controlled juvenile diets. The differences in cholesterol content of the formula did not lead to later differences in serum cholesterol, lipoprotein concentrations, or cholesterol metabolism. Breastfeeding (species-specific milk), however, affected the subsequent cholesterol metabolism, with absorption of a higher percentage of cholesterol and lower cholesterol production rates as juveniles. The baboons were bred for high or low serum cholesterol concentrations, and in both groups the breastfed animals had higher very-low-density lipoprotein (VLDL) and low-density lipoprotein (LDL) cholesterol levels from 6 months to 3 years than formula-fed animals and higher serum cholesterol from 6 months to 2 years (Figure 11-4). Baboons are vegetarian, however, and the weaning diet was not, which may have altered the results.

Overfeeding was a variable in a study of preweaning food intake influences on the adiposity of young adult baboons reported by Lewis et al.<sup>70</sup> Overfeeding did not have a major effect on the fat cell number. Overfed male baboons had a greater fat mass in 4 of 10 fat depots at necropsy at age 5 years. Overfed female baboons had significantly greater fat depot mass in general primarily because of fat cell hypertrophy. Underfeeding in the preweaning period did not affect body weight or adipose mass in either sex in the juveniles.

**Figure 11-4.** Cholesterol, very-low-density lipoprotein (VLDL), and low-density lipoprotein (LDL) in baboons: breastfed versus formula fed. Open circle, Serum cholesterol; closed circle, VLDL and LDL cholesterol; solid line, formula fed; dashed line, breastfed. (From Mott GE: Deferred effects of breastfeeding versus formula feeding on serum lipoprotein concentration and cholesterol metabolism in baboons. In Report of 91st Ross conference on pediatric research: the breastfed infant—a model performance, Columbus, Ohio, 1986, Ross Laboratories.)

Mott<sup>88</sup> suggests that the long-term effects of breastfeeding on cholesterol metabolism are not likely to result from the differences in neonatal cholesterol intake but rather from other components of breast milk, such as fatty acid composition, immunoglobulins, and hormones that might affect cholesterol metabolism.<sup>88</sup>

Formula-fed infants are metabolically different from breastfed infants at the level of lipid and energy metabolism (carnitines, ketone bodies, and Krebs cycle). The combination of maternal obesity in early pregnancy and high protein intake in infant formula feeding may predispose to obesity risk in later life.<sup>79</sup>

A practical measure of obesity is BMI.<sup>96</sup> Using the chart (Figure 11-5), the BMI can be determined by plotting for an individual adult the point where the height and the weight intersect. That is the BMI. It can be mathematically calculated as follows:

$$P = V \times I$$

$$\text{Weight (kg)} = \text{BMI} \text{ (metric)}$$

$$\text{Height (m)}^2$$

$$\text{Weight (lb)} = \text{BMI} \text{ (English)}$$

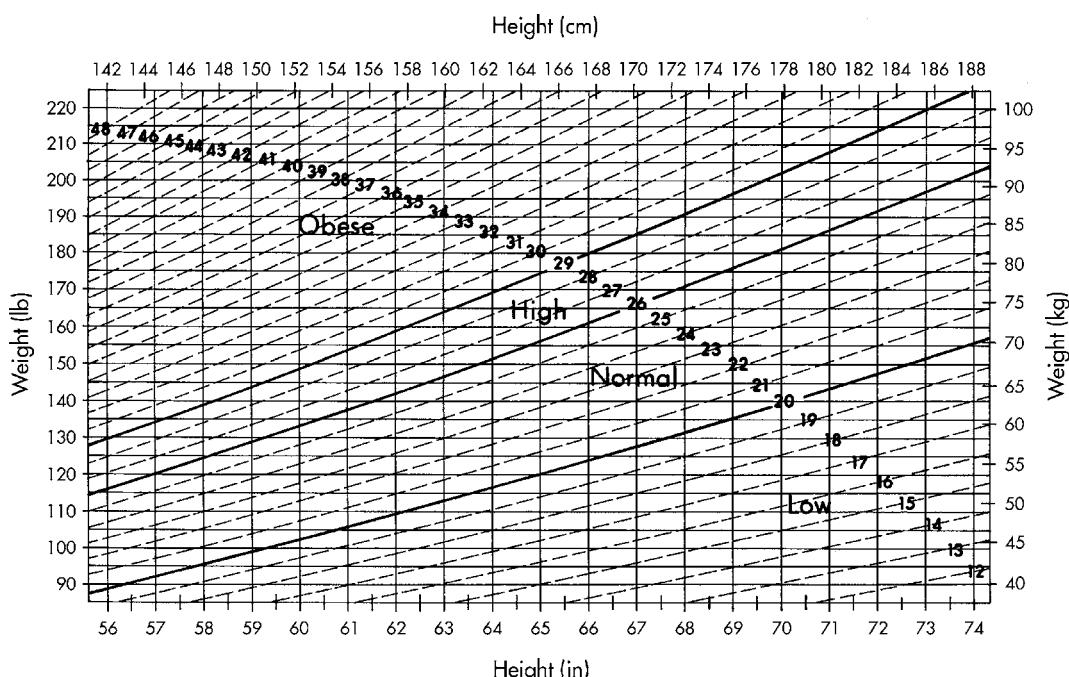

$$\text{Height (in)}^2$$

A normal BMI is 19.8 to 26, overweight is 26.1 to 29.0, obese is over 29, and underweight is under 19.8. This measurement is a more useful and universal index of obesity (Table 11-2).

An infant with a heavy bone structure and musculature but without excessive fat may appear to be obese based on the categories in Table 11-3. Infants who are overfed also grow in height and may be in an advanced percentile for height. An infant who is born with a weight in the 80th percentile (weight-for-age) and remains there may not be obese, but the infant who is born with a weight in the 50th percentile and crosses percentiles over time to the 80th percentile may be at risk for long-term obesity. Therefore, some discretion is advised when using percentiles for determining obesity.

Restraint of growth and development during critical periods of fetal life and infancy has an important effect on the development of cardiovascular disease, as reported by Barker<sup>4</sup> in a long-range study of 6500 men born between 1911 and 1930 in England; 95% of the men were breastfed, 20% of these for more than a year. Barker notes the significance of fetal growth and growth in the first year of life being unrelated to social class and cardiovascular disease in adult life when most infants had the advantage of breastfeeding.

Serum cholesterol levels (total and LDL) at ages 60 and 70 were higher in those men who had been bottle fed or exclusively breastfed beyond 1 year. These data and other studies were reviewed by Fall,<sup>29</sup> who also concludes that adult serum

**Figure 11-5.** Chart for estimating body mass index (BMI) category and BMI. To find BMI category (e.g., obese), find point where woman's height and weight intersect. To estimate BMI, read *bold number* on the *dashed line* that is closest to the point. (From Subcommittee on Nutrition During Lactation, Committee on Nutritional Status During Pregnancy and Lactation: *Nutrition during pregnancy and lactation: an implementation guide*, Washington, D.C., 1992, National Academies Press.)

**TABLE 11-2** Weight Classification According to Body Mass Index (BMI)

Relative Weight Classification	Prepregnant BMI
Underweight	<19.8
Normal	19.8-26.0
Overweight	26.1-29.0
Obese	>29.0

From *Nutrition during pregnancy and lactation: an implementation guide*, Washington, D.C., 1992, National Academy Press.

cholesterol concentrations and death rates from ischemic heart disease are related to method of infant feeding and age at weaning. Exclusive breastfeeding (i.e., no weaning foods or solids until the infant is older than 1 year) is not recommended.

In a 7-year longitudinal study of children at the Slovak Academy of Sciences, the obesity rates in children breastfed for less than 3 months were substantially higher than those in children who had been breastfed longer.<sup>102</sup> Total serum cholesterol increased with age at weaning. The atherogenic index in 6-year-old children was best in those who were breastfed more than 1 month but not more than 3 months. The authors also report

breastfeeding advantages for respiratory disease, gastrointestinal disease, and thyroid levels.<sup>102</sup>

Findings from the European Youth Heart Study that followed 2192 randomly selected school children ages 9 to 15 years from Estonia and Denmark with insulin resistance, triglyceride levels, high-density lipoprotein cholesterol, and systolic blood pressure measurements were reported by Lawlor et al.<sup>66</sup> It was concluded that exclusive breastfeeding is causally associated with reduced systolic blood pressure and more dramatically the older the child. It was not so with other components of the metabolic syndrome, although the oldest subjects were younger than 16 years of age.<sup>1</sup>

In a study of adiposity in 4-year-old Anglo- and Mexican-American children, genetic and environmental factors other than infant-feeding practices had the greater influence.<sup>115</sup> Before age 4 years, breastfeeding and delayed introduction of solids to 6 months appeared to be associated with normal lean body mass and skinfold thickness.<sup>126</sup>

No benefits are derived from infantile obesity. The concern for obesity rests with the long-range outcome as an obese adult. The problem is that obesity in infancy predisposes the child to immobility and inactivity; thus, an obese infant lags on the developmental curve or at least has delayed gross motor skills. The question of whether obesity

Age (mo)	Tentative Definition of Infant Obesity			
	Males		Females	
	Length (cm) Less Than	Weight (kg) More Than	Length (cm) Less Than	Weight (kg) More Than

At each age, values for length for each sex are the 10th, 25th, 50th, and 75th percentiles, and values for weight are the 50th, 75th, and 90th percentiles, with the mean  $\pm 2$  standard deviations.

From Fomon SJ: *Infant nutrition*, ed 2, Philadelphia, 1974, WB Saunders.

in infancy predisposes the child to obesity in adult life has not been resolved satisfactorily.

Socioeconomic status and infant-feeding practices influence early childhood obesity. Encouragement and support of breastfeeding and other healthy feeding practices are what make the difference as reported to Gibbs and Forste.<sup>39</sup> To reduce

the negative association between SES and childhood obesity, these mothers should be provided breastfeeding support and infant-led feeding strategies.

Breastfeeding is related to slower growth during the first 12 months of life. Breastfed infants also consume less protein in infancy. In a large study of 5- and 6-year-old children, a consistent, protective, and dose-dependent effect of breastfeeding on overweight and obesity was seen. Conversely, rapid growth during the first year of life is associated with increased BMI at the age of 6 years in both sexes. In boys, high intake of protein in infancy could also contribute to childhood obesity.<sup>43</sup>

The growing epidemic of childhood obesity has become a major public health problem with both short- and long-term consequences, not the least of which is the increase in adolescent type 2 diabetes. A large number of studies have been carried out, and meta-analyses have wrestled with the merits of the dozens of these historical studies. There is a growing consistency of evidence supporting the conclusion that being breastfed lowers the risk for excess weight in childhood and may well lower the risk for excess weight in later life, perhaps because it affects long-term energy metabolism.<sup>41</sup> A study of 32,200 Scottish children showed that the prevalence of obesity was significantly lower in breastfed children, even after adjusting for socioeconomic status, birth weight, and sex. The conclusion was that breastfeeding is associated with a reduction in the risk for childhood obesity. Similar results were reported in a study of over 15,000 adolescents as part of the Growing Up Today Study in the United States.<sup>40</sup> Those who had been breastfed had a lower risk for being overweight during childhood and adolescence. More than 1000 preadolescent children followed in Germany also showed significantly decreased prevalence of being overweight.<sup>71</sup> In reviewing 11 studies of at least 100 participants, Dewey<sup>25</sup> found that eight showed a lower risk for being overweight in children who had been breastfed. The three studies that did not make that conclusion lacked information on exclusivity and duration. Studies that include children "ever breastfed" dilute the impact of significant breastfeeding. A systematic review of 28 studies involving 298,900 subjects that provided odds ratios from 61 studies published since 1966 demonstrated that breastfeeding protects against obesity. An additional 33 published studies of 12,505 subjects without odds ratios did not change the results.<sup>94</sup>

Because obese children have a high risk of becoming obese adults, 9357 German children who were 5 to 6 years old were evaluated for obesity using BMI. After adjusting for confounders, breastfeeding remained a significant protective factor against overweight and obesity.<sup>109</sup> A large cohort

of Chinese children who were 4–5 years of age were included in the final analysis who had complete records—42,550 out of 97,424 were reported. Longer duration of exclusive breastfeeding was associated with a lower risk of overweight in childhood.<sup>119</sup> The association of infant breastfeeding and age at introduction of solid foods with general and abdominal fat outcomes were actually explained by sociodemographic and lifestyle-related factors.<sup>27</sup> It appears that older children (i.e., adolescents) have many other interactive factors and the protective effect of breastfeeding is muted. The HELENA Study in 10 European cities involving 3528 adolescents measured body weight, height, skinfolds, waist circumference, and dietary intake. There was a nonsignificant effect of breastfeeding<sup>99</sup> in the more obese individuals. There are scientific challenges in life-course epidemiology. In most Western industrialized countries, child and adult obesity are strongly patterned by socioeconomic status, writes Kramer and colleagues.<sup>60</sup>

The preponderance of large studies have shown a clear impact on reduced risk for obesity in childhood and adolescence in breastfed infants, probably because large numbers reduce the impact of partial breastfeeding and short duration. No studies demonstrate a null hypothesis. Dewey<sup>25</sup> suggests the effect may be due to learned self-regulation of energy intake, metabolic programming in early life, and residual confounding by parental attributes.

The mechanism responsible for this effect on infants has been suggested to result from maternal feeding styles that are less controlling and more responsive to infant cues of hunger and satiety,

resulting in greater self-regulation of energy intake.<sup>105</sup> When the mechanism was tested in 1012 mother-infant pairs in Project Viva by Taveras et al.,<sup>105</sup> the protective effect of breastfeeding on future overweight was only partially explained by maternal feeding restriction. The possible chemical impact from human milk on appetite has been a question for some time. Initially leptin was studied as a possible appetite control mechanism. Human milk is also the source of various hormones and growth factors such as adipokines (leptin and adiponectin) as well as ghrelin, resistin, and obestatin, which are thought to control food intake and energy balance and which are found in human milk but not in formula.<sup>100</sup> Higher leptin levels and lower ghrelin levels in breastfed infants compared to formula-fed infants suggest an effect on growth and intake in infants who are breastfed. Adiponectin, a circulating adipocyte protein, is associated with lower obesity and is present in human milk. In a study of infants in the United States and Mexico, it was correlated with early growth and development, with higher levels associated with lower weight-for-age Z scores and weight-for-length but not length-for-age Z scores.<sup>112</sup> Milk levels were measured and appear in Table 11-4.

Breastfed infants are rarely obese. The usual cause of obesity in breastfed infants is the early addition of solids. Solids often provide excessive kilocalories. The obese breastfed infant should have the diet and feeding pattern scrutinized. If necessary, some restriction of prolonged feeding should be suggested. In the normal course of a breastfeeding, the fat content of the milk increases

**TABLE 11-4** Hormones in Breast Milk That Influence Growth

Hormone	Year of Discovery	Receptor	Detection of Receptor in Intestine	Main Functions	Year of Discovery in Breast Milk

over the duration of the feeding and satisfies the infant after 10 to 15 minutes of nursing.

Because of general agreement that, once established, childhood obesity often becomes chronic and resistant to treatment,<sup>78</sup> it is appropriate to focus attention on prevention and early intervention. The physician can counsel a family whose breastfed infant meets the criterion for obesity (above the 85th percentile for weight-for-length). The routine use of skinfold measurement as part of well-baby care will increase the ability to diagnose obesity because it distinguishes the constitutionally larger body frame from the fat infant.

Recommendations that will help to taper unusual weight gain include the following:

1. Limit excessive feedings that are being provided on the mistaken belief that all an infant's needs are nutritional.
2. Encourage nonnutritive cuddling. If feeding is a response to all distress signals, the infant may expect feeding inappropriately, causing dissociation between appetite and energy need.
3. Use exclusive breastfeeding, that is, no solids for 6 months.
4. Increase activity and energy utilization by encouraging movement rather than containing or restricting the infant in carriers or swaddling. For an older infant, encourage play activity and crawling and minimize sitting.
5. If growth excess is persistent, it is appropriate to obtain a sample of maternal milk to rule out the rare case of hyperlipidemia with a "creamatocrit" (see Chapter 21).

The Endocrine Society Clinical Practice Guideline based on expert opinion prepared a document, "Prevention and Treatment of Pediatric Obesity." It defines overweight as BMI in at least the 85th percentile but less than the 95th and obesity as at least the 95th percentile. It emphasizes prevention of obesity by recommending breastfeeding for at least 6 months as well.<sup>107</sup>

# *Medications, Herbal Preparations, and Natural Products in Breast Milk*

---

As more women breastfeed and breastfeed longer in keeping with the World Health Organization (WHO) and the American Academy of Pediatrics (AAP) recommendations, questions about the safety of certain medications increase. A newer, excellent resource for information about drugs during lactation has been developed with the advice from an expert panel for the National Library of Medicine called LactMed. It is a drugs and lactation database, a peer-reviewed and fully referenced database of possible drugs used during lactation. The data include maternal and infant levels of drugs, possible effects on nurslings and on lactation itself, and a list of alternative drugs. The address is <http://toxnet.nlm.nih.gov/cgi-bin/sis/htmlgen?LACT>.

With the plethora of resources about drugs, many of which are available to the lay person and mother herself, there is the risk for an untrained person misinterpreting the data.<sup>16,22,64</sup> A major problem is even the professional untrained in lactation physiology who offers medical advice based on information gleaned from these resources. A professional needs to understand not just the plasma and milk levels but the pharmacology of the drug and physiology of lactation to give helpful instructions that will mitigate the effect of the drug on an infant and avoid discontinuing breastfeeding unnecessarily.

Despite the overwhelming advantages of human milk and the advantages of being breastfed, at times the risk of a maternal medication adversely affecting a nursing infant must be considered. Even when data about the medication, such as the milk/plasma

ratio, are available, a physician has to consider several factors related to each infant and each situation before deciding if breastfeeding can be initiated or continued.<sup>135</sup> The more complicated a mother's medical problems, the greater the possibility that the infant also has complications of prematurity or illness that will alter the ability to excrete the medication. This situation requires scientific information and experienced clinical judgment to appraise the problems and determine the therapeutic regimen. The clinician must determine the risk/benefit ratio of continued breastfeeding. The data are meager and sometimes conflicting for some drugs, yet maternal medication is the single most common medical problem in managing breastfeeding patients reported to the Breastfeeding and Lactation Center.

There are a number of general reviews of drugs in breast milk and hundreds of articles about the effect of a specific medication in a particular infant. The AAP Committee on Drugs<sup>22</sup> has published a list of drugs and other chemicals that transfer into human breast milk. The list, which is continually updated, is divided into those that are contraindicated, those that require temporary interruption of breastfeeding, and those that are compatible with breastfeeding. Concern about the issue of drugs in breast milk has spread. The U.S. Department of Health and Human Services and the Food and Drug Administration (FDA) have proposed a standard warning on all nonprescription drugs that are absorbed by the body: "As with any drug, if you

are pregnant or nursing a baby, seek professional advice before using this product." Because studies of pregnant women have shown that they take five to eight medications on their own during pregnancy and postpartum, clinicians' education of these patients needs to continue.

A study of more than 14,000 pregnant women in 148 hospitals in 22 countries revealed that 79% of women received an average of 3.3 drugs.<sup>22</sup> The drugs most often given were analgesics and anesthetics. Of the 91% of women who initiated breastfeeding, 36% received methylergonovine and 5% antibiotics. Another study of 885 women 3 to 5 months postpartum in Oslo showed that breastfeeding women took fewer medications (daily dose/1000 women/day) than nonbreastfeeding women.<sup>92</sup>

The most common medication in the latter group was oral contraceptives. Colds, dyspepsia, hemorrhoids, and breast infections were the disorders that precipitated the use of albuterol (salbutamol), clemastine fumarate (Tavist), dexchlorpheniramine maleate (cold preparations), phenylpropanolamine hydrochloride (Comtrex, Dimetane), cromolyn sodium, and methotrimeprazine hydrochloride (levomepromazine).<sup>92</sup>

No substitute exists for specific knowledge. It is equally inappropriate to discontinue breastfeeding when it is not medically necessary as it is to continue breastfeeding while taking contraindicated drugs.

Consideration of the pharmacokinetics contributes to the understanding of the problems involved. Some reported data have been extrapolated from experiments performed on cows, goats, and rodents. Bovine experiments have been conducted using continuous infusions, which provide data on the passage of a drug into milk under certain pH and plasma levels. In an effort to explain and clarify the issues involved, the literature has oversimplified the problem so that individuals lacking a background in pharmacology or pediatrics have misused the published data to draw unwarranted conclusions.

Factors that influence the passage of a drug into the milk in humans include the size of the molecule, its solubility in lipids and water, whether it binds to protein, the drug's pH, and diffusion rates. The following outline summarizes these factors:

- I. Drug
  - A. Route of administration
    - 1. Oral
    - 2. Intravenous (IV)
    - 3. Intramuscular (IM)
    - 4. Transdermal drug delivery system (TDDS)
  - B. Absorption rate
  - C. Half-life or peak serum time
  - D. Dissociation constant
  - E. Volume of distribution

- II. Size of molecule
- III. Degree of ionization
- IV. pH of substrate
  - A. Plasma: 7.4
  - B. Milk: 6.8
- V. Solubility
  - A. In water
  - B. In lipids
- VI. Protein binding more to plasma than to milk protein

Passive diffusion is the principal factor in the passage of a drug from plasma into milk. The drug may appear in an active form or as an inactive metabolite.

Finally, a most important factor that has received relatively little attention is the infant. Will the infant absorb the chemical from the intestinal tract? If the infant absorbs the chemical, can the infant detoxify and excrete it, or will minimal amounts in the milk build in the infant's system? Is the infant premature, small for gestational age, or high risk because of complications of the pregnancy or delivery? Is the drug a material that could be safely given to an infant directly, and at what risk? What dosages and blood levels are safe? These latter two questions are more critical than the pharmacokinetic theory. The ultimate question faced by the physician is, "Can this infant be safely exposed to this chemical as it appears in breast milk without a risk that exceeds the benefits of being breastfed?" Almost any drug present in a mother's blood will appear to some degree in her milk.

## *Characteristics of Drugs*

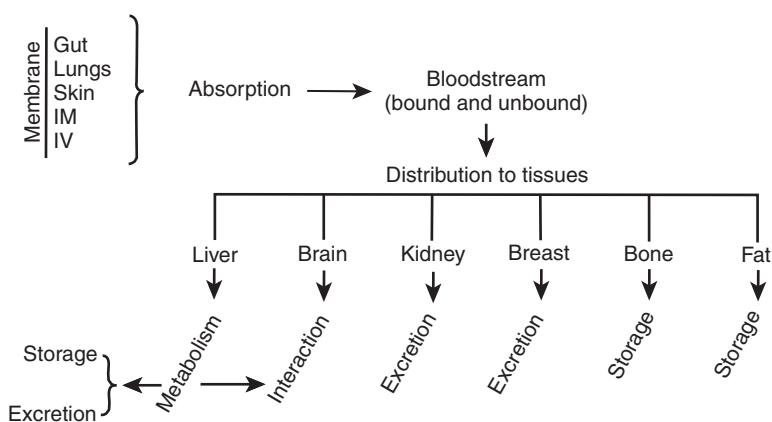

---

### **PROTEIN BINDING**

Drugs entering the circulation become protein bound or remain free in the circulation. The protein-bound component of the drug serves as an inactive reservoir for the drug that is in equilibrium with the free drug. Most drugs enter the mammary alveolar cells in the unbound form (Figure 12-1).

At term, plasma proteins may be reduced and the fatty acid and hypoprotein fraction slightly increased in the mother, which results in the displacement of some drugs from plasma proteins. During the early postpartum period, for 5 to 7 weeks the free fraction of some drugs increases and therefore more readily crosses into milk (e.g., salicylate, phenytoin, diazepam).

For most drugs, a higher concentration will be found in the plasma than in the milk. Only the small free fraction of drug can cross the biologic membrane. The total concentration in milk is only minimally influenced by binding of drugs in milk

**Figure 12-1.** Distribution pathways for drugs once absorbed during lactation. (Modified from Rivera-Calimlim L: The significance of drugs in breast milk, *Clin Perinatol* 14:51, 1976.)

proteins (milk protein concentration is 0.9% in mature milk). Only those drug molecules that are free in solution can pass through the endothelial pores, either by diffusion or by reverse pinocytosis. *Pinocytosis* is the process whereby drug molecules dissolved in the interstitial fluid attach to receptors located at the surface of the cell membrane. The cell membrane invaginates at the site of the drug attachment, bringing the drug into the cell. The membrane is pinched off, and the drug, surrounded by membrane, remains in the cell. Then the membrane is dissolved, leaving the drug molecule free in the cell.

*Reverse pinocytosis* is the process by which the apical membrane evaginates after fusion of the intracellular membrane-bound secretion granules with the plasma membrane. The granules include lipids, proteins, lactose, drug molecules, and other cellular constituents. The evagination of the plasma membrane is pinched off and released into the alveolar lumen. Within the extravascular space, the drug may be bound to proteins in the interstitial fluid. Some agents in free solution can pass into the alveolar milk directly by way of the spaces between the mammary alveolar cells. These paracellular areas account for a major portion of the fluid changes across the epithelium. These spaces between adjacent alveolar cells serve to carry water-soluble drugs from the tissue into the milk.

The intercellular junctions are "open" at delivery as lactation is being established and gradually "tighten" over the next few days. The amount of drug passed into milk on day 1 is greater than on day 3 or later. The composition of the milk changes from colostrum to mature milk, altering the amount of protein and fat, which could also influence drug levels in the milk. It is always important to know when plasma and milk samples were measured in relationship to the onset of lactation. Furthermore, some studies have been done on nonlactating women by pumping

enough milk to measure the drug. These "weaning samples" provide only misinformation.

## Ionization

Drugs that are nonionized are excreted in the milk in greater amounts than are ionized compounds. Depending on the pH of the solvent and the drug dissociation constant ( $pK_a$ ), many weak electrolytes are more or less ionized in solution. Blood plasma and interstitial fluid are slightly alkaline (pH 7.4). Drugs that are weak acids are ionized to a greater extent in alkaline solution and are more extensively bound to protein. The amount of drug excreted from plasma (pH 7.4) to milk (pH 6.8 to 7.3, average 7.0) depends on the pH of the compound. Thus a weakly acidic compound has a higher concentration in plasma than in milk. Conversely, weakly alkaline compounds are in equal or higher levels in the milk than in the plasma.

The degree of drug ionization changes with the pH of the plasma and milk. Weak bases become more ionized with decreasing pH; thus the ionized component will increase in milk. The concentration in plasma and milk for the nonionized fraction will be the same, but the total amount of drug in the milk will be greater than in plasma. The sulfonamides demonstrate the effect of the  $pK_a$  on the concentration of drug that reaches the milk. Sulfacetamide, with a low  $pK_a$  (5.4), has a low milk/plasma (M/P) ratio (0.08), whereas sulfanilamide has a  $pK_a$  of 10.4 and an M/P ratio of 1.00 (Table 12-1).

The studies done in cows and goats with constant infusions demonstrate this principle more dramatically because the pH of bovine plasma is 7.4 to 7.5 and the pH of bovine milk is 6.5. Under normal circumstances, however, concentrations of drugs are rarely constant, and there is a delay in achieving a new equilibrium. During periods of rapidly decreasing blood levels, some back diffusion occurs into the plasma.

Sulfonamide	Milk/Plasma Ratio	pK <sub>a</sub>
Sulfacetamide	0.08	5.4
Sulfadiazine	0.21	6.5
Sulfathiazole	0.43	7.1
Sulfamethazine	0.51	7.4
Sulfapyridine	0.85	8.4
Sulfanilamide	1.00	10.4

Modified from Gaginella TS: Drugs and the nursing mother-infant, *US Pharm* 3:39, 1978.

## Molecular Weight

The passage of molecules into the milk also depends on the size of the molecule, or the molecular weight (mol wt, in daltons). Water-filled membranous pores permit the movement of molecules of less than 100 mol wt. Because of action similar to the limitation of transport of certain large-molecular-weight chemicals across the placenta, insulin and heparin are not found in human milk either, presumably because of the molecule's size.

## Solubility

The alveolar epithelium of the breast is a lipid barrier that is most permeable in the first few days of lactation, when colostrum is being produced. The solubility of a compound in water and in lipid is a determining factor in its transfer. Nonionized drugs, which are lipid soluble, usually dissolve and descend in the lipid phase of the membrane. The solubility is closely linked to the manner in which the drug crosses the membranes (Table 12-2). The membrane of the alveolar epithelial cells is composed of lipoprotein, glycolipid, phospholipid, and free lipids, as described in Chapter 4. The transfer of water-soluble drugs

and ions is inhibited by this hydrophobic barrier. Water-soluble materials pass through pores in the basement membrane and paracellular spaces. Low lipid solubility of a nonionized compound will diminish its excretion into milk.

Lipid solubility affects the profile of the drug in the milk and plasma. A drug with high lipid solubility will have parallel elimination curves in the plasma and the milk. A drug with low lipid solubility will clear the plasma at a constant rate, but the clearance curve for the milk will peak lower and later, and the drug will linger in the milk. A prolonged terminal elimination phase may exist when time between feedings is long.

## Mechanisms of Transport

Drugs pass into milk by simple diffusion, carrier-mediated diffusion, or active transport, as follows:

*Simple diffusion:* Concentration gradient decreases

*Carrier-mediated diffusion:* Concentration gradient decreases

*Active transport:* Concentration gradient increases

## Pinocytosis

**Reverse Pinocytosis.** Pharmacokinetic principles relate to the specific variation with time of the drug concentration in the blood or plasma as a result of its absorption, distribution, and elimination. Ultimately, by extrapolation of these factors, one determines the effect of the drug. The most elementary kinetic model is based on the body as a single compartment. Distribution of the drug in the compartment is assumed to be uniform and rapidly equilibrated. In the single-compartment model, the volume of distribution of a drug is considered to be the same as that of the plasma, assuming a rapid uniform distribution.<sup>43</sup> The volume of distribution (V<sub>d</sub>) is calculated as follows:

$$V_d = \frac{\text{Total amount drug in body}}{\text{Concentration of drug in plasma}}$$

The absorption and elimination are considered to be exponential or first-order kinetics. A two-compartment model of drug kinetics takes into account the phase of decreasing drug concentration as the drug distributes into the tissues. Initially, concentrations fall rapidly as the drug distributes, then first-order elimination follows. When considering the pharmacokinetics of drugs in breast milk, one must also consider that elimination in the breast is by two potential routes: excreted with the milk to the infant and back diffusion into the plasma to reequilibrate with the falling level in the plasma.

General Drug Type	Milk/Plasma (M/P) Ratio
Highly lipid-soluble drugs	~1
Highly protein-bound drugs in maternal serum	<1
Small (mol wt <200) water-soluble drugs	~1
Weak acids	≤1
Weak bases	≥1
Actively transported drugs	>1

Modified from Gaginella TS: Drugs and the nursing mother-infant, *US Pharm* 3:39, 1978.

With access to the volume of distribution of the drug in question, the amount of the dose, and the weight of the mother, the concentration of drug in breast milk could be theoretically calculated as follows:

$$\text{Concentration in breast milk} = \frac{\text{Dose}}{\text{Volume of distribution}}$$

Other models have been developed for measuring the amount of drug that reaches the infant when the M/P ratio is not known. Using a stepwise linear regression for acidic and basic drugs, based on the drug's  $pK_a$ , the plasma protein binding value, and the octanol/water partition coefficient, an M/P ratio can be calculated. In a study of several proposed equations, the error is lowest for the drugs with the highest M/P ratio, that protein binding is the most important single predictor, and that the M/P ratios for basic drugs are more accurately predictable.

The concentration of the drug in the circulation of the mother depends on the mode of administration: oral, IV, IM, or TDDS. Absorption through the skin, the lungs (inhalants), or vaginally may also need to be considered.

The levels in the blood depend on the route of administration. The curves produced by bolus IV medication peak high and early and taper sharply, thus making avoiding peak plasma levels more feasible. Absorption from IM dosing is less rapid but follows a similar but less sharp curve. Oral dosing depends on other factors, such as whether the medication is taken between or during meals. Depending on the curve of uptake and removal of drug from the plasma, the area under the curve varies. Single doses are simple area-under-the-curve calculations, but calculations for multiple doses or chronic use vary with the steady state of the drug in the body. TDDS patches deliver the medication at a constant rate continuously.

Nonelectrolytes such as ethanol, urea, and antipyrine enter the milk by diffusion through the lipid membrane barrier and may reach the same concentrations in the milk as in the plasma, regardless of the pH. The main entrance site of molecules is at the basement laminal membrane, where water-soluble materials pass through the alveolar pores. Nonionized drugs cross the membrane more easily than ionized ones because of the structure of the membrane. The nonionized drugs pass through the membrane by diffusion. When simple diffusion takes place, the M/P ratio is 1.0. Passive diffusion provides the same ratio regardless of the plasma concentrations of the drug or the volume of milk secreted. Different M/P ratios depend on the binding to protein and are a measure of the protein-free fraction. The dissimilar ratios for the sulfa drugs

(see [Table 12-1](#)) partly result from the difference in protein binding and partly from ionization.

Large molecules depend on their lipid solubility and ionization to cross the membrane, because they pass in a lipid-soluble nonionized form. The M/P ratio is determined when equilibrium exists in the amount of nonionized drug in the aqueous phase on both sides of the membrane. When drugs are only partially ionized, the nonionized fraction determines the concentration that crosses the membrane. The drugs for which the nonionized fraction is not very lipid soluble will pass only in limited degree into breast milk.

Passive drug transport may occur in the form of *facilitated diffusion*. The active compound is transported across the cell membrane by a carrier enzyme or protein. The gradient is toward a lesser or equal concentration in both simple diffusion and facilitated diffusion and is controlled by chemical activity gradients. Facilitated diffusion usually involves a water-soluble substance too large to pass through the membrane pores.

*Active transport* mechanisms provide a process whereby the gradient is "uphill," or higher, in the milk. The process is similar to facilitated diffusion except that metabolic energy is required to overcome the gradient. Examples of substances actively transported include glucose, amino acids, calcium, magnesium, and sodium. Pinocytosis and reverse pinocytosis, as described previously, are involved in the transport of very large molecules and proteins. Chloride ions are secreted into milk via an active apical membrane pump, whereas sodium and potassium are diffused by electrical gradient. Because the level of sodium is kept low, an active return of sodium may occur into the plasma, referred to as a *reverse pump*. The TDDS depends on absorption of the drug through the skin at a steady rate; it has become a significant route of administration for certain medications. The delivery rate is determined by diffusion of drug from the reservoir matrix through the epidermis. This method offers some advantages, including convenience of dosing, reduced dosing frequency, ease of reaching a steady state, increased patient compliance, avoidance of first-pass hepatic biotransformation, avoidance of peaks and valleys in blood levels, and reduction of side effects through heightened selectivity of drug action.<sup>71</sup> The level in the plasma remains constant during the drug's anticipated life span while the patch is in place. The technology is limited to drugs with low molecular weight that are hydrophilic and can diffuse through the stratum corneum. The top molecular weight is 500 daltons. For patient compliance and economics the patch size is limited to 50 cm in diameter. Occasional patients experience skin irritation. Currently patches are limited to drugs that are potent in small

**TABLE 12-3**

Currently Available Transdermal Patches for Systemic Effects

Generic Drug	Brand Name	Strengths/Release Rate	Application Frequency	Total Drug Content per Patch
Clonidine	Catapres-TTS	0.1, 0.2, 0.3 mg/24 h	7 days	2.5, 5, 7.5 mg
Estradiol	Alora	0.025, 0.05, 0.075, 0.1 mg/24 h	7 days	0.77, 1.5, 2.3, 3.1 mg
	Climara	0.025, 0.0375, 0.05, 0.06, 0.75, 0.1 mg/24 h	7 days	2, 2.85, 3.8, 4.55, 5.7, 7.6 mg
	Estraderm	0.05, 0.1 mg/24 h	3-4 days	4 mg, 8 mg
	Vivelle-Dot	0.025, 0.0375, 0.05, 0.075, 0.1 mg/24 h	3-4 days	0.62/2.7 mg, 0.51/4.8 mg
Estradiol/ Norelgestromin	Ortho Evra	20 mcg/150 mcg/24 h	7 days	0.75 mg/6 mg
Fentanyl	Duragesic	12.5, 25, 50, 100 mcg/h	72 hours	1.25, 2.5, 5, 7.5, 10 mg
Lidocaine	Lidoderm	35 mg/12 h	12 h/day	700 mg
Methylphenidate	Daytrana	10, 15, 20, 30 mg/9 h	9 h/day	27.5, 41, 3, 55, 82.5 mg
Nicotine	Habitrol	7, 14, 21 mg/24 h	16-24 h/day	17.5, 35, 52.5 mg
	NicoDerm CQ	7, 14, 21 mg/24 h	16-24 h/day	36, 78, 114 mg
Nitroglycerin	Nitro-Dur	0.1, 0.2, 0.3, 0.4, 0.6, 0.8 mg/h	12-14 h/day	20, 40, 60, 80, 120, 160 mg
	Minitran	0.1, 0.2, 0.4, 0.6 mg/h	12-14 h/day	Approx 8.6, 17, 34, 51.4 mg
Oxybutynin	Oxytrol	3.9 mg/24 h	24 h	36 mg
Rotigotine	Neupro	2, 4, 6 mg/24 h	24 h	4.5, 9, 13.5 mg
Scopolamine	Transderm-Skop	1.0 mg/72 h	3 days	1.5 mg
Selegiline	Emsam	6, 9, 12 mg/24 h	24 h	20, 30, 40 mg
Testosterone	Androderm	2.5, 5 mg/24 h	24 h	12.2, 24, 3 mg

amounts and highly diffusible through the skin. To maintain a constant rate, a surplus of drug must be present, often 20 to 30 times the amount that will be absorbed during the time of application. The potential for toxicity is great. If a patch is utilized while lactating it should be applied and covered so a nursing infant cannot accidentally get to it.

TDDS patches are available for scopolamine, nicotine, clonidine, fentanyl, and other drugs (Table 12-3).

A summary of the steps in the passage of drugs into breast milk follows:

1. Mammary alveolar epithelium represents a lipid barrier with water-filled pores and is most permeable for drugs during the colostral phase of milk secretion (first week postpartum).
2. Drug excretion into milk depends on the drug's degree of ionization, molecular weight, solubility in fat and water, and relation of pH of plasma (7.4) to pH of milk (7.0).
3. Drugs preferably enter mammary cells basally in the nonionized, nonprotein-bound form by diffusion or active transport.
4. Water-soluble drugs less than 200 mol wt pass through water-filled membranous pores.

5. Drugs leave mammary alveolar cells apically by diffusion or active transport.
6. Drugs may enter milk via spaces between mammary alveolar cells.
7. Most ingested drugs appear in milk; drug amounts in milk usually do not exceed 1% of ingested dosage, and levels in the milk are independent of milk volume.
8. Drugs are bound much less to milk proteins than to plasma proteins.
9. Drug-metabolizing capacity of mammary epithelium is not understood.

## Effect on Nursing Infant

### ABSORPTION FROM GASTROINTESTINAL TRACT

Although concern surrounds the amount of a given agent in the breast milk, of greater importance is the amount absorbed into an infant's bloodstream. No accurate way exists to measure this because other factors also affect the level in an infant's bloodstream. The tolerance of the chemical

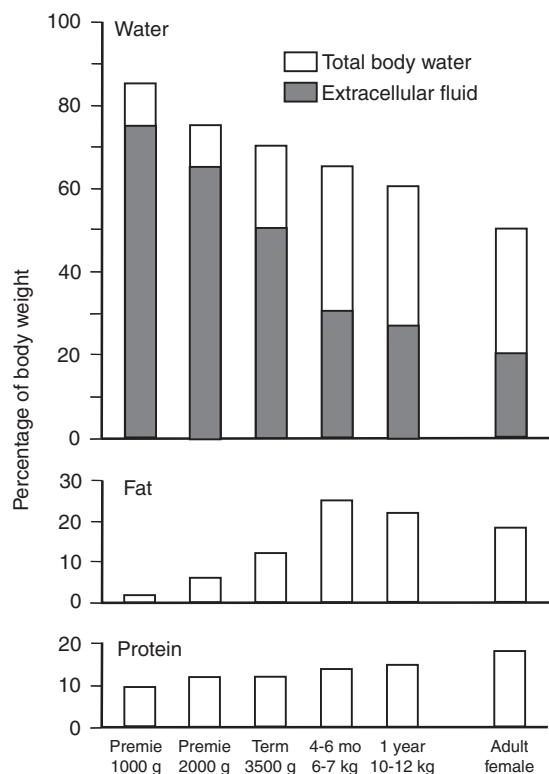

to the pH of the stomach and the enzymatic activity of the intestinal tract are significant. The volume of milk consumed is a factor as well. Some drugs are not well absorbed with food (see later discussion of food-drug interactions). Oral bioavailability of a compound is a major factor of risk for an infant.

### Infant's Ability to Detoxify and Excrete Agent

Any drug given to an infant by any route has to be evaluated according to the infant's ability to detoxify or conjugate the chemical in the liver and excrete it in the urine or stool. Some compounds that appear in milk in very low levels are not well excreted by infants and therefore accumulate in infants' systems to the point of toxicity.

Drugs that depend on the liver for conjugation, such as acetaminophen, are theoretic risks because of the limited reserve of the neonatal hepatic detoxification system. When actual measurements were made of neonates given acetaminophen, they were noted to handle it well because they conjugate it in the sulphydryl system as an alternative pathway, which is used only to a small extent in adult metabolism of acetaminophen. When a single dose of a drug is given to a mother and the level is measured in her milk and in her infant, it does not give a clear picture of the potential for accumulation in the infant's system. The competition for binding a drug to protein is also important. Some drugs, such as sulfadiazine, compete for binding sites that might normally bind bilirubin in the first week or so of life. This puts an infant in jeopardy of kernicterus at a given bilirubin level because of an increase in the fraction of bilirubin left unbound for lack of binding sites. The indirect bilirubin level may even appear to be less than the dangerous level. Some other compounds that displace bilirubin from albumin-binding sites include salicylic acid (aspirin or acetylsalicylic acid breaks down to salicylic acid), furosemide, and phenylbutazone.

The maturity of an infant at birth is an extremely important factor during the first few months of life; thus the gestational age at birth should be established. Clearly, the less mature the infant, the less well tolerated drugs are, not only because of the immaturity of the organ systems but also because of differences in body composition (Figure 12-2). The less mature an infant, the greater the water content of the body and the proportion of extracellular water. Although the percentage of body weight that is protein is similar for all newborns (i.e., 12%), the absolute amount of protein for binding is less the smaller an infant is. The amount of

**Figure 12-2.** Comparative body composition of infants and adults. (Redrawn from Bechard LJ, Wroe E, Ellisk K: Body composition and growth. In Duggan C, Watkins JB, Walker WA, editors: *Nutrition in clinical practice*, ed 4, Hamilton, 2008, BC Decker.)

body fat is also low, by percentage of body weight and in absolute values. The distribution of highly lipid-soluble drugs therefore will be more apt to deposit in the brain of a 1000-g infant with 3% body fat by weight than in a 3500-g full-term infant with 12% body fat. This may explain the more sedating effect of a drug on the central nervous system (CNS) of a smaller, younger, and less mature infant. The relative lack of plasma protein-binding sites in a small, premature infant compared with a more mature, older infant results in more free (unbound) active drug in circulation. Complications of premature birth, such as acidosis and hypoxia, also contribute to the unavailability of albumin-binding sites and thus result in more unbound drug.

The inability of the liver to metabolize drugs effectively results in the accumulation of some compounds that might be readily cleared by an older infant. At about 42 weeks' conceptual age, an infant's liver is able to metabolize most drugs competently. Renal clearance similarly is less effective with decreasing maturity, which increases the risk for drug accumulation. The need to dose a

premature infant only once or twice per day is common to many drugs, such as antibiotics, caffeine, and theophylline, and confirms that a small, premature infant does not clear drugs well.

Special problems in neonates in addition to the presence of jaundice or low serum albumin may require special consideration. Low Apgar scores at birth signifying some degree of stress, hypoxia, or acidosis may alter binding-site availability but may also alter metabolism and excretion of a drug. Continuing respiratory distress requiring ventilatory support, sepsis, and renal failure demand special consideration when determining if a sick neonate can receive the mother's milk when she is being treated with certain medications. Prescribing for such a mother should be done in consultation with the neonatologist if the woman is providing her milk for her infant.

The age of an infant makes a difference in the total volume of milk consumed; in an older child, the diet includes other items so that milk does not compose the total intake. Age makes a difference because the more mature infant can metabolize drugs more effectively; thus sulfa drugs, for instance, can be given to infants after the first month of life.

If the agent is fat soluble, the fat content of the milk may be a significant variable. The fat content at any feeding increases over time; thus the so-called foremilk is low in fat and the hindmilk is four to five times richer in fat toward the end of a feeding. Even though the total amount of fat will be about the same in each 24-hour period, the total amount of fat in a given feeding is less in the morning, peaks at midday, and drops off in the evening. The coefficient of lipid solubility for a nonionized drug determines both its penetration of the biologic membrane to gain entrance to milk and its concentration in milk fat. Sulfonamides with low fat solubility are in the aqueous and protein fraction of milk, whereas many barbiturates are in the lipid fraction. An inverse relationship exists between a drug's lipid solubility and the amount that appears in the skim fraction. The concentrations in fat differ for each member of the barbital family. Pentobarbital and secobarbital are found in the lipid phase, whereas phenobarbital is found in the aqueous phase.

The agent may appear in low levels in a mother's serum, but mammary blood flow during lactation is 500 mL/min and a mother produces between 60 and 300 mL of milk per hour. The agent that appears in minimal concentrations in the milk may present a significant problem when one considers that 1000 mL of milk may be consumed in a day by an infant. Even though the volume is low, during the colostral phase of lactation, the breast is more permeable to drugs.

## Breast Milk/Plasma Ratio for Drugs Usually Not Useful

The M/P ratio for drugs has been measured and reported for many medications. By definition, M/P ratio is the concentration of the drug in the milk versus the concentration in maternal plasma (serum) at the same time. It presumes that the relationship between the two concentrations remains constant, which in most cases it does not. If it were a constant, it would allow the estimation of the amount of drug in the milk from any given plasma level in a mother.

An inaccurate ratio, or one determined under variable circumstances, produces erroneous estimates of the amount of drug in the milk. A pharmacokinetic model is a requisite foundation for studies of drugs in breast milk. A single-point-in-time M/P ratio, or an average ratio calculated with single-dose, area-under-the-curve data, does not work for all drugs. Neither ratio accounts for the importance of time-dependent variations of drug concentration in milk.

The M/P ratio is most valuable if obtained when an infant would be nursed. If the ratio is 1:0, it means only that the levels are equal. If the level is minimal in a mother's plasma because of the large volume of distribution, and if the milk level is also low, the M/P ratio is 1:0. If levels are drawn at peak plasma level and are equal, the M/P is still 1:0, but the infant receives a large dose. Thus the M/P ratio is valuable only when the time of the measurement is known in relationship to dosing of the mother. Dose strength, duration of dosing, maternal variation in drug disposition, maternal disease, drug interactions and competition of additional drugs for metabolism or binding sites, and racial variations in drug metabolism all influence the M/P interpretation. The M/P ratio may be greater than 1, which sounds alarming; however, a drug with a large volume of distribution will have low levels in the plasma and possibly high milk levels, but neither level may be therapeutically significant. The M/P ratio only confirms that the drug gets in the milk, and the safety cannot be measured.

## Evaluating Drug Data

The paucity of carefully controlled studies on large enough samples to validate the results when such a large number of variables are active has been lamented by many authors. Some data collected are not pharmacokinetically sound. A clinician needs to understand these variables as well as pharmacokinetic principles to make a reasonable judgment about a given case.

Interethnic and racial differences in drug responsiveness are well established. The increased heterogeneity of national populations has brought increased awareness of genetic diversity. Plasma binding, especially with drugs dependent on glycoproteins for binding, often varies greatly between Caucasian and Chinese subjects, for example.<sup>150</sup> Such factors contribute to the differences in drug disposition and pharmacologic response.

It should be theoretically possible to determine how much of a specific drug reaches an infant in the mother's milk by knowing all the properties of the drug, including its volume of distribution, ionization,  $pK_a$ , lipid solubility, protein-binding activity, and rate of detoxification in the maternal system. Sufficient variation in the levels that reach an infant and in how the infant deals with the agent, however, makes it necessary to have specific data about a specific drug. Thus a few simple questions in the decision-making process are helpful in determining risk.

## Safety for Infant

Ask, "Is this a drug that can be given to the infant directly if necessary?" Antibiotics (e.g., penicillin) that one could give an infant are in this category, whereas an antibiotic such as chloramphenicol, which one would not give an infant under ordinary circumstances, should be avoided in a nursing mother. The toxicity of chloramphenicol in an infant is dose related and associated with an unpredictable accumulation of the drug. Also, an idiosyncratic reaction occurs with chloramphenicol, which is unrelated to dose but is capable of causing pancytopenia.

If the drug in question can be given to an infant, does the amount in the milk create any risk to the infant? Phenobarbital can be given to infants for various reasons; thus the question is whether enough will reach the infant to cause difficulty. The infant should be watched for symptoms of lethargy or sleepiness, such as a change in feeding or sleeping pattern. If the infant is sleeping long periods and feeding less than usual (specifically, fewer than five or six times per day), the medication may be at fault. Phenobarbital is a significant drug for a mother with seizures; therefore a careful review of the risk/benefit ratio to both mother and infant should be undertaken. Barbiturates vary in their effect in young infants. A newborn does not handle the short-acting barbiturates well because they are dependent on detoxification in the liver, whereas phenobarbital depends more on the kidney for excretion.

If the drug was taken during pregnancy, as for epilepsy, an infant will already have the drug in

his or her system via the placenta at a steady state and will have to begin to excrete it on his or her own after delivery.<sup>104</sup> Enzyme induction may have taken place in the neonate, however, because of exposure to the drug in utero; phenobarbital hastens maturation of the fetal liver.<sup>109</sup> Enzyme induction of the hepatic oxygenase system by phenobarbital, phenytoin, primidone, and carbamazepine is well established. Valproate, however, does not induce enzyme activity.

If one can safely give a drug to an infant, administration becomes a question of watching for any symptoms of excessive accumulation. The age of the infant affects the ability to clear the drug.

When the drug in question is one not normally given to an infant at that particular age, weight, or degree of maturity, decision-making is more difficult. Specific information about the amount of the drug that appears in the milk is essential in decision-making. Often, conflicting information is available. Many lists of drug-milk levels have perpetuated the same errors in calculation; thus having more than one reference report the same information may not provide confirmation of its accuracy.

If a medication will have to be taken for weeks or months, as with cardiovascular drugs, the drug has greater potential impact than when taken only for a few days. If the drug exposure has already occurred for 9 months in utero, some think it is less of a problem; however, it may compound the problem.

To determine the dose delivered to an infant, the following formula is used:

$$\begin{aligned} \text{Dose}/24\text{hours} &= \text{Concentration of drug in milk} \\ &\times \text{Weight kg of infant} \\ &\times \text{Volume of milk per kg ingested in 24 hours} \\ \text{Dose}/24\text{hours} &= C_{\text{milk}} \times \text{Weight} \\ &\times \text{Volume/kg}/24\text{hours} \end{aligned}$$

It has been recommended by Ito<sup>60</sup> and by Hale<sup>47</sup> that the calculation be the relative infant dose (RID), which is calculated as follows:

$$\text{RID} = \frac{\text{Absolute infant dose mg/kg/day}}{\text{Maternal dose mg/kg/day}} \times 100$$

It is also recommended that not more than 10% be acceptable for the calculated RID.

## Sensitization

Is sensitization a risk, even in the small dosages of a drug that might pass into the milk? This question arises most frequently with the use of antibiotics, and use of penicillin is most frequently questioned. Certainly if a family has a strong history of drug

sensitization, it should be considered. In that case, however, it should be questioned for a mother as well. Whether infants are put at risk for developing resistant strains of bacteria in their systems by small amounts of antibiotic in their feedings is a serious question. It also is as pertinent for the dairy and meat industries as for the humans who consume the food products that have a small amount of antibiotic because of administration to livestock.

## *Correlation of Drug Safety in Pregnancy and Lactation*

Very rarely is valid information on the appearance of a drug in breast milk available on the package insert because pharmaceutical companies usually merely indicate that it should not be taken during pregnancy and lactation. To provide more information they would have to study it, which they typically choose not to do. Agents that may be safe during pregnancy may not be so during lactation. During pregnancy, the maternal liver and kidney are serving as detoxification and excretion resources for the fetus via the placenta, whereas during lactation an infant has to handle the drug totally on his or her own after it has reached his or her circulation. An infant in utero receives a drug in greater quantity via the circulation, whereas a nursing infant receives only what reaches the milk. One should be cautious about translating data pertaining to these two states back and forth. Drugs that are contraindicated in pregnancy may be acceptable during lactation.

## *Oral Bioavailability*

The dose of a drug delivered via milk to an infant is significantly affected by oral bioavailability, which is the percentage of the drug absorbed into the infant's system via the gut.

Oral bioavailability is the rate and extent to which an active drug is absorbed and enters the general circulation. Absolute oral bioavailability compares the oral route with the IV route. To reach general circulation, an oral dose must pass through the wall of the gut, liver, or lungs.<sup>125</sup> First-pass metabolism or elimination in the tissues of these three organs may reduce a drug's bioavailability. It is possible for a drug to be 100% absorbed and be destroyed or eliminated and have 0% bioavailability because it is so rapidly metabolized.

If a compound is poorly absorbed, it is of less concern than one with 100% bioavailability. Most drugs administered by injection (e.g., insulin, heparin) only are not orally bioavailable.

## *Food-Drug Interactions*

When drugs are taken with meals, numerous opportunities exist for food-drug interactions to occur.<sup>103</sup> Because a breastfed infant receives all maternal medications excreted in the milk "with food," this is an important consideration in the discussion of drugs in milk. The effects of food may reduce gastrointestinal (GI) absorption or irritation. Mechanisms of food-drug interactions can be summarized as follows.

### Physiologic

1. Changes in gastric emptying
2. Increased intestinal motility
3. Increased splanchnic blood flow
4. Increased bile, acid, and enzyme secretion
5. Induction and inhibition of drug metabolism
6. Competition in active transport

### Physiochemical

1. Food as a mechanical barrier to absorption
2. Altered dissolution of drugs
3. Chelation and adsorption

### Pharmacodynamic

1. Altered enzyme activity
2. Changes in homeostasis

## *Minimizing Effect of Maternal Medication*

If a mother needs a specific medication and the hazards to the infant are minimal, the following important adjustments can be made to minimize the effects:

1. Do not use the long-acting form of the drug because the infant has even more difficulty excreting such an agent, which usually requires detoxification in the liver. Accumulation in the infant is then a genuine concern.
2. Schedule doses so the least amount possible gets into the milk. Check the usual absorption rates and peak blood levels of the drug. Having a mother take the medication immediately after breastfeeding is the safest time for the infant with most, but not all, drugs.
3. Watch the infant for any unusual signs or symptoms, such as change in feeding pattern or sleeping habits, fussiness, or rash whenever the mother takes medication.
4. When possible, choose the drug that produces the least amount in the milk (see Tables 12-1 and 12-2).

## Classification Systems

---

The transfer of drugs and other chemicals into human milk also has been detailed in a statement by the AAP Committee on Drugs in 1983, 1989, 1994, and 2001.<sup>23</sup> The list includes only those drugs about which published information is available, and it does not provide the pharmacologic properties of the compounds. The 2001 list is divided into the same seven categories as the earlier lists, grouping drugs by their risk factors in relationship to breastfeeding. The categories are the following:

1. Cytotoxic drugs that may interfere with cellular metabolism of a nursing infant
2. Drugs of abuse
3. Radioactive compounds that require temporary cessation of breastfeeding
4. Drugs for which the effect on nursing infants is unknown but may be of concern
5. Drugs that have been associated with significant effects on some nursing infants and should be given to nursing mothers with caution
6. Maternal medications usually compatible with breastfeeding
7. Food and environmental agents: effect on breastfeeding

The list of more than 300 items is not inclusive. Further, the committee encourages physicians to report adverse effects in infants consuming milk of mothers taking specific drugs to the committee at the AAP.<sup>23</sup> Other rating systems have been suggested, but this system has been used consistently since 1983. A new edition of the list is in preparation and will appear in the journal *Pediatrics*.

As new texts regarding drugs in lactation are published, many authors have chosen their own scales to describe the status of a given drug, although AAP established one in 1983. Briggs et al.<sup>17</sup> use the AAP classification. Hale et al.<sup>49</sup> designed a new system—L1, safest; L2, safer; L3, moderately safe; L4, possibly hazardous; and L5, contraindicated—which is the reverse of the AAP system. Weiner and Buhimschi<sup>141</sup> published an additional system with only three categories: S, safe; NS, not safe; and U, unknown. To facilitate consistency this text will continue to use the AAP scale.

The Breastfeeding and Human Lactation Study Center at the University of Rochester continually updates its database on drugs, medications, and contaminants in human milk. More than 4000 references pertain to drugs in the database. In addition to information gleaned from reports of specific levels in breast milk, the tables include the ratings by the AAP,<sup>23</sup> Briggs et al.,<sup>17</sup> Hale et al.,<sup>49</sup>

Schaefer,<sup>118</sup> and Weiner and Buhimschi.<sup>141</sup> In addition, other drugs typically used by women in their childbearing years about which there are no specific milk levels are listed with their oral bioavailability for infants, peak serum time in the mothers, volume of distribution for the drugs, and other pharmacologic information (pH, solubility, protein binding, metabolism) obtained from a host of resources. With this information, a physician should be able to determine relative risk and thus select the best compound and adjust the dose and the time of, and association to, the breastfeeding.

Further information is available from the Finger Lakes Regional Poison and Drug Information Center, which has a specially equipped "Lactation line" to deal with questions about toxicity and lactation, at 585-275-3232. For hearing-impaired persons, TDD services (585-273-3854) are available 24 hours per day every day. This service is staffed by physicians, nurses, pharmacists, and clinical toxicologists. The Breastfeeding and Human Lactation Center is available during limited hours (8 AM to 4 PM EST, Monday to Friday) for more complex questions (585-275-0088).

## Specific Drug Groups

---

### ANALGESICS

Drugs such as heroin have been known for decades to appear in milk, and at one time withdrawal symptoms in neonates born to heroin-using mothers were prevented or treated by breastfeeding and then gradual weaning from the breast. Codeine and meperidine (Demerol) appear in milk at low levels. The pharmacokinetics of IV meperidine in neonates and infants younger than 5 months has shown great interindividual variability in elimination half-life, median clearance, and volume of distribution. Meperidine has been removed from many hospital pharmacies. A breastfed newborn was transferred to the special care nursery at Rochester because of unusual floppiness and poor muscle tone. His mother was taking dextropropoxyphene (Darvon) every 4 hours. Temporarily stopping breastfeeding until the mother's drug level dropped and discontinuing use of the drug produced dramatic improvement, which persisted when the infant went back to nursing.

Diazepam (Valium) taken in multiple doses by the mother has caused sleepiness, mild depression, and decreased intake in some infants and tends to accumulate in neonates, especially in the first weeks of life. However, an occasional dose of diazepam is not contraindicated.

The dose schedule for analgesics is usually a single dose, especially in the postpartum period.

A mother should not be subjected to great discomfort when a dose or two of analgesics would improve her well-being. Aspirin on a single-dose schedule is safe, although it is known to pass into the milk. The case of metabolic acidosis reported in a nursing infant occurred when the mother took 650 mg of aspirin every 4 hours for arthritis.<sup>19</sup> A serum salicylate level in the infant on the third day of hospitalization with no breastfeeding was still 24 mg/dL. This demonstrates the tendency of salicylate to accumulate in the neonate. Acetylsalicylic acid, not the metabolite salicylate, is responsible for the platelet aggregate abnormalities, so there should be no concern about aspirin in this regard because it is the metabolite salicylate that appears in the milk. Reye syndrome has also been a concern because of the association with aspirin. Again the breastfeeding neonate only gets salicylic acid, not acetylsalicylic acid. Acetaminophen is remarkably well tolerated by neonates and can be given to nursing mothers. Although it does reach the milk in small amounts, neonates metabolize it well.

Prescription ibuprofen has been extensively used in 600- to 800-mg doses as an antiinflammatory agent, especially in the treatment of arthritis. Since it became available in over-the-counter preparations of 200-mg tablets, ibuprofen has become widely used by the public for pain. Pediatricians are using it liberally for fever and myalgia and generalized aches and pains. It is widely used for postpartum pain of episiotomy or cesarean delivery.

Because of the initial concern about adverse effects of prostaglandin synthetase inhibiting drugs on neonates and a report of negligible (less than 0.05 mg/mL) levels in the milk of a woman after 17 days of therapy (400 mg twice per day), a careful study of ibuprofen was undertaken. After cesarean delivery, twelve women had serum and milk samples collected at intervals for 34 hours following 400 mg ibuprofen every 6 hours for five doses. Serum half-life was 1.5 hours. No measurable amounts (capable of detecting 1 mg/mL) of ibuprofen were found in breast milk. Under normal dosing, nursing infants would be exposed to less than 1 mg of ibuprofen per day. Ibuprofen is used to close the patent ductus in premature infants.

Fentanyl citrate is frequently used to provide analgesia or anesthesia to women during the postpartum period. It is a potent synthetic phenylpiperazine with extremely high lipid solubility and high  $pK_a$  but a large volume of distribution, suggesting a predisposition to appear in breast milk but clear rapidly. In a study of postpartum lactating women receiving fentanyl, concentrations were higher in colostrum than in the serum, probably due to the open intracellular junctions, peaked at 45 minutes after administration, and were undetectable 6 to 10 hours later. The oral bioavailability of less than

50% is reduced by food, which makes the risk to an infant minimal via the mother's milk, especially if peak serum time is avoided, which occurs within minutes depending upon the method of administering: IV, IM, or transdermally.

The use of epidural anesthesia during delivery and its continuation after cesarean delivery for pain has provided considerable relief to parturient women. Despite epidurals during labor becoming commonplace, the effects of this procedure on a neonate's ability to breastfeed continue to be disputed. The obstetric literature clearly shows that epidurals in early labor result in an increased rate of interventions, including forceps use, vacuum extraction, and cesarean delivery. These in turn result in increased postpartum complications and an increase in the length of hospital stay. When women who had cesarean delivery were followed prospectively, those who had epidural anesthesia breastfed sooner and continued longer than those women who had general anesthesia.

The challenging question, however, is whether epidurals affect infants' abilities to suckle and initiate breastfeeding in women who have a vaginal delivery (see infant suckling discussion in Chapter 8). Epidural medications vary by anesthesiologist but include fentanyl, sufentanil, morphine, bupivacaine, and rodocaine. The advantage of an epidural is that the anesthetic does not reach the general maternal circulation for about 6 hours. Ideally, a mother will deliver before 6 hours if the epidural was not administered too early in labor. Infants affected in ability to suckle had mothers who received more than one dose of medication via the epidural. A prospective cohort study following 1280 women who gave birth in the Australian capitol area was conducted by Torvaldsen et al.<sup>138</sup> They mailed questionnaires at 1, 8, 16, and 24 weeks. In the first week, 93% of women were breastfeeding fully or partially; 60% continued for 24 weeks. Intrapartum analgesia and type of delivery were associated with partial breastfeeding and breastfeeding difficulties. Women who had epidurals were more likely to stop breastfeeding before 24 weeks and to partially breastfeed than women who had other analgesia.

Although labor pain relief is superior with epidural analgesia compared with meperidine, labor is prolonged, risk for uterine infection increased, and the number of operative deliveries increased, all of which interfere with successful initiation of suckling in the neonate. Meperidine is no longer used during labor, but other short-acting analgesics such as nalbuphine (Nubain) are.<sup>101,102</sup> A study of butorphanol and nalbuphine demonstrated that receiving no medication or receiving a dose less than 1 hour before delivery was associated with earlier initiation of breastfeeding and establishment of effective feeding significantly earlier compared

with mothers who received the drug more than an hour before delivery.<sup>108</sup> Righard and Alade<sup>110</sup> also observed the impact of meperidine on neonatal behavior. When they observed infants left on the maternal abdomen to find the breast and latch on, the nonmedicated infants were suckling in 20 minutes, but the medicated infants were unable to locate the breast and latch on and, in several cases, were unable to locate the breast after 40 minutes of trying.

Ketorolac tromethamine has been used for maternal pain in the first few days postpartum, especially in patients who had cesarean delivery. The concern has been the safety of breastfeeding during that time because ketorolac is an acidic pyrrolo-pyrrole prostaglandin synthetase inhibitor with a  $pK_a$  of 3.54 and 99.2% plasma protein binding. Would the drug get into the milk and interfere with the physiologic closing of an infant's ductus arteriosus? Wischnik et al.<sup>145</sup> examined this question in 10 women who received the drug 2 to 6 days after delivery. The mothers were pumping and discarding the milk because of illness in both mother and baby. Ketorolac 10 mg was given four times per day for 2 days. Plasma and milk samples were collected and levels measured; limits of detection were 10 mg/mL. The range was 5.9 mg/L to 7.9 mg/L in milk, although four patients never had measurable amounts in the milk. The M/P ratio was 0.015 to 0.037. The authors estimated that a maximum dose for an infant would be 3.16 to 7.9 mg/day. They assumed 400 to 1000 mL of milk was consumed, an improbable amount in the first few days. At maximum, the ketorolac level in milk was 0.16% to 0.40% of total daily maternal dose. Clinically, the authors concluded that significant sequelae from ketorolac are unlikely. The AAP rates ketorolac a category 6 drug, usually compatible with breastfeeding.<sup>23</sup>

## ANTIBIOTICS

Levels of antibiotics in milk vary with the concentration of the drugs in plasma and their  $pK_a$ . The risks vary among groups of antibiotics. Penicillins are not usually toxic but theoretically can cause sensitivity. Sulfa drugs should not be used in the first month of life because they can interfere with the binding of bilirubin to albumen. The risk diminishes with age, and infants are given sulfa drugs directly at 4 to 6 weeks of age. Infants with glucose-6-phosphate dehydrogenase deficiency should never receive sulfa drugs directly or via breast milk. Chloramphenicol is contraindicated in nursing very young infants because of the risk for accumulation of the drug even from small amounts in milk and the potential for idiosyncratic reaction.

Tetracycline causes staining of teeth and abnormalities of bone growth when given directly to children for a week or more. Infants who are breastfed by mothers taking tetracycline for mastitis may have stained and mottled first and second teeth when therapy exceeds 10 days. The amount in milk is half that in the mother's plasma. Tetracycline should be given to mothers only for life-threatening infections.

Erythromycin appears in higher amounts in milk than in plasma. When given intravenously to the mother, the levels are 10 times higher. When an infant is old enough to receive erythromycin directly, the mother can take it as well. The major concerns regarding erythromycin pertain to its cross-effects with other medications. Erythromycin has the potential for decreasing the clearance of carbamazepine, cyclosporine, digoxin, triazolam, theophylline, anticoagulants, and drugs metabolized by the P-450 system.<sup>17</sup>

Aminoglycosides are common constituents of postpartum antibiotic therapy and are given parenterally. They readily appear in the milk but, as with kanamycin, are not readily absorbed from the GI tract; therefore under usual circumstances they pose no problem to a neonate, who will not absorb them. Newborns are given aminoglycosides directly.

Metronidazole (Flagyl) does appear in milk at levels equal to those in serum. Most researchers consider the risk to an infant insufficient to suggest alternative therapy for the mother. Symptoms in the mother include decreased appetite and vomiting and, occasionally, blood dyscrasias.

An alternative treatment regimen is 2 g metronidazole in a single dose. When milk concentrations are measured with a 2-g dose, the highest concentrations are found at 2 and 4 hours postingestion and decline over the next 12 hours to 19.1 mg/mL and to 12.6 mg/mL at 24 hours.<sup>38,54</sup> The dose to the infant is calculated to be 21.8 mg during the first 24 hours and only 3.5 mg in the second 24 hours. It has been recommended that a single-dose regimen be used in nursing mothers, which necessitates that a mother pump and discard milk for only 24 hours. Metronidazole in gel or cream form contains only 0.75% of the medication and is poorly absorbed because the purpose is to work on tissues locally. As a result, maternal plasma levels are 1/50 of levels from comparable oral dosing. Use of the drug in this form would probably result in undetectable amounts in the milk. Normally, the gel or cream is applied in small amounts twice daily. Peak absorption could be avoided. Metronidazole is often the only drug that works in a serious trichomoniasis, giardiasis, or amebiasis infection<sup>38</sup> when all other treatments have failed. It is now used directly in infants.

Amoxicillin, cephalexin, and cefadroxil, when given orally in a single dose, peak in the milk at 4 to 6 hours.<sup>66</sup> Cephalothin, cephapirin, and cefotaxime, when given in a bolus IV injection, peak at 2 hours. Cefadroxil reached the highest levels ( $1.64 \pm 0.73$  mg/mL) at 6 hours. Little gets into the milk. These drugs are also given to children.

Cephalosporins are weak acids with variable protein binding. Third-generation cephalosporins may affect the flora of the gut. Sterilization of the gut often leads to diarrhea. In general, cephalosporins are considered safe during lactation.<sup>24</sup> Breastfed infants rapidly recolonize the gut with lactobacillus. Oral absorption is poor and little reaches the milk, so they usually are considered safe.

The serum half-lives of parenterally administered cephalosporins are three to four times longer in neonates than the serum half-lives in mothers. The half-life of ceftriaxone in the milk is 12 to 17 hours compared with the maternal serum half-life of 6 hours. Neonates can be given cephalosporins directly. Ceftriaxone is given IM to infants once per day. Fluoroquinolones had been restricted in pediatric use because of early reports of arthropathy in immature animals and a single report of pseudomembranous colitis in a breastfeeding infant whose mother had self-medicated with ciprofloxacin.<sup>52</sup> More recently ciprofloxacin has been used in pediatric patients because it is valuable in gram-negative infections and also anthrax. Levels in milk are said to be low.<sup>42</sup> The AAP committee on drugs has designated it to be safe for breastfeeding women.<sup>23</sup>

Chloroquine, gentamicin, streptomycin, and rifampin (only 0.05%) are reported by the AAP<sup>23</sup> to be safe because they are not excreted in milk.

Because antibiotics are the medications most frequently prescribed for lactating women, it is noteworthy that compliance is low. Maternal non-compliance was measured by Ito<sup>60</sup> in 203 breastfeeding women who consulted the Motherisk Program for information about antibiotics. Despite reassuring advice, one in five women either did not initiate therapy or did not continue breastfeeding. This has serious implications for recurrent infections, especially mastitis. Mastitis represents another situation in which termination of breastfeeding is not indicated, or necessary.

## ANTICHOLINERGICS

Anticholinergic drugs include atropine, scopolamine (hyoscine), and synthetic quaternary ammonium derivatives, some of which are available in over-the-counter medications. Some atropine does enter the milk. Infants are particularly sensitive to this drug; therefore an infant should be watched for tachycardia and thermal changes, which are

more easily measured in infants. The most important consideration is that milk secretion may decrease in the mother. With repeat doses, constipation and urinary retention may occur in infants. The quaternary anticholinergics, however, should not appear in milk to any degree because, as anions, they do not pass into the acidic milk. Mepenzolate methylbromide (Cantil) does not appear in milk.

Scopolamine is available by dermal patch for motion sickness and causes maternal mucous membrane dryness, which could affect milk production as it restricts the secretions of other secretory glands. Only a small amount appears in milk. The AAP rates it and atropine as category 6, drugs usually compatible with breastfeeding, although the scopolamine patch, which provides a constant level, has not been tested *per se*.<sup>23</sup> Pressure point wristbands are reported to be effective for motion sickness in pregnancy and lactation and contain no medication.

## GASTROINTESTINAL MEDICATIONS

Cimetidine (Tagamet), a potent H<sub>2</sub>-receptor antagonist, is used for conditions associated with acid peptic digestion in the GI tract, especially elevated gastric acidity. Cimetidine excretion into breast milk has resulted in concentrations higher than in the corresponding plasma sample.<sup>129</sup> Levels were highest at 1 hour after a single dose (Table 12-4). Chronic-dose studies revealed variable M/P ratios, all of which were higher than the single-dose ratio. The authors suggest an active transport mechanism for this medication. The maximum amount of cimetidine ingested by an infant was calculated at 6 mg for 1 L of milk (or 1.5 mg/kg). It is rated category 6 by the AAP.<sup>23</sup>

The neonatal dose is 10 to 20 mg/kg/24 hours for severe gastroesophageal reflux or gastric ulcer, conditions that are rare in breastfed infants. The half-life in a neonate is 1.1 to 3.4 hours. It is contraindicated when either infant or mother is receiving cisapride because of the risk for precipitating cardiac arrhythmias.<sup>129</sup>

Caution is recommended with nursing when taking cimetidine until more is known of its side effects, especially antiandrogenic features. It is used in premature infants with reflux. Cimetidine does interfere with several drugs, including phenytoin, propranolol, warfarin, tricyclic antidepressants, diazepam, and cyclosporine.

Sulfasalazine treatment of ulcerative colitis and Crohn's disease during breastfeeding has been widely discussed on theoretic grounds because the compound splits to sulfapyridine and 5-aminosalicylic acid. The sulfapyridine is absorbed from the colon and is metabolized in the liver. The 5-aminosalicylic acid is partly absorbed and

**TABLE 12-4** Antibiotic Selection for Bacterial Mastitis

Antibiotic	Spectrum	Dose	Safety	Comment
Dicloxacillin	Nonmethicillin-resistant Staphylococci	500 mg PO qid	Yes	Highest activity against MSSA
Clindamycin	Penicillin allergic Many CA-MRSA Test susceptibilities	300 mg PO qid	Probably safe	Excreted in milk; active against many strains of CA-MRSA
Erythromycin	Penicillin allergic	500 mg PO qid	Yes	GI intolerance
Azithromycin	Penicillin allergic	500-mg load, then 250 mg/day × 4 days	Probably safe	Limited <i>S. aureus</i> activity; less GI upset than erythromycin
Trimethoprim Sulfamethoxazole	Some CA-MRSA	One DS PO bid	Yes	Less effective when abscess present
Cephalexin	MSSA	500 mg PO qid	Yes	Relatively poor levels in breast tissue

*bid*, Twice per day; *CA-MRSA*, community-acquired methicillin-resistant *S. aureus*; *GI*, gastrointestinal; *MSSA*, methicillin-susceptible *S. aureus*; *PO*, by mouth; *qid*, four times per day.

From Nathan GG, Uhl K, Kennedy DL. Antibiotic use in pregnancy and lactation: what is and is not known about teratogenic and toxic risks, *Obstet Gynecol* 107:1120–1138, 2006.

rapidly excreted in the urine, so serum concentrations are low. The sulfapyridine and its metabolites do appear in the milk in lower concentrations than in the serum. A dose of 2 g/day of drug to a mother would produce 4 mg/kg of sulfapyridine in the milk, 40% of maternal levels. The oral absorption from the milk is low, so the actual amount in an infant's plasma is minimal. The risk for recurrent ulcerative colitis in the mother if medication is withdrawn outweighs the risk for sulfasalazine to the infant.<sup>70</sup>

Famotidine (Pepcid-AC) reduces gastric acidity. Milk levels are low and it has poor oral bioavailability so it is of little risk. Omeprazole (Prilosec), which also reduces gastric acidity, has milk levels that also are low. It is highly protein bound and only 40% orally bioavailable so should be safe. Levels are lower in the milk than cimetidine.

## ANTICOAGULANTS

Heparin, regular or unfractionated, is a large-molecular-weight molecule that does not pass into breast milk. Because it is not absorbed from the GI tract, its use in the breastfeeding mother is acceptable.

Low-molecular-weight (LMW) heparins are glycosaminoglycans consisting of chains of alternating residues of D-glucosamine and uronic acid. Regular or unfractionated heparin is a heterogeneous mixture of polysaccharide chains ranging from 3000 to 30,000 mol wt. LMW heparin has a mean mol wt of 5000 daltons (2000 to 8000), with slight variation among brands: ardeparin (Normiflo), dalteparin (Fragmin), enoxaparin (Lovenox), nadroparin (Fraxiparine), reviparin (Clivarine), and tinzaparin

(Innohep). Both unfractionated and LMW heparins cause anticoagulation by activating antithrombin. LMW heparins produce a more predictable anticoagulant response because of their better bioavailability, longer half-life, dose-independent clearance, and decreased tendency to bind to plasma proteins and endothelium. They are less likely to interfere with platelets. They are considered safer and more effective in the treatment of venous thromboembolism, can be given subcutaneously without laboratory monitoring, carry less risk for thrombocytopenia and osteoporosis, and can be given at home.<sup>142</sup>

No studies are reported of LMW heparin use in pregnancy or lactation. Because mol wt is greater than 2000 and only a molecule of less than 1000 mol wt crosses the placenta or into the milk, these molecules are unlikely to cross. These LMW compounds are not orally bioavailable and would not be absorbed by an infant. They are considered safe during lactation.

Analysis of the milk of mothers using warfarin does not reveal any drug in the milk or in the infants. The infants' prothrombin times remained normal. This was demonstrated by McKenna et al.,<sup>93</sup> who followed two breastfed infants whose mothers were anticoagulated before delivery and maintained on warfarin postpartum. They found no immediate or delayed biologic effect on coagulation in 56 and 131 days of follow-up. From this, it has been suggested that warfarin is the drug of choice in lactating mothers who require anticoagulant therapy and want to continue breastfeeding. If surgery is contemplated or unusual trauma occurs, a review of an infant's coagulation status is indicated

as a precautionary measure, and 1 mg vitamin K can be given orally or IM if there is concern.

## ANTITHYROID DRUGS

Iodide has been known for generations to pass into the milk in levels higher than in the maternal plasma. It has been reported to cause symptoms in infants when used not only for hyperthyroidism but also in asthma preparations and cough medicines. Iodides have been noted to be goitrogenic and to sensitize the thyroid gland to other drugs, such as lithium, chlorpromazine, and methylxanthines.

Thiouracil is actively transported into the milk and appears in higher concentration in milk than in blood or urine, reported at levels 3 to 12 times higher in milk than in blood. It has the potential of causing goiter-suppressing thyroid activity or agranulocytes. Thiouracil is contraindicated during lactation.

Methimazole (Tapazole) presents risks to nursing infants similar to those seen with thiouracil (i.e., thyroid suppression, goiter). Giving 0.125 grain of thyroid extract may not adequately protect infants, and careful monitoring of neonatal thyroid function is mandatory. Measurements of amounts of methimazole in milk and serum when a mother received 2.5 mg every 12 hours were found to be similar. Tegler and Lindström<sup>136</sup> found 7% to 16% of the maternal dose in the milk; thus a dose of 5 mg four times daily might provide an infant with 3 mg daily. Studies of carbimazole using<sup>35</sup> S-labeled compound show a similar trend, with 0.47% of the dose appearing in the milk. Studies were done on a single dose of 10 mg carbimazole.

Propylthiouracil (PTU) has been investigated by several groups with similar results reported, showing that little of the compound is excreted in the milk (0.025% to 0.077% of total dose) in single-dose studies.<sup>67</sup> An infant who was followed 5 months on maternal doses of 200- to 300-mg PTU daily showed no neonatal thyroid symptoms and normal triiodothyronine ( $T_3$ ), thyroxine ( $T_4$ ), and thyroid-stimulating hormone. On the strength of these reports, others have proceeded to use PTU and permit breastfeeding. The availability of micro-determinations for  $T_3$ ,  $T_4$ , and thyroid-stimulating hormone improves the quality of monitoring, and all infants given PTU via milk should be followed closely.<sup>27</sup> The AAP lists PTU in category 6, compatible with breastfeeding.<sup>23</sup>

## CAFFEINE AND OTHER METHYLXANTHINES

Caffeine ingestion has been singled out for discussion because it is a frequent concern, but the data provided in most reviews are misleading. With a

given dose of caffeine that is comparable with that in a cup of coffee, the level in the milk is low (1% of level in mother), and the level in an infant's plasma is also low. However, caffeine does accumulate in infants. This was learned when caffeine was introduced in neonatal intensive care units to treat apnea of prematurity.

Before the availability of the laboratory test for caffeine, cases were managed on clinical symptoms alone. Many clinicians recognized that wakeful, hyperactive infants were often the victims of caffeine stimulation. If a mother drank more than 6 to 8 cups of any caffeine-containing beverage in a day, her infant could accumulate symptomatic amounts of caffeine. Soft drinks such as colas and other carbonated drinks (e.g., Mountain Dew) often contributed to the caffeine buildup. When the situation was identified—a wide-eyed, active, alert infant who never slept for long—it was suggested that the mother try caffeine-free beverages, both hot and cold. Often the infant settled down to a reasonable sleep pattern after a few days with no caffeine.

Since information on milk and plasma levels has become available, researchers have identified three cases of caffeine excess in breastfed infants. The infants had measurable levels of caffeine in the plasma, which disappeared in a week after the caffeine was discontinued. The corresponding milk levels were as previously reported, about 1% of the mother's level, which supports the hypothesis that caffeine accumulates in infants. The infants do not need to be hospitalized, and verification of blood caffeine levels is helpful but not mandatory because a clinical trial will suffice. Smoking has been observed to augment the caffeine effect.

With an increasing number of women with asthma wanting to breastfeed, a question arises about the impact of methylxanthines that have also been used in apnea of prematurity. Information has been generated regarding dose, clearance, and toxicity in the neonate.<sup>10</sup> In addition, microdeterminations of blood levels are readily available.

Several studies of theophylline in mothers receiving regular doses have shown that the serum levels are lowest just before the oral dose and that M/P ratio is 0.60 to 0.73, with milk levels paralleling serum levels.<sup>120,113,130</sup> Infants receive an estimated 1% of the maternal dose. Data on IV and oral medication are similar in terms of M/P ratio. Maximum exposure was estimated at 7 to 8 mg/24 hours.

Dyphylline is a compound introduced clinically as a bronchodilator because of its lack of side effects.<sup>64</sup> It is excreted renally with little biotransformation. The M/P ratio was determined to be  $2.08 \pm 0.52$ , and the biologic half-life was 3.21 hours. Although this is considerably greater than that of

theophylline, it is not yet known how this would affect infants.

Theobromine, which occurs in chocolate and cocoa, has been studied to evaluate its possible cumulative effects when taken with caffeine or theophylline.<sup>10</sup> A small amount was detected in the milk, with a potential dose to an infant after one chocolate bar (1.2 oz) of 0.44 to 1.68 mg. No theobromine was found in infants' urine.<sup>11</sup>

The management of asthma has shifted in recent years to steroids, antibiotics, and inhalants. Steroids are excreted in the milk in low doses that have not presented a problem to the nursling, who is automatically weaned as the mother is weaned. Antibiotics are well tolerated, as discussed previously. Inhalants are unique because they act at the level of the bronchial mucosa and are poorly absorbed. Albuterol (Proventil, Ventolin) is a  $\beta_2$ -adrenergic agonist that is rapidly effective when inhaled, peaking within 30 minutes. The potential for drug levels in the milk is minimal because less than 10% of an inhaled drug is absorbed, and no adverse reactions have been reported in nurslings. The oral albuterol dose for infants with asthma is 0.1 to 0.3 mg/kg every 6 to 8 hours.

Fluticasone (Flovent inhaled and Flonase nasally) is administered by inhalation so that systemic levels are less than 2% given nasally and 30% by inhalation. Plasma levels are almost undetectable, and given the usual dosing schedule, no buildup should occur. Use during lactation is considered safe.

## DRUGS OF ABUSE AND ALCOHOL

The AAP Committee on Drugs<sup>23</sup> has assigned a special category to drugs of abuse: category 2, which they consider contraindicated during breastfeeding. The list is short: amphetamine, cocaine, heroin, marijuana, and phencyclidine hydrochloride (angel dust, PCP). They strongly state further that these compounds and all other drugs of abuse are hazardous not only to nursing infants, but also to the mother's physical and emotional health. Obviously, the latter is also true for bottle-feeding mothers. (See Chapter 16 for further discussion of nicotine and smoking.) Nicotine's inclusion in category 2 was controversial, especially because the data are clear that children of smoking mothers do better if breastfed in regard to general health, respiratory illness, and risk for sudden infant death syndrome (SIDS).

The epidemiologic evidence of the impact of maternal smoking on breastfeeding was studied by Amir and Donath.<sup>4</sup> They concluded that psychosocial factors are largely responsible for the lower rates of breastfeeding found in women who smoke compared with those who do not. Fewer

smokers intend to breastfeed in the first place. The duration of breastfeeding in smokers is inversely related to the number of cigarettes smoked per day.<sup>58</sup>

The consumption of alcohol during lactation also deserves careful consideration because of the wide range of effects and the wide range of intake. Beer and wine are standard beverages in many parts of the world and have been recommended to enhance lactation, especially when a mother is stressed with worldly chores. Some forms of alcohol have also been used as an aperitif to encourage a woman to eat heartily while lactating. The AAP listing is category 6.<sup>23</sup>

Alcohol is one of the most rapidly absorbed compounds. Maximum blood levels are achieved in 15 minutes in adults. Lactating and nonlactating women handle alcohol differently. Lactators tend to peak at lower levels and clear the drug more quickly.<sup>63</sup> Alcohol passes quickly between blood and milk, however, with peak levels in milk at 30 to 60 minutes and at 60 to 90 minutes when taken with food. Studies in men and nonlactating women show an increase in serum prolactin with alcohol.<sup>28,97</sup> This has not been tested in lactators. The impact of alcohol on oxytocin is dose related. No effect is seen on ingesting 0.5 g/kg or less, and varying effects are reported in different women as dose is increased.<sup>28</sup> At least a partial decrease in milk let-down is seen at 1.0 to 1.5 g/kg, and women have significant to complete block in milk ejection at 1.5 to 2.0 g/kg.

Although beer and wine have been considered galactagogues the evidence does not support this. Alcohol is an inhibitor of oxytocin release, thereby inhibiting let-down and milk expression.<sup>74</sup> Alcohol blocks the release of oxytocin rather than blocking the response of the breast. The amount of alcohol excreted into milk with doses less than 1 g/kg of absolute alcohol usually does not affect infants.<sup>82</sup>

Many investigations have measured the pharmacologic impact of alcohol consumption.<sup>56</sup> Alcohol appears quickly in both foremilk and hindmilk at a level equivalent to, or higher than, corresponding maternal blood samples. Although levels are high in the blood, no acetaldehyde is found in the milk. Levels in milk drop in parallel to those in the blood because alcohol is not stored in the breast. In a study by Lawton,<sup>81</sup> milk levels were very low despite that the participating mothers drank as much as they could as quickly as possible, averaging between 43 and 90 mL of absolute alcohol. Levels were drawn every half hour for 4 hours in this study.

When women served as their own controls in an experiment to observe feeding behavior and volume of milk consumed by infants with and without maternal alcohol, significant and uniform intensity of odor to their milk was observed, peaking

between 30 and 60 minutes after ingestion.<sup>96</sup> The odor paralleled the concentration of alcohol (0 to 32 mg/dL). Infants sucked more frequently but consumed less milk in the presence of alcohol ( $120.4 \pm 9.5$  mL vs.  $156.4 \pm 8.2$  mL). When a similar study was done with beer and nonalcoholic beer, the findings were similar: infants sucked less well with the alcohol beverage. Mothers, however, were unaware of the differences and felt they had experienced let-down and their infants had nursed well. This work has precipitated considerable response because of the belief that a little beer or wine enhances mothers' release of milk.

Although this work suggests that a little alcohol may not enhance milk volume received by infants, the alcohol was taken in a research setting and consumed in 10 minutes. When the mother takes a little wine socially, it usually creates a different ambience and may help her relax and improve her ejection reflex. In addition, many women who enjoy sipping an occasional beer or wine may well be discouraged from breastfeeding if they think wine or beer would be forbidden.

The report of Little et al.<sup>86</sup> regarding the effect of alcohol on nursing infants implies that alcohol causes developmental delay. The drinking would be classified as heavy in this group, whose infants had slight gross motor delay at 1 year. Furthermore, the infants were subjected to the alcohol in utero as well. Heavy drinking should not be condoned, however, it is important to follow the children in all the cohorts for at least 7 years until their higher learning functions are testable.

Infants spent significantly less time sleeping during the 3.5 hours after consuming alcohol-flavored breast milk by bottle (56.8 minutes) compared with plain breast milk by bottle (78.2 minutes). The authors concluded that short-term exposure to small amounts of alcohol in breast milk produces distinctive changes in an infant's sleep-wake pattern.<sup>97</sup>

The recommendation regarding alcohol requires a physician to avoid prescribing or proscribing it and to assist mothers to appropriately adjust alcohol consumption in both timing and volume.

The Academy of Breastfeeding Medicine has prepared a summary of evidence and annotated bibliography about breastfeeding among drug dependent women—protocol 21—which is available on their website.

## HERBS AND HERBAL TEAS

Herbal medicine is the use of plants or plant parts in their natural state without chemical processing. Natural is not a synonym for safe. Because herbals are considered dietary supplements, they are not

controlled by the FDA, although the FDA has spoken out on the dangers of comfrey and ephedra (Table 12-5). Herbal products contain many chemicals, some of which may have pharmacologic properties. The major concerns are quality control, unknown additives, unknown side effects, and no placebo-controlled studies regarding efficacy and toxicity. Labels in the United States must read, "This product is not intended to diagnose, treat, cure, or prevent any disease."

Use of herbs and herbal teas has increased, especially among those interested in natural foods.<sup>125</sup> As is well known to all students of pharmacology, many effective medications originated from these natural products. In the early part of the twentieth century, many compounds were being dispensed in their natural form, including foxglove leaves for digitalis. The natural product was unpredictable because one leaf or plant contains more or less active principle than another, so careful dose control was impossible and results were often unpredictable. Much of the interest in herbal teas has evolved as individuals seek a beverage that does not contain caffeine; what they receive is another compound instead, often one more potent and frequently one about which considerably less is known (Table 12-6). Contamination, adulteration, and misidentification contribute to the problems associated with use.

Herbal teas are available that are prepared carefully, using herbs only for essence (e.g., Celestial Seasonings brand tea) and avoiding heavy doses of herbs with active principles. However, the strength of any tea depends on how it is made. An ordinary teabag with hot water run over it will contain little caffeine and theobromine; however, when the tea is steeped for 5 minutes, the potency is increased tenfold. Some of the preparations are benign or even nutritious, such as rose hips tea, which contains a large amount of vitamin C. Other teas are made from plants known to toxicologists as poisonous. Isolated reports of toxicity from these preparations are appearing in the medical literature; many others probably go undiagnosed.<sup>124</sup> Use of these preparations is certainly an important part of a medical and dietary history.

**Box 12-1** lists herbal teas that are thought to be safe for infants and mothers during lactation when used as flavorings and not in therapeutic doses.

A systematic review of breastfeeding and herbs was conducted by Budzynska et al. who found only 32 studies that met inclusion criteria from 1970 to 2010. Only six were randomized controlled trials, and most were surveys or case reports. Scientific data are rare in the field of herbal consumption.

In edible plants there may be toxic parts. The potato family is well known for its toxicity in the roots, sprouts, and green coloring. Rhubarb

**TABLE 12-5** Clinically Important Effects and Perioperative Concerns of Eight Herbal Medicines and Recommendations for Discontinuation of Use Before Surgery

Herb: Common Name(s)	Relevant Pharmacologic Effects	Perioperative Concerns	Preoperative Discontinuation
Echinacea: purple coneflower root	Activation of cell-mediated immunity	Allergic reactions; decreased effectiveness of immunosuppressants; potential for immunosuppression with long-term use	No data
Ephedra: ma huang	Increased heart rate and blood pressure through direct and indirect sympathomimetic effects	Risk for myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use depletes endogenous catecholamines and may cause intraoperative hemodynamic instability; life-threatening interaction with monoamine oxidase inhibitors	At least 24 hours before surgery
Garlic: ajo	Inhibition of platelet aggregation (may be irreversible); increased fibrinolysis; equivocal antihypertensive activity	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	At least 7 days before surgery
Ginkgo: duck foot tree, maidenhair tree, silver apricot	Inhibition of platelet-activating factor	Potential to increase risk for bleeding, especially when combined with other medications that inhibit platelet aggregation	At least 36 hours before surgery
Ginseng: American ginseng, Asian ginseng, Chinese ginseng, Korean ginseng	Lowers blood glucose; inhibition of platelet aggregation (may be irreversible); increased PT-PTT in animals; many other diverse effects	Hypoglycemia; potential to increase risk for bleeding; potential to decrease anticoagulation effect of warfarin	At least 24 hours before surgery
Kava: awa, intoxicating pepper, kawa	Sedation, anxiolysis	Potential to increase sedative effect of anesthetics; potential for addiction, tolerance, and withdrawal after abstinence unstudied	At least 24 hours before surgery
St. John's wort: amber, goat weed, hardhay, hypericum, klamathweed	Inhibition of neurotransmitter reuptake, monoamine oxidase inhibition	Induction of cytochrome P-450 enzymes, affecting cyclosporine, warfarin, steroids, protease inhibitors, and possibly benzodiazepines, calcium-channel blockers, and many other drugs: decreased serum digoxin levels	At least 5 days before surgery
Valerian: all heal, garden heliotrope, vandal root	Sedation	Potential to increase sedative effect of anesthetics; benzodiazepine-like acute withdrawal; potential to increase anesthetic requirements with long-term use	No data

<b>TABLE 12-6</b> Psychoactive Substances Used in Herbal Preparations			
Labeled Ingredient	Botanical Source	Pharmacologic Principles	Suggested Use and Reported Effects
African yohimbe bark; yohimbine	<i>Corynanthe yohimbe</i>	Yohimbine	Smoke or tea as stimulant; mild hallucinogen
Broom; scotch broom	<i>Cytisus</i> spp	Cystine	Smoke for relaxation; strong sedative-hypnotic
Buckthorn	<i>Hiptothae rhamnoides</i>	Anthraquinones	Tea; cathartic toxin, severe watery diarrhea
Burdock root	<i>Arctium minus</i>	Atropine	Tea; anticholinergic blockade, anaphylactic shock
California poppy	<i>Eschscholtzia californica</i>	Alkaloids and glucosides	Smoke as marijuana substitute; mild hallucinogen
Catnip	<i>Nepeta cataria</i>	Nepetalactone	Smoke or tea as marijuana substitute; mild hallucinogen
Chamomile	<i>Chamomilla recutita</i> <i>Chamaemelum nobile</i>	Antigens of Compositae family	Tea; contact dermatitis (in patients sensitive to ragweed, asters, chrysanthemum)
Cinnamon	<i>Cinnamomum camphora</i>	?	Tea; venoocclusive disease, hepatic failure, hepatocarcinogen
Comfrey	<i>Symphytum officinale</i>	Pyrrolizidine alkaloids	Tea; malignant arrhythmias, cardiac arrest
Foxglove tea	<i>Digitalis purpurea</i>	Digitalis	Tea; venoocclusive disease, hepatic failure
Gordolobo, groundsel	<i>Senecio longilobus</i> <i>Senecio vulgaris</i> <i>Senecio spartoides</i>	Pyrrolizidine alkaloids	Smoke or tea as sedative and marijuana substitute; none
Hops	<i>Humulus lupulus</i>	Lupuline	Smoke as marijuana substitute; stimulant
Hydrangea	<i>Hydrangea paniculata</i>	Hydrangin, saponin, cyanogens	Tea; PNH-like defect, anticholinergic blockade; CNS intoxication, hallucinations, ataxia, blurred vision
Jimson tea	<i>Datura stramonium</i>	Atropine, scopolamine, hyoscyamine, stramonium	Smoke as hallucinogen; strong hallucinogen
Juniper	<i>Juniper macropoda</i>	?	Smoke or tea as marijuana substitute; mild hallucinogen
Kavakava	<i>Piper methysticum</i>	Yangonin, pyrones	Smoke, tea, or capsules as stimulant
Kolanut; gotu kola	<i>Cola</i> spp	Caffeine, theobromine, kolanin	Smoke or tea as a marijuana substitute; mild euphoriant

**TABLE 12-6** Psychoactive Substances Used in Herbal Preparations—cont'd

Labeled Ingredient	Botanical Source	Pharmacologic Principles	Suggested Use and Reported Effects
Lobelia	<i>Lobelia inflata</i>	Lobaline	Tea as hallucinogen
Mandrake	<i>Mandragora officinarum</i>	Scopolamine, hyoscyamine	Tea as stimulant; venoocclusive disease
Mate	<i>Ilex paraguensis</i>	Caffeine, pyrrolizidine	Tea as stimulant
Mormon tea	<i>Ephedra nevadensis</i>	Ephedrine	Hallucinogen, MAD inhibitor; hallucinogen, CNS intoxicant
Nutmeg	<i>Myristica fragrans</i>	Myristin	Hepatic damage
Oleander	<i>Nerium oleander</i>	Myristin Cardiac glycosides Digitogenin Nerioside Oleandroside	Malignant arrhythmias, cardiac arrest
Passion Flower	<i>Passiflora incarnata</i>	Harmine alkaloids	Smoke, tea, or capsules as marijuana substitute; mild stimulant
Periwinkle	<i>Catharanthus roseus</i>	Indole alkaloids	Smoke or tea as euphoriant; hallucinogen
Pokeroot, pokeweed	<i>Phytolacca americana</i> <i>Phytolacca decandra</i>	Saponins Pokeweed mitogen	Gastroenteritis, bloody diarrhea Respiratory depression, mitogenic alterations
Prickly poppy	<i>Argemone mexicana</i>	Protopine, berberine, isoquinolines	Smoke as euphoriant; narcotic-analgesic
Sassafras	<i>Sassafras albidum</i>	Safrole	Tea or cold beverage; hepatocarcinogen
Senna	<i>Cassia acutifolia</i> <i>Cassia angustifolia</i>	Antraquinones	Tea; cathartic toxin, severe watery diarrhea
Snakeroot	<i>Rauwolfia serpentina</i>	Reserpine	Smoke or tea as tobacco substitute; tranquilizer
Thorn apple	<i>Datura stramonium</i>	Atropine, scopolamine	Smoke or tea as tobacco substitute or hallucinogen
Tobacco	<i>Nicotiana</i> spp	Nicotine	Smoke as tobacco; strong stimulant
Valerian	<i>Valeriana officinalis</i>	Chatinine, valerie, alkaloids	Tea or capsules as tranquilizer
Wild lettuce	<i>Lactuca sativa</i>	Lactucarine	Smoke as opium substitute; mild narcotic-analgesic
Woodruff	<i>Galium odoratum</i>	Coumarin	Hemorrhagic diathesis, prolonged prothrombin time
Wormwood	<i>Artemisia absinthium</i>	Absinthin	Smoke or tea as relaxant; narcotic-analgesic
Yohimbe bark	<i>Corynanthe yohimbe</i>	Yohimbine	$\alpha_2$ -Sympathetic (presynaptic) blockade

CNS, Central nervous system; MAD, major affective disorder; PNH, paroxysmal nocturnal hemoglobinuria.

Modified from Siegel RK: Herbal intoxication: psychoactive effects from herbal cigarettes, tea, and capsules, *JAMA* 236:473, 1976; copyright © 1976, American Medical Association; and Ridker PM: Toxic effects of herbal teas, *Arch Environ Health* 42:135, 1987.

is known for its toxic leaves. Certain mushrooms, and some varieties of pea, such as grass pea (*Lathyrus sativus*), have significant toxicity. No data exist for transmission of the toxin via the milk.<sup>13</sup>

In some sense, safety is a matter of dose. In studies of herbs that will safely eliminate the nausea and emesis of pregnancy, ginger and peppermint are reported to be more effective than placebo. Dosing, however, was by capsule of powdered plant (1 g/day) for ginger and oil of peppermint,

with no dose provided. It is of concern that ginger in large doses is known as an emmenagogue, which is a promoter of menstruation because it increases the blood flow to the uterus and inhibits platelet aggregation. In literature reviews, 7% consider peppermint unsafe and 16% consider ginger unsafe in pregnancy.<sup>144</sup> There are no data for lactation, although Hale lists peppermint oil as unsafe during lactation.<sup>48</sup> Any herbal tea consumed in large volumes (32 oz) daily could be a problem.

**BOX 12-1. Herbal Teas Considered Safe During Lactation**

Tea	Origin/use
Chicory	Root/caffeine-free coffee substitute
Orange spice	Mixture/flavoring
Peppermint	Leaves/flavoring
Raspberry	Fruit/flavoring
Red bush tea	Leaves, fine twigs/beverage
Rose hips	Fruits/vitamin C

**Mother's Milk Tea**

Mother's milk tea is a blend of plants handed down for many generations as a galactagogue; it contains a mixture of fennel seeds, coriander seeds, chamomile flowers, lemon grass, borage leaves, blessed thistle leaves, star anise, comfrey leaves, and fenugreek seeds (Table 12-7).<sup>134</sup> It is promoted as containing no caffeine. Although not all the constituents have pharmacologic actions, several do and were used medicinally for centuries. These popular teas have the same potential for problems as do the common popular beverages coffee and cola. The euphoric effects are the most prominent.<sup>125</sup>

**Comfrey and Pyrrolizidine Alkaloids**

Considerable concern is mounting over the use of comfrey leaves (*Symphytum officinale*) in the United States, and they have been banned in Canada and Germany. The leaves have been used in teas, salads, and poultices. The use of comfrey has been associated with venoocclusive disease and hepatotoxicity. Comfrey is also rich in hepatotoxic pyrrolizidine alkaloids.<sup>59,110</sup> The highest level of toxin occurs in the roots, which can be obtained in powder form in capsules. Comfrey has been recommended for use to cure various pregnancy, labor, and postpartum symptoms and appears in many home remedy handbooks. It has the greatest potential for toxicity in a fetus and a suckling infant, with fatal fetal venoocclusive disease reported.<sup>1</sup> It is also known to have carcinogenic properties. All credible references caution against its use topically, orally, or in any form.<sup>36,139</sup> The FDA has cautioned against its use, and Hale et al.<sup>49</sup> also consider it dangerous.

Another herb associated with venoocclusive disease and even death is *Senecio longilobus*, commonly known as thread-leaved groundsel.<sup>59,110</sup> As with comfrey, it contains hepatotoxic pyrrolizidine alkaloids. Seven cases of hepatitis have been reported resulting from use of *Teucrium chamaedrys* (germander), a member of the mint family. Botanical

**TABLE 12-7** Possible Ingredients and Effects of Mother's Milk Tea

Plant	Constituents	Effects	Toxicity
Fennel seed	Volatile oil, anisic acid	Weak diuretic stimulant	CNS disturbances
Coriander seed	Volatile oil, coriandrol	Increases flow of saliva and gastric juice	CNS disturbances
Chamomile flower	Volatile oil, bitter glycoside	Sudorific, antispasmodic, used to lighten hair	Vomiting, vertigo
Lemongrass	Lemon flavor		
Borage leaf	Volatile oil, tannin, mineral acids	Diuretic, sudorific, euphoric	Possible
Blessed thistle leaf	Volatile oil, bitter principle	Aperitif, galactagogue, diaphoretic	Strongly emetic
Star anise	Volatile oil, anethole, resin, tannin	Stimulant, mild expectorant	
Comfrey leaf ( <i>Symphytum officinale</i> )	Protein, vitamin B <sub>12</sub> , tannin, allantoin, choline, pyrrolizidine, alkaloids	Used as mucilage to knit bones, weak sedative, demulcent, astringent	Venoocclusive disease Hepatotoxic
Fenugreek seed (Greek hayseed) (coffee substitute and natural dye)	Mucilage, trigonelline, phytosterols, celery flavor	Digestive tonic, galactagogue, uterine stimulant, reduces blood sugar	Hypoglycemia, can induce labor
<b>Other beverages</b>			
Coffee plant	Volatile oil, caffeine, tannin	Stimulant, diuretic, coloring	Insomnia, restlessness
Blue cohosh	Saponin, glucoside that affects muscles	Oxytocic, potent, acts on voluntary and involuntary muscles	Irritant, causes pain in fingers and toes

identification is essential; sometimes the packet contains substances other than those the label indicates.

Pyrrolizidine alkaloids have been identified in an herbal tea used in the Southwest that was responsible for the deaths of several children who were given the tea when they were ill. The alkaloid is excreted within 24 hours, but symptoms may not appear for several days or weeks. Death results from liver failure.

### Sassafras and Coumarins

Sassafras contains an aromatic oil, safrole, which has been shown to cause cancer in mice; it is therefore no longer permitted as a commercial flavoring, but it appears in herbal teas. It causes CNS symptoms in mice, including ataxia, ptosis, and hypothermia.<sup>124</sup> It is also thought to interfere with the action of other medications. Noted herbalists state that sassafras has no really significant medical or therapeutic use.<sup>36,139</sup>

The oil, along with many other volatile oils, does have mild counterirritant properties on external application. It has a pleasant flavor but many harmful qualities. Although banned by the FDA, sassafras appears in other natural food products. Belladonna alkaloids are common in some teas used to create euphoria or ease pain.

A hemorrhagic diathesis was described in a woman who drank quarts of herbal tea that contained tonka beans, melilot (sweet clover), and woodruff, all of which contain natural coumarins.<sup>57</sup> She narrowly avoided gynecologic surgery for excessive hemorrhaging before the history was obtained. The tea also included hawthorn, which contains cardiotonic glycosides that cause hypotension.

### Licorice

Licorice, the dry root of *Glycyrrhiza glabra*, has been used for medicinal purposes for millennia; stores of licorice were found in the tombs of Egyptian pharaohs, including that of King Tut. Its history is carefully reviewed by Davis and Morris.<sup>28</sup> The active principle is a glycoside of a triterpene called glycyrrhetic acid. Licorice continues to be used as a flavoring agent in drinks, drugs, and candies. In addition to its universal role as an expectorant and demulcent and in ointments for various skin disorders, it has been used for peptic ulcers. Its most perplexing properties are those that cause the retention of water, sodium, and chloride and the increased excretion of potassium, mimicking the effects of large doses of desoxycorticosterone. Because licorice is used to flavor chewing tobacco, chewing has been associated with hypertension, sodium retention, and hypokalemia. Licorice derivatives have been found to reroute the metabolism of aldosterone, desoxycorticosterone, and glucocorticoids.<sup>30</sup> Licorice

toxicity is well described in the literature.<sup>148</sup> Excessive amounts of licorice should be avoided by lactating women. Its use to lose weight should be discouraged. Some licorice candy contains little or no licorice, and the flavor is provided by anise, which is probably harmless. An occasional stick of licorice candy should not be a risk.<sup>116</sup>

### Echinacea

Echinacea (coneflower) is used for the common cold and when "immune system enhancement is desired."<sup>139</sup> A lipophilic fraction of the root and leaves contains the most potent immunostimulating compounds, some yet to be identified. It is used topically to stimulate wound healing and orally to enhance immune response. The public seeks it out for the common cold. No data exist about its entry into milk. It has no known side effects, however, even when injected in high doses. Placebo-controlled studies have indicated it is not effective to take echinacea for long periods prophylactically, but echinacea does appear to minimize cold symptoms when taken as symptoms begin. Taking it for more than 8 weeks has been associated with immunosuppression. It is also important to note that it is a member of the daisy/chrysanthemum family and can cause allergy in those prone to pollen allergies. It is also reported to have caused asthma, atopy, and anaphylaxis. The safety and efficacy of echinacea during lactation are reported from Mother-Risk with caution due to the lack of high quality human studies confirming its safety.

Use in children has not been effective and has a greater risk for allergic response. Echinacea may be safer in moderate amounts than the polypharmacy available for the common cold (see Table 12-5). It is not recommended for pregnant and lactating women or children younger than 2 years old according to Skidmore-Roth.<sup>126</sup> It interferes with immune suppressants and should not be used by patients who have had transplants.

Ginkgo biloba is the world's oldest living tree. It has been known in Chinese medicine since 2800 BC for brain disorders, circulatory problems, and respiratory diseases, including asthma. The safety of its use during lactation is unstudied and unknown. It should be avoided according to Dugoua et al.<sup>32</sup> until some high quality human studies are reported.

Blue cohosh (*Caulophyllum thalictroides*) during lactation is seemingly widely used but data are lacking. Mother-risk recommends it should only be used under medical supervision and not be available across-the-counter until it is studied thoroughly. A large percentage of midwives use it in labor in spite of known teratogenic, embryotoxic, and oxytoxic effects.<sup>33</sup>

Chaste tree (*Vitex agnus-castus*) was systematically reviewed in the literature in lactation. Theoretical and expert opinion revealed 5 who thought it increased lactation and 5 who reported it decreased prolactin and thus milk production.<sup>34</sup> Chaste tree has some effects on estrogen and progesterone activity. No evidence suggests it passes into milk. Careful blinded controlled studies are needed to determine chaste tree's effect on milk production.

## Ginseng

Ginseng is one of the oldest, most widely recognized, and most documented Oriental herbs. It enjoys a reputation for increasing capacity for mental work and physical activity and also "antistress" effects. The plant of origin is *Panax schinseng* (Chinese) or *P. quinquefolius* (American), two species of the Araliaceae family. Panax is derived from the Greek, meaning "all healing." It has been called an "adaptogen" because it is believed to protect the body against stress and restores homeostasis or provides nonspecific resistance.<sup>5</sup>

The root contains dozens of steroid-like glycosides (ginsenosides), which vary with the species, age, location of growth, and harvest time. It contains sterols, coumarins, flavonoids, and polysaccharides. Although animal studies suggest increased strength and stamina, Engels and Wirth<sup>38</sup> reported that in a carefully blinded and controlled study of 31 healthy men randomized to take 200 mg/day, 400 mg/day, or a placebo, no difference was found in any physiologic or psychologic parameter. They measured oxygen consumption, blood lactic acid, and heart rate while the subjects worked at maximum effort on stationary bikes. It does lower blood sugar and can cause hypoglycemia. It has some effect on coagulation pathways and on platelet coagulability, which may be irreversible (see Table 12-5).

Products available are numerous and variable, more than half are worthless according to independent studies, and 25% contain no ginseng, which is extremely expensive (\$20 per ounce). It is reported to have estrogen-like effects on some women, with mastalgia common with extended use, and mammary nodularity also reported. Although animal experimentation has been considerable, no extensive human data, no reliable or standardized preparations, no information on dosage, and no accurate recording of side effects are available. Ginseng is a medical enigma with no proven efficacy for humans, according to Tyler.<sup>139</sup> General side effects include excitement, nervousness, inability to concentrate, hypertension, hypoglycemia, and skin rash. A case of ginseng use during pregnancy and lactation is reported because the infant showed excessive hirsutism and androgen effect, which

cleared when breastfeeding was discontinued at 2 weeks of life.<sup>68</sup> Because of the reported breast effects and occasional reports of vaginal bleeding, it is considered problematic during lactation. It should not be used during pregnancy, during lactation, or in children according to Skidmore-Roth.<sup>127</sup> Panax ginseng should be consumed with caution during lactation based on the absence of studies in humans.<sup>123</sup>

## St. John's Wort

St. John's wort is touted in Europe and the United States as an antidepressant and anxiolytic and is now sold in health food stores and supermarkets. It comes from an aggressive perennial weed in meadows and roadsides noted for its spotted leaves, numerous yellow-orange flowers with black spots, and capsular fruit. It contains 10% tannin and hypericin, a reddish dianthrone pigment, other hypericum-like substances (0.2% to 0.5%), and a number of volatile oils. The extract is sold as tablets, capsules, drops, transdermal patches, oils, and teas.

The pharmacology of the extract includes inhibition of the neurotransmitters serotonin, norepinephrine, and dopamine; it also binds to  $\gamma$ -aminobutyric acid receptors in vitro. When the extract is taken orally, hypericin peaks in serum in 5 hours and reaches steady state with continued dosing in 4 days. The half-life in plasma is 25 hours.<sup>87</sup>

Studies of varying quality abound, and some are reported on the hypericum home page on the Internet. Some are carefully controlled and include standardized testing of depression and mood before and after 3 to 6 weeks of treatment with St. John's wort versus placebo or versus standard antidepressant medication. In their overview and meta-analysis, Linde et al.<sup>85</sup> conclude the evidence indicates that extracts of hypericin are more effective than placebo and equally effective as standard antidepressants for mild to moderately severe depressive disorders. Side effects of dry mouth, dizziness, constipation, and confusion occurred in 20% of subjects receiving hypericin and in 53% taking standard antidepressants. The doses, duration, and assessment tools varied widely in these 23 studies and 1757 outpatients.

Adverse effects with chronic high doses (more than 30 mg/day) include photosensitivity, abdominal symptoms, rarely tachycardia, tachypnea, fever, and fatigue. Because hypericin inhibits dopamine  $\beta$ -hydroxylase, which leads to increased dopamine, increased prolactin inhibitory factor, and suppression of prolactin, it could decrease lactation. No clinical study has investigated this pharmacologic potential. "Better, longer studies are needed to

establish the effectiveness and safety of St. John's Wort for treatment of depression. Twenty six chemicals have been extracted from St. John's Wort and hypericin may not be the most effective. The active ingredients, potency and purity of preparations sold in the USA are all unknown.<sup>95</sup> It is licensed in Germany but is considered a dietary supplement in the United States and has not been evaluated by the FDA (see Table 12-5).

Hyperforin is excreted into breast milk at low levels and was at the limit of quantification. In two infants, plasma samples' (0.1 ng/mL) M/P ratio was 0.04 and 0.13. RIDs were 0.9% to 2.5%.<sup>73</sup> In a prospective observational cohort study of 33 breastfeeding dyads with matched control that were unmedicated, no difference was found in demographics, symptoms, or adverse effects. No hypericin was found in the infant.<sup>82</sup>

## PRODUCT IDENTIFICATION

Clinicians need to inquire about all foods and beverages when taking a history. If the mother is consuming an excessive amount of any herbal product,

its contents should be checked. The regional poison control center may be able to identify active principles if the plant constituents of the food or beverage are known (Table 12-8).

## Galactagogues

A galactagogue is a material or action that stimulates milk production. When trying to increase milk supply, the action of increased pumping is the best "galactagogue." When careful lactation management has not produced adequate results, as in the case of a mother pumping for her sick premature infant, various medications and herbs have been recommended. Unfortunately, few randomized, blinded, placebo-controlled studies of efficacy or safety have been performed.

Metoclopramide has been studied in small series in which mothers took 10 mg three times daily with an increase in milk supply that in most cases dwindled when the drug was tapered after 10 days, which is the recommended limit because of possible maternal side effects. Metoclopramide has been used in infants for reflux; however, when plasma

**TABLE 12-8** Herbal Teas and Their Side Effects

Herb/Parts Used	Common Uses	Method of Application	Side Effects
Aconite (monkshood, wolfsbane)	Aconitine, hypaconitine, aconine, mesaconitine	Tea	Nausea, vomiting, hypersalivation Perioral paresthesia, progressing rapidly to neuromuscular weakness, seizures, coma Cardiac effects: Bradycardia and hypotension (most common), supraventricular or ventricular tachycardia, ventricular fibrillation, asystole
Aloe vera/pure gel from leaves	Burns Constipation Ulcers Canker sores Immunostimulant HIV infections	Gel applied topically or taken internally several times daily Does not standardize	Diarrhea, gastric cramping when taken internally Contact dermatitis from related species <i>Aloe arborescens</i>
Chamomile/flowers	Calming, sedating Aromatherapy Antispasmodic Colic Antiinflammatory Soothe diaper rash Chickenpox, poison ivy	Tea (in infants) or tinctures Essential oil used in aromatherapy or added to bath	Allergic reactions One case of botulism in infant given tea from homegrown plant
Comfrey	Pyrrolizidine Demulcent Sedative Astringent	Tea Poultice Ointment	Hepatic venoocclusive disease marked by severe abdominal pain and vomiting, which may be followed by hepatomegaly and abdominal distention with ascites Hepatic necrosis leading to cirrhosis Not recommended

*Continued*

**TABLE 12-8** Herbal Teas and Their Side Effects—cont'd

Herb/Parts Used	Common Uses	Method of Application	Side Effects
Echinacea/leaves, stalks, roots	Immunostimulant Colds, ear and sinus infections HIV infections	Tincture, capsules or tablets taken internally as immunostimulant Does not standardize	None reported
Ephedra (ma huang)/ leaves, stalks	Decongestant Asthma, allergy Weight loss "Natural high"	Generally taken internally	Hypertension, tachycardia Toxic psychosis Death Not recommended
Feverfew/fresh or dried leaves	Migraine Prophylaxis Rheumatoid arthritis Insect repellent Menstrual pain	1-3 fresh leaves, 25-50 mg capsules, or crushed, dried leaves twice per day to prevent migraine	Allergic reactions Mouth ulcers Rebound headache if discontinued abruptly
Goldenseal/roots	Diarrhea Antiseptic Antimicrobial for acne, conjunctivitis, eczema, ear infections Possible immunostimulator Antiarrhythmic	¼ to ½ tsp of tincture or ½ tsp of fluid extract three or four times per day for diarrhea Can be mixed with 4 oz water or juice	Nausea, vomiting, diarrhea Displaces bilirubin from albumin Not recommended for infants
Pennyroyal	Pulegone	Tea Oil	Hepatotoxicity, hepatic failure, nausea, vomiting, abdominal pain Renal failure Delirium, confusion, restlessness, dizziness, seizures, alternating lethargy and agitation Abortion Not recommended
Tea tree oil/essential oil from leaves	Minor skin infections Fungicide Acne Vaginitis	Applied topically 2 to 4 times per day	Contact dermatitis if applied to broken or irritated skin As little as 10 mL by mouth can affect CNS function and cause muscle weakness Not for internal use

CNS, Central nervous system; HIV, human immunodeficiency virus.

Modified from Mack RB: "Something wicked this way comes"—herbs even witches should avoid, *Contemp Pediatr* 15:49, 1998; and O'Hara MA, Kiefer D, Farrell K, et al: A review of 12 commonly used medicinal herbs, *Arch Fam Med* 7:523, 1998.

levels were studied, the less mature the infant, the less good the clearance, and it is accumulated.<sup>140</sup> A risk for extrapyramidal side effects is possible in some individuals.<sup>37</sup> The FDA has issued a black box warning of tardive dyskinesia even after the drug has been stopped.

Sulpiride, an antidepressant and antipsychotic, is no longer available in the United States and Canada because of its drug interactions and risk for dyskinesia and neuroleptic malignant syndrome. It does increase prolactin levels as a dopamine agonist. Even small doses have maximum effect on the prolactin levels but less effect on milk production. It does pass into milk.

Domperidone (Motilium) also increases prolactin as a dopamine antagonist. When 46 mothers of premature (less than 31 weeks' gestation) babies were given domperidone for lactation failure, levels of nutrients in the milk were compared to controls. By day 14, volume had increased by 267% but only 18.5% in controls. Prolactin increased 97% versus 17%.

Protein declined by 9.6% in the study group and rose by 3.6% in controls. There was no change in calories, fat, sodium, or phosphate. Carbohydrate and calcium were increased in the study group. Essentially, the milk was not significantly changed except in volume.

Another randomized double-blind placebo-controlled trial of domperidone on milk production in mothers of premature newborns showed an increase in milk production,  $49.5 \pm 29.4$  mL/day compared with  $8.0 \pm 39.5$  mL/day in the control group (44.5% increase with the drug and 16.6% with the placebo). The prolactin levels rose significantly with domperidone. A small amount was found in the milk.<sup>26</sup> A systematic review and meta-analysis of randomized control trials found only a few small studies of high quality. They confirmed that domperidone produces a greater increase in breast milk supply than placebo.

A great advantage is that it is less likely to cross the blood-brain barrier, resulting in fewer extra pyramidal side effects.

A thorough review of the pharmacology of domperidone is available in Drugdex, a product of Micromedex, available by subscription to poison centers and medical libraries. Domperidone has a long history with many trials for nausea and vomiting and postprandial dyspepsia. It undergoes extensive first-pass hepatic and gut wall metabolism, which results in oral bioavailability of 13% to 17%. After IV administration the half-life is 7.5 hours, and after oral dosing the half-life is 14 hours with time to peak serum levels of 30 to 110 minutes. The volume of distribution is 440. It is metabolized in the liver. Reported adverse effects include arrhythmias, extrapyramidal tract effects, and dystonic reactions more common in children and in patients on antipsychotic medication. Side effects include dry mouth, headache, and abdominal cramps. Galactorrhea is a secondary effect that is not universal. It occurs in both males and females along with mastalgia and gynecomastia. The augmentation of preexisting lactation in a breast that has been primed by pregnancy appears different. It has been used effectively as an aid to induced or relactation efforts.

Dosage is 10 to 20 mg three to four times per day for 3 to 8 weeks. Some women respond within 24 hours, some take 2 weeks, and some never respond. There are cases of longer term usage. Withdrawal symptoms have been described of gastric irritability and nausea. The average milk concentrations when 10 mg are taken three times per day are 1.2 mcg to 2.6 mcg/L. Total daily dose would be only 180 ng/kg/day. Oral availability is low, 13% to 17%.<sup>26</sup> Domperidone was given to mothers who were pumping for their premature infants and had poor milk production. Two thirds of the mothers increased their supply at both 30 and 60 mg/day relative to the dose. The amount measured in the milk was low, the mean RID was 0.012% at 30 mg and 0.009% at 60 mg maternal

dose per day.<sup>141</sup> No effect on the infants was observed. The AAP<sup>23</sup> rates domperidone a category 6, compatible with lactation. Hale et al.<sup>49</sup> rate it L1, safest of medications, and Schaefer<sup>118</sup> consider it safer than metoclopramide and more effective. Because it is banned by the FDA,<sup>46</sup> use in the United States is difficult. Information about resources is available at <http://www.breastfeedingonline.com/domperidonewhere.shtml> (accessed 17 Dec 2014).

Herbs listed as galactagogues are numerous and known by hearsay and historic usage but not by scientific study. Most prominent on the list are fenugreek, fennel, milk thistle (not blessed thistle, which is an entirely different species), lemongrass, goat's rue, and anise.

Fenugreek (*Trigonella foenum graecum*) is a member of the Leguminosae family of plants also called Fabaceae, which includes peanuts and chick peas.<sup>127</sup> Fenugreek is the dried ripe seeds of a small southern European herb known as Greek hayseed, which contains 40% mucilage. In addition to being used for poultices and ointments, it is used in teas and syrups and has a faint flavor similar to maple syrup. It is soothing, flavorful, and possibly nutritious. It is available as a spice, flavoring, and tea. It is used as a galactagogue and goes back to ancient times. It is generally regarded as safe by the FDA, although it has been noted to cause colic in the infants of mothers using it, similar to that caused by peanuts and chickpeas and other allergic symptoms in individuals with asthma.<sup>106</sup> It has been noted to lower cholesterol in normal individuals and also produce hypoglycemia in patients with diabetes. Several cases of mistaken diagnosis of maple syrup urine disease have been published as case reports in which the infant was found to smell of maple syrup. All body fluids smell like maple syrup when an individual receives fenugreek.

In moderate use, fenugreek is considered harmless. As with all things in pregnancy and lactation, moderation is essential. Transport into milk is not documented, but the milk smells like maple syrup as may the infant. Fenugreek has been touted as a galactagogue, but no scientific reports support or refute this claim. Because it is in the same botanical family as peanuts, soy beans, and chick peas, a potential for allergy exists. It is also recognized to aggravate symptoms of allergy. It can interact with anticoagulants and monoamine oxidase (MAO) inhibitors and should not be combined with warfarin (Coumadin) nor glyburide and other antidiabetic medications.

The dose is 2 to 3 capsules four times per day, recognizing that varieties differ and dose potency will change with variations in plant products.

Potential for colic in the infant should be watched for.

Fennel seed (*Foeniculum vulgare*) is a common spice with estrogenic properties that has a reputation as a galactagogue but has no supporting evidence.<sup>107</sup>

Milk thistle (*Silybum marianum*) also has a reputation as a galactagogue. It is taken as a tea two or three times per day. It is also used as an antispasmodic and has many other uses. Milk thistle is a member of the family Asteraceae but should not be confused with blessed thistle, which is *Cnicus benedictus*, an entirely different plant. The active parts of the milk thistle plant are the small hard fruits known as achenes (they are not seeds). The leaves have no therapeutic efficacy. The usable material silymarin is an extract of the fruits. It has been credited with inhibiting oxidative damage to liver cells and stimulating regenerative capacity of liver cells. Micronized silymarin has been studied as a galactagogue in humans because it was well known in the bovine. Silymarin is an extract of *S. marianum*, which is the same milk thistle. Fifty healthy lactating women were given 420 mg/day of silymarin compared with women who received a placebo. The milk production was increased by 85.9%. Those who received the placebo increased production by 32.1%. No side effects were recorded and no women dropped out.<sup>32</sup> There is no known toxicity to the milk thistle teas. It has been used as a strained tea (simmer 1 tsp crushed fruits in 8 oz water for 10 minutes low dosage).<sup>90</sup>

Lemon grass (*Cymbopogon citratus*) is used for its dried leaves and oil of citronella. The latter is used as an insect repellent in the United States. It is used for joint pains and GI discomforts. Herbal references do not mention lactation.<sup>107</sup>

Grapefruit seed extract has been noted in animal experimentation to be an antiinfective, antiviral, antibacterial, and antifungal. Grapefruit itself has been known to contain quinine, especially in the bitter skin and section fibers. Grapefruit seed extract has been recommended as an extract for use by direct application on sore nipples. If it has antiinfectious properties, it should be effective when traumatized nipples have become infected.

Laboratory studies have been reported on the Internet claiming that grapefruit seed extract inactivated herpes simplex (HSV-1), influenza A, and other viruses (see Nutri Team: [support@nutriteam.com](mailto:support@nutriteam.com)).

An illustration of one of the problems associated with herbals, that there are no guarantees regarding contamination or accuracy of labeled amounts, is the tryptophan (another amino acid) withdrawal. The eosinophilia-myalgia syndrome had been noted in more than 1500 patients taking L-tryptophan supplements. Characteristics included

severe, incapacitating myalgia and eosinophilia. This outbreak was exclusively linked to L-tryptophan manufactured by a single Japanese manufacturer, and thus a contaminant was suspected; however, the identity of the contaminant is still unknown.

Furthermore some herbals, especially those from Asian sources, can be contaminated with toxic heavy metals or even, in some cases, laced with prescription medications. Lead is the most common contamination identified. Pay-loo-ah is a powder containing lead that is used to treat headaches, muscle aches, and abdominal pain and is widely marketed. Patients who have consumed such products should have lead levels checked.

## Lactation Suppression

Pseudoephedrine is widely used as a nasal mucous membrane and sinus decongestant. Its effects on milk production were measured by Aljazaf et al.,<sup>2</sup> who found it had no effect on breast blood flow or temperature. The mean change in prolactin compared with placebo was minimal. The milk production, however, was reduced by 24% with a single dose. Little drug was found in the milk. This confirms the standard advice that breastfeeding women should not take decongestants and should rely instead on saline nose drops and moisture (vaporizers) for relief of upper respiratory symptoms.

Sage has one major physiologic effect—it is antisudorific in cases of excessive sweating, and it is said to reduce lactation. Considering the similarity between sweat glands and alveolar cells of the breast, this cross-relationship is not surprising. No references are found regarding lactation, although there are many references to confirm the antisudorific effect.

The sage family is a large group of horticulturally important plants consisting of more than 750 species distributed throughout the world. Some are of culinary use and others medicinal. A Central American species is a powerful hallucinogen, traditionally used in religious and ceremonial rites. The best known is *Salvia officinalis*, which has been cultivated for thousands of years. The name salvia is from the Latin word *salvus*, meaning to be in good health. It is also used as an antiseptic and a gargle and for many other symptoms. It is specifically contraindicated during pregnancy.

The literature supports the use of sage to decrease milk supply, treat engorgement, or hasten weaning. From that standpoint, it would be unwise to use it on nipples themselves in spite of the fact that it has antibacterial, astringent, and disinfectant properties according to most herbal references. Other medications that suppress milk production include those that have been used postpartum for

women who choose not to breastfeed, such as androgens, estrogens, including those found in low-dose contraceptives; dopaminergic agents, such as bromocriptine (Parlodel), amantadine, and antiparkinsonian drugs; anticholinergics, the smooth muscle relaxants for the GI tract and urinary tract; and some antihistamines and cold preparations. Diuretics have also affected milk production.

## Cardiovascular Drugs and Diuretics

Digitalis is given to infants, but only for serious reasons. Measurements of digitalis in the milk in mothers maintained on digitalis throughout pregnancy and lactation showed concentrations of 0.825 nmol/L, which was 59% of the maternal plasma level in one study<sup>20</sup> and 75% in another.<sup>39</sup> If one calculates the predicted level of digitalis using the higher volume of distribution, 7.5 L/kg, an infant would receive 1.1 ng/mL in the milk of a 60-kg (132-lb) mother receiving a 0.5-mg dose of digoxin. Authors agree that digoxin levels would be low and the dosage to the infant low, but the long-range effects are not known.<sup>39,89</sup> There is sufficient experience accumulated to date, however, to conclude that mothers taking sustaining doses of digitalis preparations may nurse their infants without any harm to the infants. The AAP rates digitalis as category 6, compatible with breastfeeding. Peak plasma levels occur 1.5 to 3 hours after ingestion, so breastfeeding should be avoided during that time.

Propranolol, a beta blocker, was found in the milk of mothers but does not appear to accumulate in infants. Thus experienced cardiologists have permitted mothers taking propranolol to nurse their infants without any ill effect observed in the infants. In 1973, Levitan and Manion<sup>83</sup> reported significant quantities of propranolol in breast milk. Propranolol and its major metabolites were measured in milk and found by Smith et al.<sup>128</sup> to provide an infant with a maximum dose of less than 0.1% of the maternal dose or approximately 7 mg/dL. The half-life of elimination from the milk was 3 to 5 hours.<sup>8</sup> β-Adrenergic blockade effects, including hypoglycemia, have been described in an infant breastfed by a mother taking propranolol. Because the reports are conflicting, it is necessary to monitor a breastfed infant carefully when the mother is taking propranolol. Monitoring plasma levels of the infant may be helpful if there is any concern. It is a category 6 on AAP scales, considered safe for breastfeeding.

The antihypertensive drugs atenolol (Tenormin), metoprolol tartrate (Lopressor), and nadolol (Corgard, Corzide) have been evaluated in human

milk.<sup>29,31,85</sup> Metoprolol has a peak level in blood of 713 ng/dL at 1.1 hours and in milk of 4.7 ng/dL at 3.8 hours. The data suggest that metoprolol appears minimally in milk and is probably safe for breastfeeding neonates.<sup>31</sup> Nadolol appears in serum at 77 ng/dL and in milk at 357 ng/dL.<sup>29</sup> Atenolol levels in milk are also higher than in the maternal serum.<sup>85</sup> Of this group, metoprolol would be the safest. These drugs are rated category 6 by the AAP. Serum levels of atenolol in one breastfed infant reached 0.16 mmol/L. It is rated category 5 by AAP, give with caution. Acebutolol is rated category 6 by the AAP, but the dose must be at or less than 400 mg/day.<sup>16</sup>

A number of effective antihypertensive medications are available. Clinicians should review the properties and amount excreted in breast milk when choosing the best drug for a mother.

Most diuretics are weak acids and little passes into milk. Use of diuretics, however, requires careful observation because they have the potential for causing a diuresis in the neonate that could be extremely dehydrating.<sup>6</sup> Although diuretics such as furosemide (Lasix) are given to neonates, this is done only when fluid and electrolyte levels can be followed closely. Oral diuretics were used to suppress lactation in a study by Healy<sup>54</sup> in 40 post-partum women who chose not to breastfeed. Ben-droflumethiazide (Naturetin) was used, 5 mg twice daily for 5 days. He found it more effective than estrogens, with fewer side effects. Milk volume may be reduced by thiazides.

Reports document the interaction of three diuretics with bilirubin-albumin complexes.<sup>143</sup> Chlorothiazide presented the greatest risk for producing free bilirubin, with ethacrynic acid and furosemide producing considerably less. The latter two are clinically effective in lower doses as well. The levels of chlorothiazide and hydrochlorothiazide in milk are less than 100 ng/mL.<sup>98</sup> For most infants, these are safe; however, these findings certainly suggest caution is necessary if an infant is jaundiced or immature.

Furosemide has been shown by several techniques not only to displace bilirubin from albumin in the newborn, but also to be slowly excreted by the newborn, with only 84% excreted in 24 hours when given to an infant directly. It is reported, however, that furosemide is not excreted into breast milk and is poorly absorbed orally; thus it would be safe for a lactating mother, although it may suppress milk supply in some women.<sup>49</sup>

A mother who is lactating may actually require substantially less medication, particularly diuretics. Close monitoring of a mother during lactation to try to reduce her medications may provide a therapeutic balance that is good for the mother and safe

for the infant. With the short half-life of most diuretics in the adult, dosing can be timed to avoid peak plasma levels during feedings.

### Cholesterol-Lowering Drugs

Adjunct cardiovascular treatment includes the aim to lower total cholesterol. This has created a problem for a breastfeeding mother. Some basic biochemistry needs to be considered. Cholesterol levels in healthy breastfeeding women are elevated during lactation, which needs to be considered when deciding on the need to lower cholesterol. It has been shown that regardless of dietary intake, mother's milk always contains cholesterol and is remarkably stable at 240 mg/100 g of fat or 9 to 41 mg/dL (average 20 mg/dL). Breastfeeding infants' plasma cholesterol levels are high compared with formula-fed infants who receive no cholesterol in their artificial feeds. Pravastatin has been studied. 0.4% of the weight-related dosage reaches the milk.<sup>105</sup> No untoward effects have been reported to date.<sup>105</sup> The lipid-binding resins, colestipol and cholestyramine, which are not absorbed orally, are not considered a problem during lactation.<sup>120</sup> They do absorb some medications. Fenofibrate reduces total cholesterol and triglycerides and belongs to a large group of lipid reducers, such as atorvastatin, fluvastatin, simvastatin, and xantinol nicotinate, about which little is known during lactation. Except in unusual cases, it would appear safe to postpone the use of these medications during lactation; cholesterol reduction is a long-term therapy and breastfeeding could be considered therapeutic. It could be considered after an infant is older than 6 months and consuming an other diet.

### Central Nervous System Drugs

Phenobarbital can be given to infants and is usually safe, but careful observation of infants for variations in sleeping and feeding habits is important.<sup>77</sup>

Phenytoin in breast milk has been associated with vomiting, tremors, rash, blood dyscrasias

(rarely), and methemoglobinemia, but not with drowsiness and lethargy. Many mothers have nursed without apparent incident while taking phenobarbital and phenytoin.<sup>131</sup> Phenytoin levels in milk of mothers treated for epilepsy have been measured, and levels in infants have been calculated to provide less than 5% of the therapeutic dose for infants. Valproic acid in maternal milk is low (3% of maternal serum concentrations), but the mean half-life is 47 hours, four times that in adults, so accumulation is a risk.<sup>103</sup> An infant would have to be closely monitored (Table 12-9).<sup>104,131</sup> The AAP rating for valproic acid and phenytoin is category 6.

A single case of carbamazepine exposure during pregnancy and breastfeeding is reported to have caused cholestatic hepatitis, diagnosed when the infant was 3 weeks of age.<sup>41</sup> The mother did not develop hepatic symptoms and continued the drug. Breastfeeding was discontinued, and the hepatitis resolved. Diagnosis was confirmed by liver function studies and liver biopsy. Carbamazepine hepatitis has been described in children and adults as a rare complication of therapy.

Poor weight gain after birth of infants whose mothers received antiepileptic medication during pregnancy has been reported by Kaneko et al.<sup>67</sup> They also report inadequate suckling and high incidence of vomiting immediately after birth with difficulty establishing lactation. The drug continues to be provided through the milk, and the poor sucking becomes protracted. Table 12-9 lists levels of drug in the milk. When newborn levels are high, the authors suggest giving mixed feedings for the first few days postpartum until the level of drug in the infant drops and the infant is able to clear the drug that was in the system transplacentally before birth. Clinicians should observe these infants closely to be sure they receive adequate calories until they can suck vigorously. The mother should supplement the infant's sucking stimulus to the breast with a breast pump. With proper management in the first few days, the adjustment can be smooth and the infant can go on to nurse effectively.

**TABLE 12-9** Anticonvulsant Concentrations in Maternal Serum and Milk

Drug (Half-Life in Neonate)	Maternal Serum (mcg/mL)	Milk (mcg/mL)	Milk/Serum		
			Day 1	Day 7	Day 30
Diphenylhydantoin (9-6 h)	3.0	0.7	18±15	19±4	13±6
Phenobarbital (156±29 h)	12.0	5.0	30±16	36±7	30±5
Primidone (23±8 h)	4.0	2.1	141±9	56±15	46±7
Carbamazepine (13-6 h)	4.0	1.8	41±16	38±8	—
Valproic acid (47 h)	123 µmol/L	3 µmol/L	0.01 to 0.16	—	—

Modified from Kaneko S, Suzuki K, Sato T, et al: The problems of antiepileptic medication during the neonatal period: is breastfeeding advisable? In Janz D, Dam M, Richens A, et al, editors: *Epilepsy, pregnancy, and the child*, New York, 1982, Raven.

and safely.<sup>15</sup> When infant plasma level determinations are available, it might be advisable to check the plasma level after 1 or 2 weeks of nursing, providing an opportunity to evaluate possible accumulation.

Early childhood development was evaluated in children of women with epilepsy to determine the results of exposure to antiepileptic drugs during pregnancy and breastfeeding. The study had recruited 78,744 dyads, of which 223 were using antiepileptic drugs. Fine motor skills were noted to be reduced by 25% versus 4.8% in the reference group. Social skills were also diminished 23.5% compared to 10.2% in control. Continuous breastfeeding in children of women using antiepileptic drugs less often impaired development at 6 and 18 months compared with those not breastfeeding or breastfed less than 6 months. At 36 months, however, drug exposure was associated with adverse development regardless of breastfeeding. The authors thought that women should be encouraged to breastfeed regardless of need for drug treatment.

## Psychotherapeutic Agents

Lithium is the one drug in the psychotherapeutic group with a clear risk for toxicity in the neonate and clear evidence that it reaches the breast milk. Lithium is contraindicated in pregnancy but has been used cautiously in lactation. Infants have been reported to be hypotonic, flaccid, and "depressed" when nursing mothers take lithium. Although rated a category 6 by the AAP at one time, it is now a 5, use with caution pending the dose used by the mother.

After a careful review of the clinical data, Schou<sup>121</sup> states that accumulating evidence points strongly to the beneficial effects of breastfeeding while taking lithium for both infants and mothers, mentally and physically. Lithium concentrations in breastfed infants have been measured at one tenth to one half of the concentration in the mothers' blood.<sup>122</sup> Such concentrations are considered harmless in adults, but the risk is unknown in children. A pitfall of measuring lithium levels in neonates was pointed out by Tanaka et al.<sup>134</sup> who describe two cases in which blood samples from the neonates were placed in tubes with lithium heparin as the anticoagulant. Schou<sup>121</sup> also states that, with support from her husband and physician, the mother should make her own choice. Initiating lithium therapy after delivery or when a breastfeeding infant is several months old greatly minimizes the theoretic risks. The Lactation Study Center has been contacted about several infants being breastfed by mothers taking lithium with the psychiatrist's and the pediatrician's consent. No

symptoms were apparent. No long-term follow-up is yet available on these children. In parts of the world where water supplies are not well controlled, lithium is a common contaminant—while lithium does appear in the milk of inhabitants, the levels in formula-fed infants are higher than the breastfed infants' levels because the formula is diluted with the water.<sup>51</sup>

Chlorpromazine or phenothiazine appears in the milk in small amounts, even at doses of 1200 mg, but apparently does not accumulate.<sup>7</sup> Doses of 100 mg/day do not appear to cause symptoms in infants. It is usually taken once per day, peaking in plasma 1 to 2 hours after dose, and breastfeeding should be timed to avoid peak. Diazepam (Valium) has been detected in milk and in breastfed infants' serum and urine. It has caused depression and poor feeding with weight loss in infants. In a single dose it should not present a problem. Shorter-acting lorazepam is safer for multiple dose therapy. Chlordiazepoxide (Librium) and clorazepate (Tranxene) do reach the milk and may cause drowsiness and poor sucking. These substances' metabolites are also active, and therefore the half-life of therapeutic activity is prolonged. Meprobamate (Miltown, Equanil) has an M/P ratio greater than 1 and has been identified in milk. Infants whose mothers are taking meprobamate may become drowsy, but dosage adjustment may be indicated if there is significant benefit for the mothers to breastfeed.<sup>7</sup> Usual dosing is three to four times per day, which makes avoiding peak plasma times difficult.

Tricyclic antidepressants, such as imipramine, are lipid soluble and have been identified in the breast milk; thus cautious use may be appropriate.<sup>23</sup> In an extensive study of tricyclic antidepressants in pregnancy and lactation, Misri and Sivertz<sup>98</sup> found that an attitude of informed and cautious encouragement may be appropriate regarding the growing information that suggests it is safe to breastfeed while taking such medication.<sup>146</sup> Consulting LactMed or a University of Rochester phone service may help in selecting the best drug for a given dyad (585-275-0088). When Yoshida et al.<sup>149</sup> investigated the pharmacokinetics and possible adverse effects in infants exposed to tricyclic antidepressants in breast milk, they found no reason to prevent mothers who are taking established tricyclic antidepressants from breastfeeding. The drugs were imipramine, amitriptyline, clomipramine, and dothiepin. They compared infants breastfed by mothers medicated with a tricyclic antidepressant with infants bottle fed by medicated mothers. In addition, they measured the drugs in all maternal plasma and urine and in the foremilk and hindmilk of the lactators. Infant plasma and urine levels were also measured. Levels in the mother and her milk

were correlated with the dose. The daily dose of drug via the breast milk was 1% of the maternal dose per kilogram of weight. Amounts were barely detectable in infants' plasma and urine. The 30-month follow-up detected no differences in growth and development.<sup>149</sup>

The selective serotonin reuptake inhibitors are a class of drugs developed as antidepressants and used in the treatment of panic attacks, obsessive-compulsive disorder, obesity, substance abuse, sleep disorders, chemotherapy-induced nausea and vomiting, migraine, and appetite suppression. Serotonergic dysfunction has been implicated in these illnesses. This group of drugs has antidepressant actions and selectively blocks the reuptake of serotonin into presynaptic neurons (Box 12-2).

These agents undergo extensive metabolism to clinically inactive compounds, have large volumes of distribution, and are highly bound to maternal plasma proteins, suggesting little transfer into milk. The elimination half-lives in the mother range from 15 to 26 hours. Reports of isolated cases have recorded maternal plasma and milk levels of a few of the compounds, but no long-term follow-up of the nurslings. In general, no symptoms have been reported in the infants.

The clinician must weigh the risk/benefit ratio of each drug, keeping in mind that being cared for by depressed mothers is not beneficial for infants. Some mothers have been medicated with antidepressants during their pregnancies, and the withdrawal experienced when the infants are not breastfed may go undiagnosed and be attributed to colic, fussiness, or other disorders. If a mother is to begin medication during lactation, a baseline for the infant should be established by the pediatrician so that any effects of the medication received via the milk can be detected. The age of the infant and the feeding pattern are important issues in the decision (see Box 12-2).

Fluoxetine (Prozac), a common and usually effective therapy for depression and other neuropsychiatric disorders, is reported to have few side effects. Pharmacologically, it is chemically unrelated to antidepressants, has few autonomic effects,

and is considered an alternative to standard antidepressant therapy. Its peak plasma time is 6 to 8 hours, and it is highly protein bound.<sup>18,60</sup> Case studies on lactating women taking fluoxetine have reported no changes in the infants. Maternal blood and milk samples have one fifth to one quarter as much drug (i.e., M/P ratio = 0.20 to 0.25) when fluoxetine and the active metabolite norfluoxetine are measured.<sup>60</sup> Total ingestion by an infant per day was no more than 15 to 20 mcg/kg, a low exposure when the mother had received 20 mg at bedtime for 53 days. The reported levels in milk depend on sampling and lipid content of the milk and range from 47 to 469 ng/mL.<sup>19</sup> Hale et al.<sup>50</sup> report a case in which a mother took fluoxetine throughout pregnancy and while breastfeeding. At 11 days, the infant was somnolent, then unresponsive. Levels were measurable in milk and in the infant. Another case reports severe colic and crying until the drug was stopped.<sup>83</sup>

The AAP considers the psychotropic drugs to be of special concern because they are taken for a long time. Although no adverse effects have been published, the drugs do appear in milk and could conceivably alter short-term and long-term CNS function. These drugs clearly require a physician's careful consideration of the benefits of breastfeeding and the therapeutic risks in each case.<sup>100</sup> The peak plasma time varies from 1½ to 12 hours, so avoiding a peak is difficult. Giving a feeding of formula once daily would dilute the impact. Other selective serotonin reuptake inhibitors, such as sertraline (Zoloft), paroxetine (Paxil), and citalopram (Celexa), may be better choices. Neonatal paroxetine withdrawal syndrome has been described in four term infants who presented with jitteriness and necrotizing enterocolitis after paroxetine exposure in utero. Neonatal withdrawal from paroxetine in infants who did not breastfeed is 10 times higher (0.3/1000) than with sertraline and fluvoxamine and 100 times higher than with fluoxetine (0.002).<sup>133</sup>

Citalopram exposure in breastfeeding infants was examined prospectively in three groups: (a) depressed women treated with citalopram, (b) depressed women not treated with citalopram, and (c) normal women. The infants were no different in the three groups in feeding, medication, or adverse events.<sup>83</sup>

In a study of 78 infants<sup>83</sup> who were exposed to antidepressants through breast milk, the mothers' mood status was evaluated along with infants' weight gain.<sup>55</sup> Weights were not significantly different from the population of normal infants. The infants whose mothers relapsed to significant depression, however, did gain less weight. The authors concluded that the drugs did not decrease weight gain but maternal depression may influence

behaviors that throughout 2 months could affect infants' weight gain. Bupropion (Wellbutrin, Zyban) is a well-known antidepressant and smoking deterrent that is unrelated to the tricyclics. No quantifiable amounts have been detected in infants nor were any adverse effects noted.<sup>8</sup> Peak milk levels have been observed 2 hours after dosing. Estimated dose to infant is only 2% of the maternal dose. Seizures were reported in a 6-month-old infant 4 days after administration of 150 mg per day of bupropion for the mother. The maternal drug was discontinued and no further seizures were observed although breastfeeding was continued.<sup>21</sup> The AAP rates bupropion a category 4, which is a drug for which the effect on nursing infants is unknown or may be of concern. Hale et al.<sup>48</sup> rate it moderately safe (L3), and Briggs et al.<sup>17</sup> say it has potential toxicity based on little data. Schaefer<sup>118</sup> point out that the relative dose, including metabolites, is 0.14%.

### **Methadone Maintenance and Risks of Breastfeeding**

Methadone maintenance treatment for heroin and other addictions has had a significant impact on the recovery of many addicts. When first introduced, it was hoped it would be an ideal treatment for neonatal withdrawal syndrome. It was not. It was also hoped that withdrawal from methadone for an infant born to a woman receiving maintenance therapy would be negligible, but it is not. When pregnant women were maintained on 25 mg/day or less, neonatal withdrawal rarely required treatment. Present regimens during pregnancy typically are for maternal doses of more than 150 mg/day. Neonatal withdrawal from this level is substantial, requiring treatment.

The therapeutic use of methadone in opiate addiction has become a common concern in the childbearing years, especially during pregnancy and lactation. The recommended daily dose has been increased sharply from 25 mg/day to as high as 150 mg/day. Neonatal abstinence syndrome has become more common, often requiring 6 to 8 weeks of hospitalization for the neonate. The question of breastfeeding is frequently asked.

Two women had M/P ratios that remained constant at 0.32 and 0.61, and the infants received a calculated 0.01 to 0.03 mg of methadone per day. Kreek et al.<sup>75</sup> estimated daily infant intake from a mother taking 50 mg daily, assuming consumption of almost a liter of breast milk per day, with a maximum of 0.112 mg/day. Kreek et al.<sup>75</sup> also noted peak levels in the milk at 4 hours after dosing. Pumping and discarding the milk at 3 to 4 hours after dosing has been suggested as a method of reducing exposure.

A study of eight mother-baby pairs in which mothers were on at least 40 mg/dL methadone daily showed the infants received 2.8% of mothers' dose, not sufficient to prevent neonatal abstinence syndrome.<sup>9</sup> In a second study<sup>93</sup> of mothers on methadone who were receiving 25 to 180 mg/day, the methadone levels ranged from 27 to 260 ng/mL, with a mean of 95 ng/mL. No adverse events were associated with breastfeeding or weaning. It was estimated the infant received 0.05 mg/day, which parallels other estimates. An additional study of 12 methadone-maintained mothers found that the methadone concentrations were small, ranging from 21 to 314 ng/mL and unrelated to mothers' doses. The authors suggest that methadone-maintained women can breastfeed.<sup>62</sup> Five mothers who were methadone-maintained (doses 60 to 110 mg/day) were followed with breast milk and plasma samples for up to 6 months by Jansson et al.<sup>63</sup> Concentrations in the milk were small (daily dose to infant 0.15 to 0.30 mg/day). One child was still breastfeeding at a year and had methadone in low concentration in the plasma. A retrospective chart review of 190 drug dependent dyads grouped patients by feeding type—85 were breastfed, 105 were formula fed. Tracking by neonatal abstinence scores (Finnegan Scores), mean scores were significantly lower in the breastfed group. Fewer breastfed infants required withdrawal treatment and the median time to withdrawal was much later in this group. Controlling for type of drugs involved and prematurity still demonstrated reduced need for withdrawal therapy in breastfed infants.

Home-based detoxification for neonatal abstinence syndrome is associated with reduced hospital stays and increased rates of breastfeeding without prolonging therapy in selected dyads.

If the infant is weaned from the breast gradually, there should be no withdrawal, and breastfeeding should not be withheld. See Chapter 16 for discussion of smoking and marijuana (Table 12-10).

### **Pesticides and Pollutants**

Since 1950 human milk has been used as a bio-monitoring tool for assessing mothers' and infants' exposures to environmental chemicals. Since that time a solid database has been created on DDT, dioxins, furans, and polychlorinated biphenyls (PCBs) in various geographic areas. Consistency of analytic methods, sampling techniques, postpartum timing, and reporting chemical concentrations has been lacking. A technical workshop on Human Milk Surveillance and Research on Environmental Chemicals in the United States was held in 2002 and a published report appeared in the *Journal of Toxicology and Environmental Health*.<sup>12</sup> More and

From McCarthy JJ, Posey BL: Methadone levels in human milk, *J Hum Lact* 16:115, 2000.

more often, human milk is being used as the biologic marker of environmental exposures. The disturbing backlash is that the public interprets this to mean that breast milk is contaminated and the problem is getting worse.

Monitoring chemical exposure in a breastfed infant is the task of the epidemiologist and the chemist.<sup>126</sup> Human milk has been known to contain insecticides. Chlorinated hydrocarbons, such as DDT and its metabolites dieldrin, aldrin, and related compounds, are the best known. The major reason these compounds appear in breast milk is that they are deposited in body lipid stores and move with lipid. A fetus receives the greatest dose in utero, and adult body fat has approximately 30 times the concentration in milk. DEET has been shown to be absorbed through the skin in adult males within two hours of application and excreted from the plasma through the urine within 4 hours.

PCBs in heavily contaminated pregnant Japanese women produced small-for-gestational-age infants who had transient darkening of the skin ("cola babies"). Polybrominated biphenyls (PBBs) are similar compounds associated with a heavy exposure to farm animals and contaminated cattle in the lower Michigan peninsula. The women in the United States who have the greatest risk for high exposure to PCBs or PBBs are those who have extensively worked with, or eaten, the fish caught by sport fishing in contaminated waters.

Studies have refuted earlier observations of concern. No information is available in the United States on the levels of polychlorinated dibenzodioxins or polychlorinated dibenzofurans in anglers who consume a lot of fish.<sup>71</sup> Persons at high risk are those who live near a waste disposal site or have been involved in environmental spills. Unless there is heavy exposure, however, no contraindication exists to breastfeeding.

In most cases the levels of pesticides in human milk have been less than those in cow milk. The accumulated amounts have not usually exceeded safe allowable limits. Several extensive reviews explore the dilemma of pollutants in human milk.<sup>112,113,144,147</sup> In a 1997 review of world reports on occurrence and toxicity, Rogan<sup>114</sup> has reaffirmed that breastfeeding should be recommended despite the presence of chemical residues. He further states that the benefits of breastfeeding outweigh the risks of pollutants. It has been suggested that the body burden at birth can be added to by exposing an infant to small levels in the milk that may indeed exceed the exposure limits allowable for daily intake set by the WHO.<sup>132</sup> Human milk levels are used epidemiologically as markers of human exposure in community exposure because of a close correlation between milk levels and the levels in fat stores. Unselected mothers in the Great Lakes region were tested by the State of New York in 1978, and no chemical (PCB, PBB) was found in any milk in random sampling of residents. Thus unless the circumstances are unusual, breastfeeding should not be abandoned on the basis of insecticide contamination.

Chemicals that are lipophilic, biologically stable, nonionized at a physiologic pH, and of low molecular weight transfer easily into maternal milk. Ten to twenty times more of a mother's body burden of persistent organohalogens are transferred via the milk than via the placenta, according to Jensen and Slorach,<sup>64</sup> who published an extensive review of chemical contaminants in human milk. They further caution that the absolute amount transferred depends on the structure of the chemical. PCBs, for instance, are highly chlorinated and transfer more easily than less chlorinated PCBs. No difference was observed in placental and milk transfer of heavy metals.

If extractable fat is measured, the levels of persistent organohalogens are about the same in milk, blood, adipose tissue, and muscle. Mobilization from fat stores is greater than that from dietary intake during lactation.<sup>65</sup>

Agent Orange, the best known of the dioxins, was identified in Vietnam as a powerful teratogen. Dioxin has been found in human milk from pooled samples from high-risk women with known exposure. No evidence suggests that the population at large is at

risk. Women working in dry-cleaning plants, viscose rayon plants, photographic laboratories, and chemical industries where proper precautions are not taken have been noted to absorb tetrachloroethylene, carbon disulfide, and bromides.<sup>44</sup>

Flame retardants, polybrominated diphenyl ethers, which are found in upholstery, electronics, automotive interiors, and plastics, have been banned in several states because of rising body burdens as reflected in several studies in breast milk. A fortyfold increase has been recorded since 1972. At high levels, polybrominated diphenyl ethers cause cognitive and behavior disorders. The risk is in utero. Risk is minimal from breastfeeding, so it is recommended that breastfeeding should take place.<sup>45</sup> Mother to child transfer of essential and toxic elements through breast milk in a mine-waste polluted area is reported by Castro and colleagues.<sup>20</sup> They reported that lower amounts of toxic elements are ingested by breastfed infants compared to infants who receive formula reconstituted with locally contaminated water. Extensive review of industrial chemicals and environmental contaminants in human milk is available in Schaefer, Peters, and Miller.<sup>119</sup>

## Heavy Metals

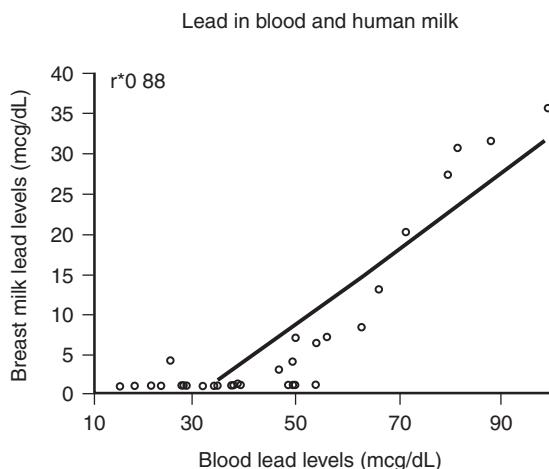

Heavy metals that have been found in milk include lead, mercury, arsenic, cobalt, magnesium, and cadmium and are positively correlated with fish consumption.<sup>14</sup> Whenever maternal exposure occurs, a breastfed infant and the milk should be tested. The intake of lead and cadmium by breastfed infants, as reported by the WHO study, is the same as, or somewhat lower than, that of infants fed formula mixed with local water.<sup>80</sup> Levels of these heavy metals in milk, however, are lower than would be predicted from maternal levels.<sup>118</sup> Placental transfer is greater than by breastfeeding. Most common air pollutants are not found in human milk.

Although removal of lead from gasoline has been associated with a drop in blood lead levels in children from 15 mg/dL in 1978 to 2 mg/dL in 1999,<sup>115</sup> lead has become a significant issue because of the number of mothers testing positive for lead on routine screens for lead in family members of young infants. Release of lead from bone in pregnancy and lactation was studied by Manton et al.,<sup>91</sup> who concluded that the entire skeleton undergoes resorption and blood lead levels of nursing mothers continue to rise, reaching maximum at 6 to 8 months postpartum. They also noted that lead levels fall from pregnancy to pregnancy, suggesting that the greatest risk is with the first pregnancy.<sup>91</sup> The Centers for Disease Control and Prevention (CDC) has revised the standards for treatment downward (Table 12-11). Meta-analysis reflects a 2.6 to 5.8 point decline in IQ for an increase in lead level from 10 to 20 mg/dL.<sup>115</sup> Blood lead concentrations less than 10 mg/dL are inversely associated with children's IQ scores at 3 to 5 years of age according to studies by Canfield.<sup>19</sup> The first step is always to clean up the environment and identify the source. Lead abatement resources are available from the U.S. Department of Health. The level of lead in milk depends on its ionization and tight binding to red blood cells. The M/P ratio is 0.2. A lead level of 40 mg/dL or less in a nursing mother is considered below the level of transfer through the breast milk (Figure 12-3). In addition to environmental sources of lead (e.g., old paint, contaminated ground, lead batteries), diet should be reviewed. In some cities, the water supply is a significant source, especially in formula making. Herbs and herbal teas may also be a source. A long list of traditional and folk remedies contain lead, especially from China, Mexico, India, and Pakistan. A mother's diet should include extra calcium and iron to reduce the absorption of lead from the diet and mobilization from the bone. Newer lead removal medications are safer than the traditional

**TABLE 12-11** Classes and Management of Lead Levels in Blood

Blood Lead Level (mcg/dL)	Class	Management
<10	I	Not considered lead poisoning
10-14	IIA	Many children (or a large proportion of children) with blood lead levels in this range should trigger community-wide childhood lead poisoning prevention activities. Children in this range may need to be rescreened more frequently.
15-19	IIB	Nutritional and educational interventions and more frequent screening; if level persists in this range, environmental investigation and intervention is recommended.
20-44	III	Environmental evaluation and remediation and a medical evaluation; possible pharmacologic treatment of lead poisoning
45-69	IV	Both medical and environmental intervention, including chelation therapy
>69	V	Medical emergency; immediate medical and environmental management

Modified from Centers for Disease Control and Prevention: Blood levels—United States, 1988-1991, MMWR 43:545, 1994.

**Figure 12-3.** Graph showing regression line between blood lead levels and milk lead levels. (From Namihira D, Saldivar L, Pustilnik N, et al: Lead in human blood and milk from nursing women living near a smelter in Mexico City, *J Toxicol Environ Health* 38:225, 1993.)

British anti-lewisite. Succimer is believed safe during lactation and in infants older than 1 year if milk is pumped and discarded for 5 days.<sup>12</sup>

Arsenic is a heavy metal noted to contaminate some waterways and water supplies. It has been evaluated in several parts of the world, including Argentina, Germany, and India. The data are available from these regions on the levels in breast milk and the nursing infants. The arsenic level in drinking water in an Argentinean village was 200 mcg/L, the level in maternal blood 10 mcg/L, and the level in maternal urine 320 mcg/L. The average amount in the milk was 2.3 mcg/kg. Two infants were tested and levels in the urine were 17 and 47 mcg/L, considered very low. In India's West Bengal, an arsenic-affected area, 226 women were tested, some of whom had skin lesions and high levels in their hair. They had arsenic in the breast milk. Most of the arsenic in the milk was inorganic, but the infant levels ranged from 0.3 to 29 mcg/L; those infants who were partially breastfed and formula fed had levels from 0.4 to 1520 mcg/L. The authors conclude that little arsenic is excreted in breast milk, even when the exposure is high from contaminated water; thus exclusive breastfeeding appears to be protective and safer than formula feeding.

Organic mercury is another heavy metal that is being increasingly identified in food around the world. Fish is a major source, as are herbs and tonics. Levels of mercury in mothers' blood are about three times higher than levels in milk. Methylmercury is attached to red blood cells and so has limited access, although it is easily absorbed by infants. Inorganic mercury enters milk easily but is poorly absorbed by infants. When the source of the

methylmercury is from breast milk, the developmental scores exceed those of formula-fed infants, suggesting that the advantages of breastfeeding are significant.<sup>14</sup> A similar, more extensive study in the Seychelles Islands of mothers and children followed from birth for 15 years suggests that the value of a fish diet over time and during breastfeeding is significant despite measurable mercury levels.<sup>92</sup> Almost all the infants in the Seychelles were breastfed for at least 6 months and meet or exceed international developmental scores.<sup>92</sup> Acute exposures to methylmercury from industrial or environmental sources should be evaluated on a case-by-case basis, although it appears breastfeeding is safe.

An increasing number of environmental chemicals are being measured in milk as a consequence of improved analytic capabilities and increased interest in biomonitoring.<sup>78</sup> The tolerable daily intake has been determined by the WHO. This intake is based on the lowest observed adverse effect levels based on laboratory studies from several species. Dioxin concentrations in the lipids of breastfed infants are higher than in formula-fed infants initially but the differences disappear with time. Subtle effects were associated with transplacental rather than lactational exposures in large epidemiological studies in Rotterdam, Amsterdam, and Duisburg. The conclusions supported the WHO position that the health significance of dioxin-like contamination does not reduce the value of promoting and supporting breastfeeding. In studies across time, according to the authors, even when environmental chemicals are high, beneficial effects associated with breastfeeding prevail.<sup>78</sup>

## Well Water

Drinking well water has been a concern because of varying levels of minerals, especially nitrate. More than 18% of wells in the state of Iowa are reported to exceed the maximum contaminant level of 45 mg of nitrate/L or 10 mg NO<sub>3</sub>/L. Infants younger than 6 months of age are especially susceptible to methemoglobinemia, which can lead to anoxic injury and death. It reportedly occurs at nitrate concentrations greater than 100 mg/L. Although this is a major issue for formula-fed infants, Dusdieker et al.<sup>35</sup> explored the question, "Does increased nitrate ingestion elevate nitrate levels in human milk?" Carefully studying 20 healthy mothers with breastfeeding infants older than 6 months subjected to 47, 168, and 270 mg of nitrate per day, they found that urine spot tests rose from 36 mg on day 1 to 66 mg on day 2 and 84 mg on day 3. Nitrate concentrations in the milk on days 1, 2, and 3 were 4.4, 5.1, and 5.2 mg/L, respectively. The authors concluded that "women who consume

water with a nitrate concentration of 100 mg/L or less do not produce milk with elevated nitrate levels.<sup>35</sup>

## Chemicals in the Workplace

An increasing number of women return to the workplace after the birth of an infant, and an increasing number are breastfeeding their infants. The need for information regarding the transfer of chemicals in the workplace to human milk is an increasing problem.

Volatile chemicals in the workplace represent an important but little understood hazard, especially in paint shops, repair shops, garages, and the chemical industry. Fisher et al.<sup>39</sup> developed a physiologically based pharmacokinetic model for lactating women to estimate the amount of chemical that their nursing infants ingest for a given nursing schedule and maternal occupational exposure. The two major factors are the blood/air partition coefficient, a thermodynamic factor that governs

the body burden that may be achieved from inhalation of a chemical, and the pharmacokinetics of the chemical, which determines the length of time a chemical remains in the systemic circulation and is available to transfer into milk. Because milk fat is available, preferential uptake of lipophilic chemicals occurs. Of the 19 chemicals simulated in the study, the authors consider bromochloromethane, perchloroethylene, and 1,4-dioxane exposure the highest risk to infants based on U.S. Environmental Protection Agency (EPA) drinking water guidelines (Table 12-12). Protective gear in the workplace is the most practical way of minimizing exposure to both mothers and infants.

The Occupational Health and Safety Act of the province of Quebec has mandated the establishment and maintenance of a Toxicological Index that provides information on chemical and biologic contaminants potentially present in the workplace.<sup>44</sup> Information can also serve as a basis for the protective reassignment of pregnant or breastfeeding employees. The Infotox database has

**TABLE 12-12** Predicted Amount of Chemical Ingested by Nursing Infant (AMILK) During 24-Hour Period and EPA Drinking Water Health Advisory Values

Chemical	Threshold Limit Value (ppm)	AMILK (mg)	EPA Health Advisory Intake* (mg/day)

information about 5500 chemicals. Of the substances in the database, 2.2% (153 of 5736) show evidence of milk transfer and pose relative risks to breastfed infants.<sup>44</sup>

### **Psychologic Impact of Toxin in Milk**

The psychologic reactions of a group of nursing mothers from the lower Michigan Peninsula whose breast milk was contaminated with a toxic fire-retardant chemical, PBB, were studied.<sup>53</sup> Every tenth woman who had had her milk tested for PBB was contacted for the study (a sample of 200 women); 139 responded and received a questionnaire, and 97 (70%) filled out the questionnaire. The subjects knew their own level and that the range for all mothers was from undetected to 0.46 ppm, with an average of 0.1 ppm. The testing was voluntary and cost \$25. Of those tested, 96% had measurable amounts.

The data were collected in a six-page questionnaire. Two modes of coping emerged: denial and mastery. In general, the findings indicated that the greater the level of toxic contamination of PBB reported in a mother's milk, the greater the denial, to the point of not having correct information, even about her own level. Ambivalence toward nursing was correlated with guilt in both groups (only 15% discontinued breastfeeding). The "draw-a-baby" test showed an unusual amount (94%) of distortion and expressions of anguish. These findings were consistent throughout all test modalities; thus they were not thought to be a function of personality.<sup>53</sup>

### **Radioactive Materials**

Because of the increasing number of diagnostic tests that use radioactive materials, a nursing mother may have such a procedure done, calculating the dose of radiation to the breastfed infant, as most radio pharmaceutical doses are estimated based on data from injected doses rather than oral exposure. Estimates assume the compound is absorbed from the stomach unchanged as in the adult.

Radioactive iodine (<sup>125</sup>I and <sup>131</sup>I) passes into milk at levels as high as 5% of the dose. When this is used for diagnostic purposes, breastfeeding should be discontinued until milk is clear. The excretion by the breast may alter the validity of the test result. If radioactive iodine is to be used therapeutically, breastfeeding must be discontinued until the iodine has cleared the system, which may be 1 to 3 months. A carefully collected sample of milk can be tested for radioactivity so that the period that the infant is off the breast is not unnecessarily long. If a 30 mCi dose of <sup>131</sup>I is used, 24 hours may be adequate to pump and discard.

If an infant is older and receiving other foods, time can be altered accordingly. A lung scan (300-mCi dose) requires 7 days, and renography requires 2 days of pumping and discarding the milk.<sup>69</sup>

Gallium-67 citrate appears in significant amounts in the milk. It does clear the body quickly and is relatively safe for use in patients. Breastfeeding should be discontinued for at least 72 hours.

Technetium-99m (<sup>99m</sup>Tc) is reported to clear the milk in 6 to 48 hours. The stage of lactation, whether the breast is emptied before receiving the dose, and the method of clearing the breast may be responsible for inconsistent results. Discontinuing breastfeeding for at least 24 hours is advisable.

The amount of radioactivity excreted in breast milk after administration of <sup>99m</sup>Tc hexakis 2-methoxyisobutyl isonitrile in a single dose was reported by Rubow et al.<sup>116</sup> The measurement was highest in the first sample at 3.3 hours, 0.488 kilobecquerel (kBq)/mL, with negligible amounts thereafter (less than 0.180 kBq/mL). Less than 2.96 kBq/mL is considered safe. Only the first sample needs to be discarded.<sup>117</sup>

The American College of Radiology (ACR) has recognized the need for good information about the administration of contrast medium to nursing mothers. When a conflict of opinion exists, one can refer to the 2010 edition of the *Contrast Manual* published by ACR.<sup>3</sup>

The ACR summarizes a review of the literature as follows:

1. Less than 1% of an administered maternal dose of contrast agent is excreted into breast milk.
2. Less than 1% of contrast medium in breast milk ingested by an infant is absorbed from the GI tract.

Iodinated x-ray media, both ionic and nonionic, when given intravenously, have a plasma half-life of approximately 2 hours, with nearly 100% clearance in 24 hours. Less than 1% is in the milk, and less than 1% is absorbed by an infant; therefore an infant receives less than 0.01% of the dose. The recommended dose for an infant receiving directly for a procedure is 2 mL/kg. Although not necessary, a mother may pump and discard her milk for 2 to 24 hours, if she chooses.

### **GADOLINIUM-BASED CONTRAST AGENTS**

Free gadolinium is a neurotoxic, but it is safe when complexed with a variety of chelates. These hydrophilic agents behave much like the iodinated x-ray contrast media discussed previously with a plasma half-life of 2 hours and total clearance by 24 hours. In the case of gadolinium, only 0.04%

is excreted into the milk, and the expected dose absorbed by the infant is less than 0.0004% of the maternal dose.<sup>76</sup> The pediatric dose is 0.2 mmol/kg and breast milk dose would be less than 0.00008 mmol/kg. No untoward effects have been reported.

With the advent of ultrasound examination, computed tomography scanning, magnetic resonance imaging, and other techniques, in many situations alternatives to the use of radioactive material during lactation exist.

## DERMATOLOGIC MEDICATION

The key issue involved with the dermatologic application of medications is whether or not they are absorbed through the skin. A small amount on the skin covering a few square inches may not be a problem from a dose standpoint. An important issue is the direct application to the nipple and areolar tissue because this area is in the baby's mouth during a feeding. Application to the breast should not be done until after the feeding in any case. Most prescription dermal medications indicate the percentage of active ingredient absorbed so the health care provider can determine the risk during lactation. Most antibiotics, antivirals, and antifungals applied dermally are safe because they could be given directly to the infant.

Scabies treatment should avoid lindane and malathion during lactation. Psoriasis therapy is a risk during lactation—anti-itch products are safe except doxepin. Acne treatments that include vitamins are a risk to an infant.

## Immunizations

### IMMUNIZING BREASTFED INFANTS

Questions often arise about whether breastfed infants should be immunized on a different schedule because of the protective maternal antibodies that might interfere with an infant's response to antigen stimulation. Following are some brief guidelines on the more common situations of concern.<sup>25</sup>

1. The AAP recommends that all infants should be vaccinated on the regular schedule regardless of the mode of feeding.
2. Vaccinations for diphtheria-pertussis-tetanus are not altered by breastfeeding, and the regular schedule should be followed for the infants.
3. Because oral poliovirus vaccine is a live virus vaccine, it was a concern that the maternal antibodies would inactivate it. However, the CDC recommendation is that the same schedule be followed. The current scientific literature

indicates that for infants older than 6 weeks, the earliest age of vaccination recommended, no indication exists for withholding breastfeeding in relationship to oral poliovirus vaccine administration, and no need exists for extra doses of vaccine. Furthermore, antibody responses to parenteral and oral vaccines are better in breastfed than formula-fed infants. The same is true for diphtheria and tetanus toxoid.<sup>24</sup>

4. Rubella, mumps, and measles vaccines should be given at the regularly scheduled times.<sup>24</sup>
5. A *Haemophilus influenzae* type B vaccine is available for infants. The *H. influenzae* type B conjugate vaccines should be given at 2 months of age or as soon as possible thereafter, following the AAP Red Book guidelines in the Report of the Committee on Infectious Disease. No modification of the immunization schedule is necessary for breastfed infants. Furthermore, data suggest breastfed infants ultimately have higher antibody titers than formula-fed infants.

## IMMUNIZING THE NURSING MOTHER

There is no reason for concern about the potential presence of live viruses from vaccines in a mother's milk if she is vaccinated during the postpartum period. Breastfeeding women may follow the same schedule for adults that is followed for other adults for measles, mumps, rubella, tetanus, diphtheria, influenza, *Streptococcus pneumoniae* infection, hepatitis A, hepatitis B, and varicella. When traveling to an endemic area, inactivated poliovirus vaccine can be given.<sup>25</sup>

### Smallpox

Smallpox vaccination is inadvisable for the mother of any infant younger than 1 year of age, nursing or not. The personal contact, not the breastfeeding, causes the risk; therefore no advantage exists to weaning if vaccination is necessary. This vaccination is not given routinely and is rarely indicated.

### Rh Immune Globulin

Only rare trace amounts of anti-Rh are present in colostrum and none is found in the mature milk of women given large doses of Rh immune globulin immediately postpartum. No adverse response was noted, even with these high dosages. Any Rh antibodies in the mother's milk are thought to be inactivated by the gastric juices. Rh immune globulin or Rh sensitization is not a contraindication to breastfeeding.

## Rubella

Following are the recommendations with respect to rubella:<sup>25</sup>

1. Approximately 85% to 90% of the adult female population are thought to have a high level of naturally acquired immunity, and only 10% to 15% are considered to be susceptible to rubella infection.
2. Vaccination of pregnant women is contraindicated under all circumstances.
3. No woman of childbearing age should be vaccinated without having been first tested for immunity.
4. If the test is negative, the woman may be vaccinated if there is reasonable assurance that she will not become pregnant for at least 2 months.

The rubella virus was found in the milk of 69% of the women immunized with live attenuated rubella (HPV-77 DE5 or RA 27/3 strains).<sup>88</sup> A virus-specific immunoglobulin A antibody response was seen in the milk of all the women. Infectious rubella virus or virus antigen was recovered from the nasopharynx and throat of 56% of the breastfed infants and none of the nonbreastfed infants. No infant had the disease in this study, but 25% of the breastfed group had seroconversion transiently. Infants given early strains of the virus via the milk were reported to develop mild symptoms.<sup>72,79</sup> Although the attenuated virus may appear in the milk, this should not dissuade one from vaccinating a breastfeeding mother at the safest time, that is, immediately postpartum.

## CHAPTER 13

# *Transmission of Infectious Diseases Through Breast Milk and Breastfeeding*

---

A large body of evidence clearly demonstrates the protective effects of breastfeeding and documents the transmission of specific infections to infants through breast milk. The fear and anxiety that arise with the occurrence of any infectious disease are even greater for the breastfeeding mother-infant dyad. Uncertainty and lack of knowledge often lead to proscribing breastfeeding out of fear, which then deprives the infant of the potential protective, nutritional, and emotional benefits of breastfeeding exactly at the time when they are most needed (see the discussion of immunologic benefits of human milk in [Chapter 5](#)). Decisions concerning breastfeeding in a mother with an infectious illness should balance the potential benefits of breastfeeding against the known or estimated risk for the infant acquiring a clinically significant infection via breastfeeding and the potential severity of the infection.

Documenting transmission of infection from mother to infant by breastfeeding requires not only the exclusion of other possible mechanisms of transmission but also the demonstration of the infectious agent in the breast milk and a subsequent clinically significant infection in an infant that was caused by a plausible infectious process. The first step is to establish the occurrence of a specific infection (clinically or immunologically evident) in a mother and to demonstrate the persistence of the infectious agent, such that it could be transmitted to the infant. Isolation or identification of the infectious agent from the colostrum, the breast

milk, or an infectious lesion of the breast is important, but it is not necessarily proof of transmission to an infant. Epidemiologic evidence of transmission must be considered, including identifying characteristics of the organism that relate an isolate from an infant to the maternal isolate. Infectious organisms can reach the breast milk either by secretion in the fluid or cellular components of breast milk or by contamination of the milk at the time of or after expression. A reasonable mechanism of infection via breast milk should be evident and proved through either animal or human studies. Demonstration of a subclinical or clinically evident infection in an infant should follow these outlined steps.

Exclusion of other possible mechanisms of transmission (exposure to mother or other persons/animals via airborne, droplet, arthropod, or vector modes of transmission or through direct contact with other infectious fluids) would complete the confirmation of transmission of infection via breastfeeding. It is essential to exclude prenatal or perinatal transmission of infection to a fetus or infant, but doing this can often be difficult.

Clinical case reports or studies confirming the isolation of an infectious agent from the milk are important. To determine a reasonable estimate of the risk for infection via breast milk, larger epidemiologic studies are needed that compare infection rates in breastfed infants versus formula-fed infants, addressing the issues just identified. The timing of breastfeeding is important relative to the timing

of maternal infection and to the presence of a pathogen in the colostrum or breast milk. The duration of breastfeeding is another important variable to consider in the estimate of risk, because the shedding of a pathogen in breast milk may be intermittent.

These considerations are only some of the variables to be taken into account, in general, to assess the risk for transmission of an infectious agent from mother to infant via breast milk or breastfeeding. Efforts to prove transmission of infection in a particular maternal-infant dyad can be just as difficult and must consider many of the same factors.

This chapter focuses on a discussion of specific, clinically relevant, infectious agents and diseases, with reasonable estimates of the risk for infection to infants from breastfeeding. The basic tenet concerning breastfeeding and infection is that breastfeeding is rarely contraindicated in maternal infection.<sup>270</sup> The few exceptions relate to specific infectious agents with strong evidence of transmission and to the association of an infant's illness with significant morbidity and mortality.

The risk or benefit of breastfeeding relative to the immunization of a mother or infant is discussed for certain microorganisms. Appendix F addresses precautions and breastfeeding recommendations for maternal infections. Chapter 5 reviews how breastfeeding may protect against infection. Chapter 21 addresses specific concerns relating to banked breast milk and includes standards developed by the Human Milk Banking Association of North America to guide the appropriate handling of banked human milk relative to possible infectious agents.

## *Infection-Control Considerations*

Isolation precautions have undergone some revisions in terminology and conceptualization.<sup>158</sup> Understanding that the transmission of microorganisms can occur with a known infection and with unrecognized sources of infection, recommendations have been made for standard precautions to be applied to all patients to protect health care workers from potentially infectious body fluids. Additionally, precautions based on the predominant modes of transmission have been recommended to protect against infection through the airborne route, direct contact, or contact with droplets. Although these precautions are intended to be used in clinical situations to protect health care workers, they may be applied in certain situations to the mother-infant dyad to prevent the transmission of infectious agents from one to the other or to other

hospitalized mothers and infants. These precautions are useful most often when a mother and infant are still hospitalized. The use of such precautions within the home is not meant to limit breastfeeding. These precautions are intended to allow breastfeeding in the majority of cases and to facilitate the continuation of breastfeeding with some additional safeguards in certain situations, after short temporary periods of stopping breastfeeding. The guidelines also indicate when to safely use expressed breast milk (see Appendix F).

## **STANDARD PRECAUTIONS**

Standard precautions include preventing contact with blood, all body fluids, secretions and excretions, nonintact skin, and mucous membranes by (1) careful handwashing before and after every patient contact; (2) use of gloves when touching body fluids, nonintact skin, mucous membranes, or any items contaminated with body fluids (linens, equipment, devices, etc.); (3) use of nonsterile gowns to prevent contact of clothing with body fluids; (4) use of masks, eye protection, or face shields when splashing with body fluids is possible; and (5) appropriate disposal of these materials. Standard precautions should be applied to all patients regardless of actual or perceived risks. The Centers for Disease Control and Prevention (CDC) does not consider breast milk to be a body fluid with infectious risks, and thus these policies do not apply to breast milk. (See section on misadministration of breast milk later in this chapter as a possible exception to this concept.)

In considering breastfeeding infant-mother dyads and standard precautions, body fluids other than breast milk should be avoided, and only in specified situations should breast milk also be avoided. In general, clothing or a gown for the mother, and bandages if necessary, should prevent direct contact with nonintact skin or secretions. Avoiding infant contact with maternal mucous membranes requires mothers to be aware of and understand the risks and to make a conscious effort to avoid this type of contact. The use of gloves, gowns, and masks on infants for protection is neither practical nor appropriate. The recommendations concerning the appropriateness of breastfeeding and breast milk are addressed for specific infectious agents throughout this chapter. Human immunodeficiency virus (HIV) infection is an example of one infection that can be prevented by the use of standard precautions, including avoiding breast milk and breastfeeding. The recommendations concerning breastfeeding and HIV and the various variables and considerations involved are discussed later.

## AIRBORNE PRECAUTIONS

Airborne precautions are intended to prevent transmission via droplet nuclei (dried respiratory particles smaller than 5  $\mu\text{m}$  that contain microorganisms and can remain suspended in the air for long periods) or dust particles containing microorganisms. Airborne precautions include the use of a private room with negative-air-pressure ventilation and masks at all times. In the case of pulmonary tuberculosis (TB), respiratory protective devices (requiring personal fitting and seal testing before use) should be worn. Airborne precautions are recommended with measles, varicella or disseminated zoster, and TB. Breastfeeding in the presence of these maternal infections is prohibited during the infectious period. This is to protect against airborne transmission of the infection from the mother and to allow the infant to be fed the mother's expressed breast milk by another individual. The exception to allowing breast milk would be local involvement of the breast by varicella-zoster lesions or *Mycobacterium tuberculosis*, such that the milk becomes contaminated by the infectious agent.

## DROPLET PRECAUTIONS

Transmission via droplets occurs when an individual produces droplets that travel only a short distance in the air and then contact a new host's eyes, nose, mouth, or skin. The common mechanisms for producing droplets include coughing, sneezing, talking (singing or yelling), suctioning, intubation, nasogastric tube placement, and bronchoscopy. In addition to standard precautions applied to all patients, droplet precautions include the use of a private room (preferred) and a mask if within 3 feet (0.9 m) of the patient. Droplet precautions are recommended for adenovirus, diphtheria, respiratory infections, *Haemophilus influenzae*, *Neisseria meningitidis* or invasive infection, influenza, mumps, mycoplasma, parvovirus, pertussis, plague (pneumonic), and rubella, as well as streptococcal pharyngitis, pneumonia, or scarlet fever. The institution of droplet precautions with a breastfeeding mother who has these infections should be specified for each particular infection. This may require some period of separation for the infant and mother (for the duration of the illness, for the short term, or complete treatment of the mother, for the infectious period) with use of expressed breast milk for nutrition in the interim. Prophylactic treatment of the infant, maternal use of a mask during breastfeeding or close contact, combined with meticulous hand washing and the mother's avoidance of touching her mucous membranes, may be adequate and reasonable for certain infections.

## CONTACT PRECAUTIONS

Contact precautions are meant to prevent the transmission of an infectious agent via direct contact (contact between the body surfaces of one individual and another) and indirect contact (contact of a susceptible host with an object contaminated with microorganisms from another individual). Contact precautions include cohorting or a private room, gloves and gowns at all times, and handwashing after removal of gown and gloves. Contact precautions are recommended for a long list of infections, such as diarrhea in diapered or incontinent patients with *Clostridium difficile* infection, *Escherichia coli* O157:H7, *Shigella*, rotavirus, hepatitis A, respiratory illness with parainfluenza virus or respiratory syncytial virus (RSV), multidrug-resistant (MDR) bacteria (e.g., enterococci, staphylococci, gram-negative organisms), enteroviral infections, cutaneous diphtheria, impetigo, herpes simplex virus (HSV) infection, herpes zoster (disseminated or in immunocompromised individuals), pediculosis, scabies, *Staphylococcus aureus* skin infection, viral hemorrhagic fevers (e.g., Ebola, Lassa), conjunctivitis and abscesses, cellulitis, and decubitus that cannot be contained by dressings.<sup>102</sup> For a breastfeeding mother-infant dyad, the implementation of precautions for each of these infections in a mother requires meticulous attention to gowning and handwashing by the mother and a specialized plan for each situation. This is particularly true for uncommon, but potentially serious or fatal, infections such as viral hemorrhagic fevers, including Ebola virus disease (EVD), or exposure. (Bausch DG et al.: JID, 2007, <http://www.cdc.gov/vhf/ebola/hcp/infection-prevention> (accessed 17.01.15.) <http://www.cdc.gov/vhf/ebola/prevention/index.html> (accessed 9/6/15).

Each of these transmission-based precautions can be used in combination for organisms or illnesses that can be transmitted by more than one route. They should always be used in conjunction with standard precautions, which are recommended for all patients. The *Red Book: Report of the Committee on Infectious Diseases* by the American Academy of Pediatrics (AAP)<sup>103</sup> remains an excellent resource for infection control guidelines and recommendations to prevent transmission in specific situations and infections.

## CULTURING BREAST MILK

The routine culturing of breast milk or the culturing of breast milk to screen for infectious agents is not recommended, except when the milk is intended as donor milk for another mother's child directly or through human milk banks. See Chapter 21 for specific bacterial count standards for raw donor milk

and for pasteurization of donor milk. Breastfeeding and the expression of or pumping of breast milk (referred to as expressed breast milk) for later use are not sterile activities. An emerging practice related to an increase in the use of donor human milk is milk-sharing. (This is addressed in the next section and Chapter 21.)

In general, expressed breast milk should not contain large numbers of microorganisms (less than  $10^4$  for raw milk and less than  $10^6$  for milk to be pasteurized), nor should it contain potential pathogens such as *S. aureus*,  $\beta$ -hemolytic streptococci, *Pseudomonas* species, *Proteus* species, or *Streptococcus faecalis* or *faecium*. Few studies have examined the "routine" culturing of milk and the significance of specific bacterial colony counts relative to illness in infants.<sup>265</sup> Other studies have been primarily concerned with premature or low-birth-weight (LBW) infants who remain hospitalized and are commonly fed via enteral tubes. A study from Canada tested 7610 samples of milk for use in 98 preterm infants.<sup>269</sup> The study did not identify any adverse events in the infants attributed to organisms growing in the milk samples, and the routine bacteriological testing of expressed breast milk was not recommended. A study from Chicago examined gram-negative bacilli in the milk used for premature infants.<sup>55</sup> Samples were tested before feeding and from the nasogastric tubes during feeding. Milk samples from before feeding were less likely to contain gram-negative bacilli (36%) than milk samples from the nasogastric tubing (60%). Feeding intolerance was observed when there were more than  $10^3$  colony-forming units per milliliter (CFU/mL), and episodes of sepsis were identified when the bacterial counts in the milk were greater than or equal to  $10^6$  CFU/mL. This study recommended the routine bacteriologic testing of expressed breast milk. Another study from Arkansas focused on the contamination of feeding tubes during the administration of expressed breast milk or formula.<sup>311</sup> Ten infants in the neonatal intensive care unit (NICU) were exposed to greater than  $10^5$  gram-negative bacteria in their feeding tubes. The three infants who were fed expressed breast milk with contamination at greater than  $10^5$  organisms remained well, but the seven formula-fed infants with high levels of bacterial contamination in the feeding tubes developed necrotizing enterocolitis. The gram-negative bacteria with high-level contamination in the feeding tubes were either *Enterobacter* or *Klebsiella* in all cases. Many NICUs consider  $10^5$  to  $10^6$  CFU/mL as the significant bacterial count for gram-negative bacilli in breast milk that places premature and LBW infants at greater risk for infection.

Even fewer data are available concerning specific bacterial colony counts for gram-positive

organisms and the risk to the infant. Generally less than  $10^3$  gram-positive organisms per mL of milk is considered acceptable, with only case reports and no controlled trials to support this cutoff.

When the presence of an infectious illness in an infant and/or the breastfeeding mother's breast and breast milk is seriously considered as a possible mechanism of transmission to the infant, culturing breast milk to identify the organism may be warranted and useful. More important than hurrying to culture breast milk is the careful instruction of mothers on the proper technique for collecting expressed breast milk, storing it, and cleaning the collection unit. The reinforcement of proper technique from time to time, especially when a question of contamination arises, is equally important. Many small reports comment on the contamination of breast milk with different collection methods. Relative comparisons suggest decreasing contamination of expressed breast milk when collected by the following methods: drip milk, hand-pumped milk, manual expression, modern electric-pumped milk. One group from Malaysia published results showing no difference in contamination between milk collected by electric pump versus manual expression when collected in the hospital. Expressed breast milk collected at home by breast pump had higher rates of contamination with staphylococci and gram-negative bacteria.<sup>53</sup> Discussion continues about the need to discard the first few milliliters of milk to lower bacteria numbers in expressed breast milk without any evidence to suggest if this is truly necessary.<sup>69,377</sup> No evidence shows that cleansing the breast with anything other than tap water decreases the bacterial counts in cultured expressed breast milk.<sup>459</sup> If an infant is directly breastfeeding, collecting milk for culture by manual expression and trying to obtain a "midstream" sample (as is done with "midstream" urine collection for culture) is appropriate. If an infant is being fed expressed breast milk, collecting and culturing the milk at different points during collection (utilizing the same technique the mother uses [manual expression, hand pump, or electric pump]) and administration are appropriate. This might include a sample from immediately after collection, another of stored expressed breast milk, and a sample of milk from the most recent infant feeding at the time the decision to culture is made. See Box 13-1 for the basic steps in culturing expressed breast milk.

The interpretation of such culture results can be difficult and should involve a pediatric infectious disease expert, a microbiologist, and a hospital epidemiologist. Additional organism identification is often required, utilizing antibiogram patterns or molecular fingerprinting by various techniques to correlate a bacterial isolate from breast milk with an isolate causing disease in infant or mother.

**BOX 13-1. Culturing Breast Milk**

1. Wash hands as per routine.
2. Wash breast with warm tap water and a clean washcloth.
3. Manually express breast milk ("midstream" collection is not required) or attach breast pump flange (previously cleaned as per routine) for collection and collect milk.
4. Place a 3- to 5-mL sample of expressed breast milk in a sterile container with a nonleakable top.
5. Deliver to the laboratory in less than 1 hour or refrigerate at 4°C until delivery. Before sending samples to the viral lab or for nucleic acid/polymerase chain reaction (PCR) testing, confirm that the laboratory will accept and process the sample as requested and that the appropriate collection container and prelaboratory management of the specimen are utilized.
6. Processing of specimens:
  - a. Direct examination by Gram stain is not required.
  - b. Culture on blood agar (BA) and MacConkey agar (MAC) media as per lab standards.
  - c. Quantitate all isolates.
  - d. Send separate samples for fungal culture, acid-fast bacilli, and viral culture, as indicated, based on the clinical situation.

Perform routine sensitivity testing on all potential pathogens. (This will require some discussion with the clinician and perhaps a pediatric infectious disease specialist.)

of their human milk products. Donor selection, screening, exclusion, and education, Holder pasteurization (HP) or high-temperature short-time (HTST) pasteurization, and postpasteurization bacterial culture testing are the main components utilized to maintain the safety and quality of donor milk from human milk banks<sup>264</sup> (see Chapter 21).

The proper pasteurization of donor human milk virtually eliminates any infectious risks from donor human milk. Risk from drug exposure in donor milk is primarily addressed through donor selection and exclusion, although Prolacta includes donor milk drug testing as part of the screening process.

The notable increase in donor human milk sharing via Internet sites has raised concerns about the safety and quality of milk obtained in this manner. Although several of the larger Internet organizations (e.g., Human Milk for Human Babies [HM4HB, <http://www.hm4hb.net>], Eats on Feets [<http://www.eatsonfeets.org>], and MilkShare [<http://milkshare.birthingforlife.com>]) promote the concepts of safe and ethical milk sharing, informed consent, "informal donor screening," safe collection, storage, shipment and handling, and home pasteurization, there are many other avenues on the Internet for milk sharing, and the safety of milk sharing via the Internet has not been extensively studied.

Two publications by the same group have looked at the process of purchasing human milk on the Internet in terms of the ease and reliability of the process, shipping, costs, delays, the condition of packaging and milk containers, the temperature of the milk samples on arrival, and microbial contamination. Geraghty et al.<sup>161</sup> and Keim et al.<sup>234</sup> reported receiving 50% of the packages on the day after shipment and 37% on the second day after shipment. Nine percent of these shipping boxes were rated as severely damaged, 15% of the milk containers had evidence of leaking milk, and 45% of the milk samples arrived with a surface temperature of the milk > 4°C, the recommended refrigerator temperature for the storage of human milk. The surface milk temperature was noted to correlate with the cost of shipping, time in transit, and milk-container condition rating. The authors also compared the bacteriologic culture results of milk obtained via the Internet and milk obtained from a human milk bank. The Internet samples were colonized with gram-negative bacteria 74% of the time or had colony counts of >10<sup>4</sup> CFU/mL. Compared with samples from a human milk bank, Internet samples had higher mean total aerobic counts, total gram-negative counts, coliform counts, and *Staphylococcus* sp. counts. Milk bank samples were CMV DNA positive 5% of the time, with 21% of Internet samples being CMV DNA positive. None of the samples tested positive for HIV-RNA.<sup>161,234</sup>

## DONOR HUMAN MILK

The WHO, the United Nations Children's Fund (UNICEF), and the AAP recommend the use of donor human milk when the infant's own mother's milk is unavailable. The AAP recommends pasteurized donor milk. The possible sources of donor human milk include wet nursing, cross nursing, milk sharing, and human milk banks. Milk sharing is a more informal process, as compared to human milk banks with guidelines and procedures to maintain safety and quality of the donated milk. Milk sharing occurs more directly among family and friends or now at greater distances between unknown donors and recipients via the Internet. Human milk banks are either not-for-profit banks (e.g., Human Milk Banking Association of North America [HMBANA] or established milk banks in numerous other countries) or commercial entities (e.g., Prolacta).

The federal government in the United States does not regulate or oversee milk banking, but HMBANA maintains milk-banking guidelines and procedures for banks within their association. Prolacta Bioscience, Inc. follows FDA guidelines for both food and pharmaceuticals in the production

Despite the fact that the larger milk-sharing websites recommend guidelines for hygienic collection, appropriate storage, and shipping, the quality and safety of human milk obtained via milk sharing on the Internet fall short of expected standards for donor human milk. This highlights the relative importance of proper, effective home pasteurization of donor human milk by the receiving mother prior to giving it to an infant.

Clearly, more study of the safety and quality of donor human milk obtained via the Internet is needed, with a particular focus on obtaining outcome data on the infants receiving this milk. Additionally, increasing the availability and decreasing the cost of donor human milk from not-for-profit and commercial milk banks, while maintaining quality and safety, is essential to providing for the needs of an increasing number of infants who have an inadequate supply of their own mother's milk.

## *Misadministration of Breast Milk*

The misadministration of breast milk, also known as misappropriation, breast milk exposure, and accidental ingestion of breast milk, among other terms, is a medical-legal issue when it occurs in a hospital. This scenario occurs when one infant receives breast milk from another mother by mistake. This occurrence can be very distressing to the families (recipient patient, recipient parent, and donor mother) and medical staff involved. The actual risk for transmission of an infectious agent to an infant via a single ingestion of expressed breast milk (the most common occurrence) from another mother is exceedingly low. In this scenario, the CDC recommends treating this as an accidental exposure to a body fluid that could be infectious.<sup>89</sup> Bacterial, fungal, or parasitic infection from the one exposure is highly unlikely. The concern is about viral pathogens, known to be blood-borne pathogens that have been identified in breast milk and include but are not limited to hepatitis B virus (HBV), hepatitis C virus (HCV), cytomegalovirus (CMV), West Nile virus, human T-cell lymphotropic virus (HTLV), and HIV.

Most hospitals have protocols for managing the situation from both the infection control/prevention and the medical-legal perspectives. These protocols advise informing both families about what occurred, discussing the theoretical risks of harm from the exposure, and reviewing test results and/or recommending testing to determine the infectious status of each mother relative to the mentioned viruses. HCV is not a contraindication to breastfeeding, and West Nile virus infection in lactating women is rare.<sup>80,195</sup> Neither infection has a

documented effective form of prevention or acute treatment. Testing either the donor mother or the mother of the recipient infant for these agents is not warranted. Prenatal testing for HIV is more commonplace throughout the world. The incidence of HIV among women of childbearing age is low, although it varies significantly by geographic location, and the hospital or locale-specific incidence would be important to know in order to estimate risk. Most women and medical staff are aware that HIV can be transmitted by breastfeeding; therefore, breast milk from HIV-positive women is rarely if ever stored in hospitals. The risk for transmission of HIV via breastfeeding is due to the volume of feedings over months (estimated at 400 to 500 feedings in the first 2 months of life) compared to the small "dose of exposure" from one or two "accidental feedings." Transmission of HIV from a single breast milk exposure has never been documented. Immunologic components in breast milk, along with time and cold storage temperatures, inactivate the HIV in expressed breast milk. For these reasons, the risk for transmission of HIV via expressed breast milk consumed by another child is thought to be extremely low. HTLV-I/II infection in childbearing women is uncommon, except in certain geographic regions (Japan, Africa, the Caribbean, and South America). Transmission of HTLV via breast milk does occur and, like HIV, appears to be related to the volume and duration of breastfeeding. Limiting the duration of breastfeeding is effective in decreasing transmission.<sup>452,453,497,498</sup> Freezing and thawing expressed breast milk decreases the infectivity of HTLV-I.<sup>11</sup> In areas of low prevalence, a positive test in a mother should be suspected to be a false positive test, and retesting with both antibody and polymerase chain reaction (PCR) testing should be performed. For these reasons the transmission of HTLV-I/II via accidental expressed breast milk exposure is thought to be extremely low. Although the majority of women are CMV-positive by childbearing age and CMV transmission occurs via breastfeeding, the risk for CMV in a full-term infant is low. Premature or LBW infants are at greater risk for developing disease with CMV infection. Freezing expressed breast milk (at -20°C) for 3 to 5 days significantly decreases the infectivity of CMV. Here again, the risk for CMV transmission from a single accidental exposure to CMV-positive expressed breast milk is extremely low.

Any discussion of theoretical risk should be accompanied by a discussion of possible preventive interventions, such as vaccination or antimicrobial postexposure prophylaxis. If donor mothers are positive for HBV, it is appropriate to give recipient infants hepatitis B virus immunoglobulin (HBIG)

and HBV vaccines if they have not already received them. If a donor mother is HIV- or HTLV-I/II-positive, the potential utility of postexposure prophylaxis with antiretroviral medications should be considered on a case-by-case basis. Clinicians participating in these decisions can refer to the AAP *Red Book*<sup>102</sup> or the updated *United States Public Health Service Guidelines for the Management of Occupational Exposures to HIV and Recommendations for Post-exposure Prophylaxis* (available at [http://nccc.ucsf.edu/wp-content/uploads/2014/03/Updated\\_USPHS-Guidelines\\_Mgmt\\_Occupational\\_Exposures\\_HIV\\_Recommendations\\_PEP.pdf](http://nccc.ucsf.edu/wp-content/uploads/2014/03/Updated_USPHS-Guidelines_Mgmt_Occupational_Exposures_HIV_Recommendations_PEP.pdf) (Accessed 9/6/15).<sup>363</sup>

It may also be appropriate to consult a pediatric infectious disease specialist.

Additional important components of the hospital-based protocols for managing accidental expressed breast milk exposure include ongoing psychosocial support for the families and staff, documentation of medical discussions with the families, investigative steps, consents and interventions, and the demonstration of ongoing infection control efforts to prevent additional events of misadministration of breast milk.

## Clinical Syndromes and Conditions

Microorganisms produce a whole spectrum of clinical illnesses affecting mothers and infants. Many situations carry the risk for transmission of the involved organism from a mother to the infant, or vice versa; in general, however, infants are at greater risk because of such factors as inoculum size and immature immune response. As always, an infection must be accurately diagnosed in a timely manner. Empiric therapy and initial infection-control precautions should begin promptly based on the clinical symptoms and the most likely etiologic agents. When dealing with a maternal infection, clarifying the possible modes of transmission and estimating the relative risk for transmission to the infant are essential first steps to decision making about isolating a mother from her infant and the appropriateness of continuing breastfeeding or providing expressed breast milk. Breastfeeding is infrequently contraindicated for specific maternal infections.<sup>270</sup> Often, the question of isolation and interruption of breastfeeding arises when symptoms of fever, pain, inflammation, or other manifestations of illness first develop in a mother and the diagnosis is still in doubt. A clinical judgment must be made based on the site of infection, probable organisms involved, possible or actual mechanisms of transmission of these organisms to the infant, estimated virulence of the organism, and likely susceptibility of the infant. Additionally, by the time the illness is clearly recognized or

diagnosed in a mother, the infant has already been exposed. Given the dynamic nature of the immunologic benefits of breast milk, the continuation of breastfeeding at the time of diagnosis or illness in a mother can provide the infant protection rather than continued exposure in most illnesses. Stopping breastfeeding is rarely necessary. Many situations associated with maternal fever do not require separation of mother and infant, such as engorgement of the breasts, atelectasis, localized nonsuppurative phlebitis, or urinary tract infections.

**Appendix F** lists a number of clinical syndromes, conditions, and organisms that require infection-control precautions in hospitals. This appendix also includes short lists of possible etiologic agents for these conditions and appropriate precautions and recommendations concerning breastfeeding for different scenarios or organisms. This chapter considers specific infectious agents that are common, clinically significant, or of particular interest.

## Bacterial Infections

---

### ANTHRAX

*Bacillus anthracis*, a gram-positive, spore-forming rod, causes zoonotic disease worldwide. Human infection typically occurs due to contact with animals or their products. Three forms of human disease occur: cutaneous anthrax (the most common), inhalation anthrax, and gastrointestinal (GI) anthrax (rare). Person-to-person transmission can occur as a result of discharge from cutaneous lesions, but no evidence of human-to-human transmission of inhalational anthrax is available. No evidence of transmission of anthrax via breast milk exists.<sup>310</sup> Standard contact isolation is appropriate for hospitalized patients or patients with draining skin lesions.

The issue of anthrax as a biologic weapon has exaggerated its importance as a cause of human disease. The primary concerns regarding anthrax and breastfeeding are antimicrobial therapy or prophylaxis in breastfeeding mothers and the possibility that infant and mother were exposed by intentional aerosolization of anthrax spores. The CDC published recommendations for treatment and prophylaxis in infants, children, and breastfeeding mothers.<sup>78</sup> The recommendations include the use of ciprofloxacin, doxycycline, amoxicillin, and several other agents without discontinuing breastfeeding. Little information is available on ciprofloxacin and doxycycline in breast milk for prolonged periods of therapy or prophylaxis (60 days) and possible effects on infants' teeth and bone or cartilage growth during that time period.<sup>78</sup> Depending on the clinical situation and sensitivity testing of the identified anthrax strain, other agents can

be substituted to complete the 60-day course. The CDC has approved the use of ciprofloxacin and doxycycline for breastfeeding women for short courses of therapy (less than several weeks).

The simultaneous exposure of infant and mother could occur from primary aerosolization or from spores "contaminating" the local environment. In either case, decontamination of the mother-infant dyad's environment should be considered.

Breastfeeding can continue during a mother's therapy for anthrax as long as she is physically well. Open cutaneous lesions should be carefully covered, and, depending on the situation, simultaneous prophylaxis for the infant may be appropriate.

## BOTULISM

Considerable justifiable concern has been expressed because of the reports of sudden infant death from botulism. Infant botulism is distinguished from foodborne botulism from improperly preserved food containing the toxin and from wound botulism caused by spores entering a wound. Infant botulism occurs when the spores of *Clostridium botulinum* germinate and multiply in the gut and produce the botulinal toxin in the GI tract.<sup>19,20</sup> The toxin binds presynaptically at the neuromuscular junction, preventing acetylcholine release. The clinical picture is a descending, symmetric flaccid paralysis. Not every individual who has *C. botulinum* identified in the stool experiences a clinical illness. The age of infants seems to relate to their susceptibility to illness. The illness is mainly in children younger than 12 months of age; the youngest patient described in the literature was 6 days old.<sup>19</sup> Most children become ill between 6 weeks and 6 months of age. The onset of illness seems to occur earlier in formula-fed infants compared with breastfed infants. When a previously healthy infant younger than 6 months of age develops constipation, followed by weakness and difficulty sucking, swallowing, crying, or breathing, botulism is a likely diagnosis. The organisms should be looked for in the stools, and electromyography may or may not be helpful.

In a group reviewed by Arnon et al.,<sup>21</sup> 33 of 50 patients hospitalized in California were still being nursed at onset of the illness. A beneficial effect of human milk was observed in the difference in the mean age at onset, with breastfed infants being twice as old as formula-fed infants with the disease. The breastfed infants' symptoms were milder. Breastfed infants receiving iron supplements developed the disease earlier than those who were breastfed but unplemented. Of the cases of sudden infant death from botulism, no infants were breastfed within 10 weeks of death. All were receiving iron-fortified formulas. In most cases, no

specific food source of *C. botulinum* can be identified, but honey is the food most often implicated, and corn syrup has been implicated in infants older than 2 months of age. Honey may contain botulism spores, which can germinate in the infant gut. However, botulin toxin has not been identified in honey. It has been recommended that honey not be given to infants younger than 12 months of age. This includes putting honey on a mother's nipples to initiate an infant's interest in suckling.

Arnon<sup>20</sup> reviewed the first 10 years of infant-botulism monitoring worldwide. The disease has been reported in 41 of the 50 states in the United States and in eight countries on four continents. The relationship to breastfeeding and human milk is unclear. In general, the acid stools (pHs 5.1 to 5.4) of human milk-fed infants encourage *Bifidobacterium* species. Few facultative anaerobic bacteria, or clostridia, existing as spores, are present in breastfed infants. In contrast, formula-fed infants have stool pHs ranging from 5.9 to 8.0, with few bifidobacteria, primarily gram-negative bacteria, especially coliforms and *Bacteroides* species. *C. botulinum* growth and toxin production decrease with declining pH and usually stop below pH 4.6. Breast milk also contains additional protective immunologic components, which purportedly have activity against botulinum toxin.<sup>303</sup>

The relationship between the introduction of solid foods or weaning in both formula-fed and breastfed infants and the onset of botulism remains unclear. For a breastfed infant, the introduction of solid food may cause a major change in the gut, with a rapid rise in the growth of enterobacteria and enterococci, followed by progressive colonization by *Bacteroides* species, clostridia, and anaerobic streptococci. Feeding solids to formula-fed infants minimally changes the gut flora because these organisms already predominate. Although more hospitalized infants have been breastfed, sudden-death victims are younger and have been formula fed, which supports the concept of immunologic protection in the gut of a breastfed infant.

Much work remains to understand this disease. Clinically, constipation, weakness, and hypotonicity in a previously healthy child constitute botulism until ruled out, especially with recent dietary changes. At this time, no reason exists to suspect breastfeeding as a risk for infant botulism, and some evidence suggests a possible protective effect from breastfeeding. Breastfeeding should continue if botulism is suspected in the mother or infant.<sup>414</sup>

## BRUCELLOSIS

*Brucella melitensis* has been isolated in the milk of animals. Foods and animals represent the primary sources of infection in humans. Brucellosis

demonstrates a broad spectrum of illness in humans, from subclinical to subacute to chronic illness with nonspecific signs of weakness, fever, malaise, body aches, fatigue, sweats, arthralgia, and lymphadenitis. In areas where the disease is enzootic, childhood illness has been described more frequently. The clinical manifestations in children are similar to those in adults.<sup>291</sup> Infection can occur during pregnancy, leading to abortion (infrequently), and can produce transplacental spread, causing neonatal infection (rarely).

The transmission of *B. melitensis* through breast milk has been implicated in neonatal infection.<sup>291,293</sup> There have been eight cases of brucellosis in infants that were possibly associated with breastfeeding, but *Brucella* was not isolated from the breast milk in any of those cases.<sup>5,29,68,293,292,359,360,475</sup> One case of brucellosis in an infant caused by breast milk transmission involved *B. melitensis* being isolated from the breast milk before antibiotic treatment was given to the mother.<sup>460</sup> Additionally, *B. melitensis* has been cultured from women with breast lumps and abscesses.<sup>332</sup> Only one of six women described in this report was lactating at the time of diagnosis, and no information about the infant was given. Brucellosis mastitis or abscess should be considered in women presenting with appropriate symptoms and occupational exposure to animals, contact with domestic animals in their environment, or exposure to animal milk or milk products (especially unpasteurized products). The breast inflammation tends to be granulomatous in nature (without caseation) and is often associated with axillary adenopathy; occasionally, systemic illness in the woman is evident. Brucellosis mastitis or abscess should be treated with surgery or fine-needle aspiration, as indicated, accompanied by 4 to 6 weeks of combination antibiotic therapy with two or three medications. The temporary interruption of breastfeeding with breast pumping and discarding the milk to continue the stimulation of milk production is appropriate. Breastfeeding should then continue after an initial period of 48 to 96 hours of therapy in the mother. Acceptable medications for treating the mother, while continuing breastfeeding, include gentamicin, streptomycin, tetracycline, doxycycline, trimethoprim-sulfamethoxazole, and rifampin.

## *Chlamydial Infections*

Chlamydial infection is the most frequent sexually transmitted disease (STD) in the United States and is a frequent cause of conjunctivitis and pneumonitis in an infant from perinatal infection. The major determinant of whether chlamydial infection occurs in a newborn is the prevalence rate of chlamydial infection of the cervix.<sup>406</sup> Specific chlamydial

immunoglobulin A (IgA) has been found in colostrum and breast milk in a small number of postpartum women who were seropositive for *Chlamydia*. No information is available on the role of milk antibodies in protecting against infection in infants.<sup>433</sup> It is not believed that *Chlamydia* is transmitted via breast milk. The use of erythromycin or tetracycline to treat mothers and oral erythromycin and ophthalmic preparations of tetracyclines, erythromycin, or sulfonamides to treat suspected infection in infants is appropriate during continued breastfeeding. Separating infants from mothers with chlamydial infections or stopping breastfeeding is not indicated. The simultaneous treatment of mothers and infants may be appropriate in some situations.

## DIPHTHERIA

*Corynebacterium diphtheriae* causes several forms of clinical disease, including membranous nasopharyngitis, obstructive laryngotracheitis, and cutaneous infection. Complications can include airway obstruction from membrane formation and toxin-mediated central nervous system (CNS) disease or myocarditis. The overall incidence of diphtheria has declined, even though immunization does not prevent infection but does prevent severe disease from toxin production. Fewer than five cases are reported annually in the United States.

Transmission occurs via droplets or direct contact with contaminated secretions from the nose, throat, eye, or skin. Infection occurs in individuals whether they have been immunized or not, but infection in the nonimmunized is more severe and prolonged. As long as the skin of the breast is not involved, no risk for transmission exists via breast milk. No toxin-mediated disease from a toxin transmitted through breast milk has been reported in an infant.

Breastfeeding, along with chemoprophylaxis and the immunization of affected infants, is appropriate in the absence of cutaneous breast involvement (see Appendix F).

## Gonococcal Infections

Maternal infection with *Neisseria gonorrhoeae* can produce a large spectrum of illness ranging from uncomplicated vulvovaginitis, proctitis, pharyngitis, and conjunctivitis, as well as more severe and invasive disease, including pelvic inflammatory disease, meningitis, endocarditis, and disseminated gonococcal infection. The risk for transmission from mother to infant occurs mainly during delivery in the passage through the infected birth canal and occasionally from postpartum contact with the mother (or her partner). The risk for transmission

from breast milk is negligible, and *N. gonorrhoeae* does not seem to cause local infection of the breasts. Infection in neonates is most often ophthalmia neonatorum and less often a scalp abscess or disseminated infection. Mothers with presumed or documented gonorrhea should be reevaluated for other STDs, especially *Chlamydia trachomatis* and syphilis, because some therapies for gonorrhea are not adequate for either of these infections.

With the definitive identification of gonorrhea in a mother, empiric therapy should begin immediately, and the mother should be separated from the infant until the completion of 24 hours of adequate therapy. Treatment of the mother with ceftriaxone, cefixime, penicillin, or erythromycin is without significant risk for the infant. Single-dose treatment with spectinomycin, ciprofloxacin, ofloxacin, or azithromycin has not been adequately studied, but it would presumably be safe for the infant, given the 24-hour separation and a delay in breastfeeding without giving the infant the expressed breast milk (pump and discard). Doxycycline use in a nursing mother is not routinely recommended.

Careful preventive therapy for ophthalmia neonatorum should be provided, and close observation of the infant should continue for 2 to 7 days, the usual incubation period. Empiric or definitive therapy against *N. gonorrhoeae* may be necessary, depending on an infant's clinical status, and it should be chosen on the basis of the maternal isolate's sensitivity pattern. The mother should not handle other infants until after 24 hours of adequate therapy, and the infant should be separated from the rest of the nursery population, with or without breastfeeding.

## **HAEMOPHILUS INFLUENZAE**

*H. influenzae* type B can cause severe invasive disease such as meningitis, sinusitis, pneumonia, epiglottitis, septic arthritis, pericarditis, and bacteremia. Shock can also occur. Because of the increased utilization of the *H. influenzae* type B conjugate vaccines, invasive disease caused by *Haemophilus* has decreased dramatically, with a greater than 95% reduction in the United States. Most invasive disease occurs in children 3 months to 3 years of age. Older children and adults rarely experience severe disease but do serve as sources of infection for young children. Children younger than 3 months of age seem to be protected because of passively acquired antibodies from the mothers, and some additional benefits may be received from breast milk.

Transmission occurs through contact with respiratory secretions, and droplet precautions are protective. No evidence suggests transmission through

breast milk or breastfeeding. Evidence supports that breast milk limits the colonization of *H. influenzae* in the throat.<sup>203</sup>

In the rare case of maternal infection, an inadequately immunized infant in a household is an indication to provide rifampin prophylaxis and close observation for all household contacts, including the breastfeeding infant. Expressed breast milk can be given to an infant during the 24-hour separation after the mother's initiation of antimicrobial therapy, or if the mother's illness prevents breastfeeding, it can be reinitiated when the mother is able (see Appendix F).

## **LEPROSY**

Although uncommon in the United States, leprosy occurs throughout the world. This chronic disease presents with a spectrum of symptoms depending on the tissues involved (typically the skin, peripheral nerves, and mucous membranes of the upper respiratory tract) and the cellular immune response to the causative organism, *Mycobacterium leprae*. Transmission occurs through long-term contact with individuals with untreated or multibacillary (large numbers of organisms in the tissues) disease.

Leprosy is not a contraindication to breastfeeding, according to Jeliffe and Jeliffe.<sup>222</sup> The importance of breastfeeding and the urgency of treatment are recognized by experts who treat infants and mothers early and simultaneously. No mother-infant contact is permitted except to breastfeed. Dapsone, rifampin, and clofazimine are typically and safely used for infant and mother, regardless of the method of feeding (see Appendix D).

## **LISTERIOSIS**

Listeriosis is a relatively uncommon infection that can have a broad range of manifestations. In immunocompetent individuals, including pregnant women, the infection can vary from being asymptomatic to presenting as an influenza-like illness, occasionally with GI symptoms or back pain. Severe disease occurs more frequently in immunodeficient individuals or infants infected in the perinatal period (pneumonia, sepsis, meningitis, and granulomatosis infantisepticum).

Although listeriosis during pregnancy may manifest as mild disease in a mother and is often difficult to recognize and diagnose, it is typically associated with stillbirth, abortion, and premature delivery. Transmission seems to occur through the transplacental hematogenous route, infecting the amniotic fluid, although ascending infection from the genital tract may occur.<sup>134</sup> Early and effective treatment

of a woman can prevent fetal infection and sequelae.<sup>227,286</sup> Neonatal infection occurs as either early- or late-onset infection from transplacental spread late in pregnancy, ascending infection during labor and delivery, infection during passage through the birth canal, or, rarely, during postnatal exposure.

No evidence in the literature suggests that *Listeria* is transmitted through breast milk. Treatment of the mother with ampicillin, penicillin, or trimethoprim-sulfamethoxazole is not a contraindication to breastfeeding as long as the mother is well enough. Expressed colostrum or breast milk can also be given if the infant is able to feed orally. The management of lactation and feeding in neonatal listeriosis is conducted supportively, as it is in any situation in which an infant is extremely ill, beginning feeding with expressed breast milk or directly breastfeeding as soon as reasonable.

## Meningococcal Infections

*N. meningitidis* most often causes severe invasive infections, including meningococcemia or meningitis, often associated with fever and a rash and progressing to purpura, disseminated intravascular coagulation, shock, coma, and death.

Transmission occurs via respiratory droplets. Spread can occur from an infected, ill individual or from an asymptomatic carrier. Droplet precautions are recommended until 24 hours after initiation of effective therapy. Despite the frequent occurrence of bacteremia, no evidence indicates breast involvement or transmission through breast milk.

The risk for maternal infection to an infant after birth is from droplet exposure and exists whether the infant is breastfeeding or bottle feeding. In either case, the exposed infant should receive chemoprophylaxis with rifampin, 10 mg/kg/dose every 12 hours for 2 days (5 mg/kg/dose for infants younger than 1 month of age), or ceftriaxone, 125 mg intramuscularly (IM) once, for children younger than 15 years of age. Close observation of the infant should continue for 7 days, and breastfeeding during and after prophylaxis is appropriate. The severity of maternal illness may prevent breastfeeding, but it can continue if the mother is able, after the mother and infant have been receiving antibiotics for 24 hours. A period of separation from the index case for the first 24 hours of effective therapy is recommended; expressed breast milk can be given during this period.

## PERTUSSIS

Respiratory illness caused by *Bordetella pertussis* evolves in three stages: catarrhal (nasal discharge, congestion, increasing cough), paroxysmal (severe paroxysms of cough sometimes ending in an inspiratory whoop, i.e., whooping cough), and convalescent (gradual improvement in symptoms).

Transmission is via respiratory droplets. The greatest risk for transmission occurs in the catarrhal phase, often before the diagnosis of pertussis. The nasopharyngeal culture usually becomes negative after 5 days of antibiotic therapy. Chemoprophylaxis for all household contacts is routinely recommended. No evidence indicates transmission through breast milk, with similar risk to breastfed and bottle-fed infants.

In the case of maternal infection with pertussis, chemoprophylaxis for all household contacts, regardless of age or immunization status, is indicated. In addition to chemoprophylaxis of the infant, close observation and subsequent immunization (in infants older than 6 weeks of age) are appropriate. Prophylaxis for the infant should be azithromycin or erythromycin, although trimethoprim-sulfamethoxazole can be used when the infant is 6 weeks or older. Despite chemoprophylaxis, droplet precautions and the separation of mother and infant during the first 5 days of effective maternal antibiotic therapy are recommended. Expressed breast milk can be provided to the infant during this period.

## Staphylococcal Infections

Staphylococcal infection in neonates can be caused by either *S. aureus* or coagulase-negative staphylococci (most often *Staphylococcus epidermidis*) and can manifest in a wide range of illnesses. Localized infection can be impetigo, pustulosis in neonates, cellulitis, or wound infection, and invasive or suppurative disease includes sepsis, pneumonia, osteomyelitis, arthritis, and endocarditis. *S. aureus* requires only a small inoculum (10 to 250 organisms) to produce colonization in newborns, most often of the nasal mucosa and umbilicus.<sup>212</sup> By the fifth day of life, 40% to 90% of the infants in the nursery will be colonized with *S. aureus*.<sup>139</sup> The organism is easily transmitted to others from mother, infant, family, or health care personnel through direct contact.

Outbreaks in nurseries were common in the past. Mothers, infants, health care workers, and even contaminated, unpasteurized, banked breast milk were sources of infection.<sup>41a,337,366</sup> Careful use of antibiotics, changes in nursery layout and procedures,

standard precautions, and cohorting as needed decreased the spread of *S. aureus* in nurseries. Now the occurrence of methicillin-resistant *S. aureus* (MRSA) is again a common problem, requiring cohorting, occasional epidemiologic investigation, and careful infection-control intervention. There are numerous reports of MRSA outbreaks in NICUs.<sup>37,159,231,282,322</sup> The significance of colonization with *Staphylococcus* and the factors leading to development of disease in individual patients are not clear. The morbidity and mortality related to *S. aureus* infection in neonates is well described,<sup>210,215,241</sup> and the management of such outbreaks has been reviewed.<sup>163,278</sup> Little has been written about the role of breastfeeding in colonization with *S. aureus* in NICUs, well-baby nurseries, or at home.

MRSA is an important pathogen worldwide. Community-acquired MRSA is different from hospital-acquired MRSA. Community-acquired MRSA is usually defined as occurring in an individual without the common predisposing variables associated with hospital-acquired MRSA. Community-acquired MRSA also lacks an MDR phenotype (common with hospital-acquired MRSA); frequently carries multiple exotoxin virulence factors (such as Panton-Valentine leukocidin toxin), as well as the smaller type IV staphylococcal cassette cartridge for the *MecA* gene on a chromosome (hospital-acquired MRSA carries the types I-III staphylococcal cassette cartridge); and is molecularly distinct from the common nosocomial strains of hospital-acquired MRSA. Community-acquired MRSA is most commonly associated with skin and soft tissue infections and necrotizing pneumonia and less frequently associated with endocarditis, bacteremia, necrotizing fasciitis, myositis, osteomyelitis, or parapneumonic effusions. Community-acquired MRSA is so common that it is now being observed in hospital outbreaks.<sup>26,159,182,401</sup> Community-acquired MRSA transmission to infants via breast milk has been reported.<sup>37,159,231,282,322</sup> Premature or small-for-gestational-age infants are more susceptible to and at increased risk for significant morbidity and mortality due to MRSA, in part because of prolonged hospitalization, multiple courses of antibiotics, invasive procedures and intravenous (IV) lines, their relative immune deficiency related to prematurity and illness, and altered GI tract due to different flora and decreased gastric acidity. Therefore, colonization with MRSA may pose a greater risk to infants in NICUs in the long run. Full-term infants develop pustulosis, cellulitis, and soft tissue infections, but invasive disease has rarely been reported.<sup>87,147,337</sup>

Fortunov et al.<sup>147</sup> from Texas reported 126 infections in term or late-preterm previously well infants, including 43 with pustulosis, 68 with cellulitis or

abscesses, and 15 invasive infections. A family history of soft tissue skin infections and male sex were the only variables associated with risk for infection; cesarean delivery, breastfeeding, and circumcision were not.<sup>147</sup> Nguyen et al.<sup>337</sup> reported MRSA infections in a well-infant nursery from California. The eleven cases were all in full-term boys with pustular-vesicular lesions in the groin. The infections were associated with longer length of stay, lidocaine injection use in infants, maternal age older than 30 years, and circumcision. Breastfeeding was not an associated risk factor for MRSA infection.<sup>337</sup> The question of the role of circumcision in MRSA outbreaks was addressed by Van Howe and Robson.<sup>473</sup> They reported that circumcised boys are at greater risk for staphylococcal colonization and infection.<sup>473</sup>

Others report that *S. aureus* carriage in infants (and subsequent infection) is most likely affected by multiple variables, including infant factors (antibiotics, surgical procedures [circumcision being the most common], duration of hospital stay as a newborn), maternal factors (previous colonization, previous antibiotic usage, mode of delivery, length of stay), and environmental factors (MRSA in the family or hospital, nursery stay versus rooming-in, hand hygiene).<sup>57,96,210,221,368,400,401</sup> Gerber et al.<sup>163</sup> from the Chicago area published a consensus statement for the management of MRSA outbreaks in the NICU. The recommendations, which were strongly supported by experimental, clinical, and epidemiologic data, included using a waterless, alcohol-based hand hygiene product, monitoring and enforcing hand hygiene, placing MRSA-positive infants in contact precautions with cohorting if possible, using gloves and gowns for direct contact and masks for aerosol-generating procedures, cohorting nurses for care of MRSA-positive infants when possible, periodic screening of infants for MRSA using nares or nasopharyngeal cultures, clarifying the MRSA status of infants being transferred into the NICU, limiting overcrowding, and maintaining ongoing instruction and monitoring of health care workers in their compliance with infection-control and hand-hygiene procedures. The evaluation of the outbreak could include screening of health care workers and environmental surfaces to corroborate epidemiologic data and laboratory molecular analysis of the MRSA strains if indicated epidemiologically. The use of mupirocin or other decolonizing procedures should be determined on an individual basis for each NICU.

*S. aureus* is the most common cause of mastitis in lactating women.<sup>356,439,440,484</sup> Recurrence or persistence of symptoms of mastitis is a well-described occurrence and an important issue in the management of mastitis. Community-acquired MRSA has

been associated with mastitis as well<sup>383,401,440</sup> (see Chapter 16 for a complete discussion of mastitis).

Two studies, one from France and one from Brazil, investigated the occurrence of MRSA in expressed breast milk.<sup>28,339</sup> Barbe et al.<sup>28</sup> cultured 9171 expressed breast milk samples from 378 women and tested 2351 samples before pasteurization and 6820 samples after pasteurization. MRSA and methicillin-susceptible *S. aureus* were identified, respectively, in 8 samples (0.8%) from 3 mothers and 281 samples (19.3%) from 73 mothers, using the tested expressed breast milk before pasteurization. After pasteurization, *S. aureus* was not detected in any of the 6820 samples of expressed breast milk. Colonization of one infant with MRSA was identified, but no MRSA infections were identified in any of the hospitalized infants in the NICU during the 18 months of the study.<sup>28</sup> Novak et al.<sup>339</sup> identified MRSA in 57 of 500 samples (11%) of expressed fresh-frozen milk from 500 different donors from five Brazilian milk banks. Only 3 of the 57 samples were positive with high-level bacterial counts of MRSA (greater than 10,000 CFU/mL). These were the only samples that would not have been acceptable by bacteriological criteria according to Brazilian or American criteria for raw milk use. They did not investigate other epidemiological data to identify possible variables associated with low- or high-level contamination of expressed breast milk with MRSA.<sup>339</sup>

The management of an infant and/or mother with MRSA infection, relative to breastfeeding or use of breast milk, should be based on the severity of disease and whether the infant is premature, LBW, very low birth weight (VLBW), previously ill, or full term.

When full-term infants or their mothers develop mild to moderate infections (impetigo, pustulosis, cellulitis/abscess, mastitis/breast abscess, or soft tissue infection), those infants can continue breastfeeding after a short period of interruption (24 to 48 hours). During this time, pumping to maintain the milk supply should be supported, an initial evaluation for other evidence of infection should be done in the maternal-infant dyad, the infected child and/or mother should be placed on "commonly" effective therapy for the MRSA infection, and ongoing observation for clinical disease should continue. The mother and infant can "room-in" together in the hospital, if necessary, with standard and contact precautions. Culturing the breast milk is not necessary. Empiric therapy for the infant may be chosen based on medical concerns for the infant and the known sensitivity testing of the MRSA isolate. Appropriate antibiotic choices include short-term use of azithromycin (erythromycin use during

infancy [less than 6 weeks of age], or breastfeeding associated with an increased risk for hypertrophic pyloric stenosis), sulfamethoxazole-trimethoprim (in the absence of G6PD deficiency and older than 30 days of age), clindamycin, and perhaps linezolid for mild to moderate infections.

When infants in NICUs (premature, LBW, VLBW, and/or previously ill) or their mothers have a MRSA infection, those infants should have the breast milk cultured and suspend breastfeeding or receiving breast milk from their mothers until the breast milk is shown to be culture-negative for MRSA. The infant should be treated as indicated for infection or empirically treated if symptomatic (with pending culture results) and closely observed for the development of new signs or symptoms of infection. Pumping to maintain the milk supply and the use of banked breast milk are appropriate. The infant should be placed on contact precautions, in addition to the routine standard precautions. The infant can be cohorted with other MRSA-positive infants, with nursing care cohorted as well. The mother with MRSA infection should be instructed concerning hand hygiene; the careful collection, handling, and storage of breast milk; contact precautions to be used with her infant; and the avoidance of contact with any other infants. The mother can receive several possible antibiotics for MRSA that are compatible with breastfeeding when used for a short period. If the mother remains clinically well, including without evidence of mastitis, but her breast milk is positive for MRSA greater than  $10^4$  CFU/mL, empiric therapy to diminish or eradicate colonization would be appropriate. Various regimens have been proposed to "eradicate" MRSA colonization, but none has been proven to be highly efficacious. These regimens usually include systemic antibiotics with one or two medications (rifampin added as the second medication), as well as nasal mupirocin to the nares twice daily for 1 to 2 weeks with routine hygiene, with or without the usage of hexachlorophene (or similar topical agent or cleanser) for bathing during the 1- to 2-week treatment period. There is no clear information concerning the efficacy of using similar colonization-eradication regimens for other household members or pets in preventing recolonization of the mother or infant. Before reintroducing the use of the mother's breast milk to the infant, at least one negative breast milk culture should be obtained after the completion of therapy.

The routine screening of breast milk provided by mothers for their infants in NICUs for the presence of MRSA is not indicated in the absence of MRSA illness in the maternal-infant dyad, a MRSA outbreak in NICUs, or a high frequency of MRSA infection in a specific NICU.

## TOXIN-MEDIATED STAPHYLOCOCCUS DISEASE

One case of staphylococcal scalded skin syndrome was reported by Katzman and Wald<sup>229</sup> in an infant breastfed by a mother with a lesion on her areola that did not respond to ampicillin therapy for 14 days. Subsequently, the infant developed conjunctivitis with *S. aureus*, which produced an exfoliative toxin, and a confluent erythematous rash without mucous membrane involvement or Nikolsky sign. No attempt to identify the exfoliative toxin in the breast milk was made, and the breast milk was not cultured for *S. aureus*. The child responded to IV therapy with nafcillin. This emphasizes the importance of evaluating mother and infant at the time of a suspected infection and the need for continued observation of the infant for evidence of a pyogenic infection or toxin-mediated disease, especially with maternal mastitis or breast lesions.

This case also raises the issue of when and how infants and their mothers become colonized with *S. aureus* and what factors lead to infection and illness in each. The concern is that *Staphylococcus* can be easily transmitted through skin-to-skin contact, colonization readily occurs, and potentially serious illness can occur later, long after colonization. In the case of staphylococcal scalded skin syndrome or toxic shock syndrome (TSS), the primary site of infection can be insignificant (e.g., conjunctivitis, infection of a circumcision, or simple pustulosis), but a clinically significant amount of toxin can be produced and lead to serious disease.

TSS can result from *S. aureus* or *Streptococcus pyogenes* infection and probably from a variety of antigens produced by other organisms. TSS-1 has been identified as a "superantigen" that affects the T lymphocytes and other components of the immune response, producing an unregulated and excessive immune response and resulting in an overwhelming systemic clinical response. TSS has been reported in association with vaginal delivery, cesarean delivery, mastitis, and other local infections in mothers. Mortality rates in mothers may be as high as 5%.

The case definition of staphylococcal TSS includes meeting all four major criteria: fever greater than 38.9°C, rash (diffuse macular erythroderma), hypotension, and desquamation (associated with subepidermal separation seen on skin biopsy). The definition also includes involvement of three or more organ systems (GI, muscular, mucous membrane, renal, hepatic, hematologic, or CNS); negative titers for Rocky Mountain spotted fever, leptospirosis, and rubella; and lack of isolation of *S. pyogenes* from any source or *S. aureus* from the cerebrospinal fluid (CSF).<sup>410</sup> A similar case definition has been proposed for streptococcal TSS.<sup>502</sup>

Aggressive empiric antibiotic therapy against staphylococci and streptococci and careful supportive therapy are essential for decreasing illness and death. Oxacillin, nafcillin, first-generation cephalosporins, clindamycin, erythromycin, and vancomycin are acceptable antibiotics, even for a breastfeeding mother. The severity of illness in the mother may preclude breastfeeding, but it can be reinitiated when the mother is improving and wants to restart. Standard precautions, with breastfeeding, are recommended.

Staphylococcal enterotoxin F has been identified in breast milk specimens collected on days 5, 8, and 11 from a mother who developed TSS at 22 hours postpartum.<sup>476</sup> *S. aureus* that produced staphylococcal enterotoxin F was isolated from the mother's vagina but not from breast milk. Infant and mother lacked significant levels of antibodies against staphylococcal enterotoxin F in their sera. The infant remained healthy after 60 days of follow-up. Staphylococcal enterotoxin F is pepsin inactivated at pH 4.5 and therefore is probably destroyed in the stomach environment, presenting little or no risk to the breastfeeding infant.<sup>39a</sup> Breastfeeding can continue if the mother is able.

## COAGULASE-NEGATIVE STAPHYLOCOCCUS

Coagulase-negative staphylococcal infection (*S. epidermidis* is the predominant isolate) produces minimal disease in healthy, full-term infants but is a significant problem in hospitalized or premature infants. Factors associated with increased risk for this infection include prematurity, high colonization rates in specific nurseries, invasive therapies (e.g., IV lines, chest tubes, intubation), and antibiotic use. Illness produced by coagulase-negative staphylococci can be invasive and severe in high-risk neonates but rarely in mothers. There are reports of necrotizing enterocolitis associated with coagulase-negative *Staphylococcus*. At 2 weeks of age, for infants still in the nursery, *S. epidermidis* is a frequent colonizing organism at multiple sites, with colonization rates as high as 75% to 100%. Serious infections with coagulase-negative staphylococci (e.g., abscesses, IV line infection, bacteremia/sepsis, endocarditis, osteomyelitis) require effective IV therapy. Many strains are resistant to penicillin and the semisynthetic penicillins, so that sensitivity testing is essential. Empiric or definitive therapy may require treatment with vancomycin, gentamicin, rifampin, teicoplanin, linezolid, or combinations of these for synergistic activity. Transmission of infection in association with breastfeeding appears to be no more common than with bottle feeding. As with *S. aureus*, infection control includes contact and standard precautions.

Occasionally, during presumed outbreaks, careful epidemiologic surveillance may be required, including cohorting, limiting overcrowding and understaffing, surveillance cultures of infants and nursery personnel, reemphasis of meticulous infection-control techniques for all individuals entering the nursery, and, rarely, removal of colonized personnel from direct infant contact.

*S. epidermidis* has been identified as part of the fecal microbiota of breastfed infants.<sup>223</sup> *S. epidermidis* has also been identified in the breast milk of women with clinical evidence of mastitis.<sup>119</sup> Nevertheless, *S. epidermidis* is rarely associated with infection in full-term infants. Conceivably, breast milk for premature infants could be a source of *S. epidermidis* colonization in the NICUs. The other factors associated with hospitalization in an NICU noted previously presumably play a significant role in both colonization and infection in premature infants. The benefits of early full human milk feeding potentially outweigh the risk for colonization with *S. epidermidis* via breast milk.<sup>390</sup> Ongoing education and assistance should be provided to mothers about the careful collection, storage, and delivery of human breast milk for their premature infants.<sup>395</sup>

## Streptococcal Infections

### Group A

*S. pyogenes* ( $\beta$ -hemolytic group A *Streptococcus* [GAS]) is a common cause of skin and throat infections in children, producing pharyngitis, cellulitis, and impetigo. Illnesses produced by GAS can be classified into three categories: (1) impetigo, cellulitis, or pharyngitis without invasion or complication; (2) severe invasive infection with bacteremia, necrotizing fasciitis, myositis, or systemic illness (e.g., streptococcal TSS); and (3) autoimmune-mediated phenomena, including acute rheumatic fever and acute glomerulonephritis. GAS can also cause puerperal sepsis, endometritis, and neonatal omphalitis. Significant morbidity and mortality rates are associated with invasive GAS infection; the mortality rate is 20% to 50%, with almost half the survivors requiring extensive tissue débridement or amputation.<sup>389</sup> Infants are not at risk for the autoimmune sequelae of GAS (rheumatic fever or poststreptococcal glomerulonephritis). Transmission is through direct contact (rarely indirect contact) and droplet spread. Outbreaks of GAS in the nursery are rare, unlike with staphylococcal infections. Either mother or infant can be initially colonized with GAS and transmit it to the other.

In the situation of maternal illness (extensive cellulitis, necrotizing fasciitis, myositis, pneumonia,

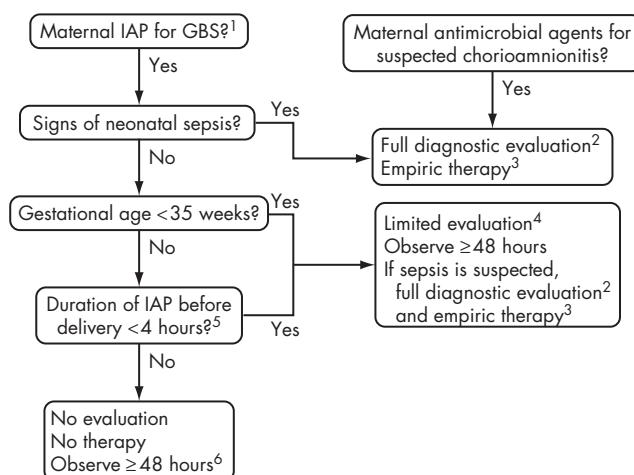

TSS, and mastitis), it is appropriate to separate mother and infant until effective therapy (penicillin, ampicillin, cephalosporins, and erythromycin) has been given for at least 24 hours. Breastfeeding should also be suspended and may resume after 24 hours of therapy for the mother.

### Group B

Group B *Streptococcus* (GBS, *Streptococcus agalactiae*) is a significant cause of perinatal bacterial infection. In parturient women, infection can lead to asymptomatic bacteriuria, urinary tract infection (often associated with premature birth), endometritis, or amniionitis. In infants, infection usually occurs between birth and 3 months of age (1 to 4 cases per 1000 live births). It is routinely classified by the time of onset of illness in the infant: early onset (0 to 7 days, majority less than 24 hours) and late onset (7 to 90 days, generally less than 4 weeks). Infants may develop sepsis, pneumonia, meningitis, osteomyelitis, arthritis, or cellulitis. Early-onset GBS disease is often fulminant, presenting as sepsis or pneumonia with respiratory failure; three-quarters of neonatal disease is early onset. Type III is the most common serotype causing disease.

Transmission is believed to occur in utero and during delivery. Colonization rates of mothers and infants vary between 5% and 35%. Postpartum transmission is thought to be uncommon, although it has been documented. Risk factors for early-onset GBS disease include delivery before 37 weeks of gestation, rupture of membranes for longer than 18 hours before delivery, intrapartum fever, heavy maternal colonization with GBS, or low concentrations of anti-GBS capsular antibody in maternal sera.<sup>104</sup> The common occurrence of severe GBS disease before 24 hours of age in neonates has led to prevention strategies. Revised guidelines developed by the AAP Committees on Infectious Diseases and on the Fetus and Newborn have tried to combine various variables for increased risk for GBS infection (prenatal colonization with GBS, obstetric and neonatal risk factors for early-onset disease) and to provide intrapartum prophylaxis to those at high risk<sup>90,104</sup> (CDCP Prev of Perinatal GBS Disease MMWR 2010 and Comm on Inf Dis and Comm on the Fetus and Newborn Pediatrics 2011) (Figure 13-1). The utilization of these guidelines, universal culture-based screening, and intrapartum prophylaxis across the United States have decreased the incidence of early-onset disease by approximately 80% from an estimated 1.4 cases of early-onset GBS disease (EOD) per 1000 live births in 1990 to 0.28 cases per 1000 live births in 2012 (Van Dyke et al.)<sup>472</sup>

The incidence of late-onset GBS disease (LOD) remains unchanged since 1990 (~0.3 to 0.4 cases

<sup>1</sup> If no maternal IAP for GBS was administered despite an indication being present, data are insufficient on which to recommend a single management strategy.

<sup>2</sup> Includes complete blood cell (CBC) count with differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed.

<sup>3</sup> Duration of therapy varies depending on results of blood culture, cerebrospinal fluid findings (if obtained), and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48 hours.

<sup>4</sup> CBC including WBC count with differential and blood culture.

<sup>5</sup> Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens.

<sup>6</sup> A healthy-appearing infant who was ≥38 weeks' gestation at delivery and whose mother received ≥4 hours of IAP before delivery may be discharged home after 24 hours if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any one of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until criteria for discharge are achieved.

**Figure 13-1.** Empiric management of a neonate born to a mother who received intrapartum antimicrobial prophylaxis (IAP) for the prevention of early-onset group B streptococcal (GBS) disease. CSF, Cerebrospinal fluid; CBC, complete blood count. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate. (From Committee on Infectious Diseases, American Academy of Pediatrics: *Red book report of the committee on infectious disease*, ed 26, Elk Grove, Ill., 2003, American Academy of Pediatrics, p 590.)

per 1000 live births) despite the implementation of screening and guidelines for preventing EOD (CDCP 2013 Active Bacterial Core Surveillance Report). LOD is thought to be the result of transmission during delivery or in the postnatal period from maternal, hospital, or community sources. Dillon et al.<sup>124</sup> demonstrated that 10 of 21 infants with late-onset disease were colonized at birth, but the source of colonization was unidentified in the others. Gardner et al.<sup>157</sup> showed that only 4.3% of 46 children who were culture-negative for GBS at discharge from the hospital had acquired GBS by 2 months of age. Anthony et al.<sup>17</sup> noted that many infants are colonized with GBS, but the actual attack rate for GBS disease is low and difficult to predict.

Acquisition of GBS through breast milk or breastfeeding is uncommon and remains a controversial topic.<sup>38,143,275</sup> Cases of LOD associated with GBS in the maternal milk have been reported.<sup>65,236,352,408,485</sup> Some of the mothers had bilateral mastitis, at least one had delayed evidence of unilateral mastitis, and the others were asymptomatic. It was not clear when colonization of the infants occurred or when infection or disease began in the infants. The authors discussed the possibility that the infants were originally colonized during delivery, subsequently colonized the

mothers' breasts during breastfeeding, and then became re-infected at a later time. Butter and DeMoor<sup>63</sup> showed that infants initially colonized on their heads at birth had GBS cultured from their throat, nose, or umbilicus 8 days later. Whenever they cultured GBS from the nipples of mothers, the authors also found it in the nose or throat of the infants.

Berardi et al.<sup>37a</sup> studied GBS colonization prospectively in 160 mother-infant dyads. They noted that few culture-positive women had GBS cultured from their milk through 60 days post hospital discharge. Neonates who were colonized at more than one site (throat, ear, or rectum) were most commonly born to culture-positive carrier mothers who were GBS positive at delivery. One of the three cases of neonatal GBS infection presented as LOD at 35 days of age, and one presented with EOD at birth. The third infant presented with EOD at 20 hours of age and was adequately treated. That same infant was retreated at 18 days of age for a GBS urinary tract infection. They concluded that there was no evidence that mother's milk was the cause of the neonatal infections and that the occurrence of GBS in human milk could have been contamination or colonization from infants who were already heavily colonized with GBS.<sup>39</sup> Filleron et al.<sup>143</sup> reviewed 48 cases in the literature of

late-onset neonatal infection (LONI) associated with GBS and breast milk. They noted four cases of LONI that occurred in the absence of maternal GBS detection, in infants born by cesarean section and with GBS-positive mother's milk as the probable source of infection. Their analysis also demonstrated a high rate of recurrence of LONI (35% of the 48 neonates) had more than one LONI. They concluded,<sup>143</sup> as others have recommended (Berardi et al.,<sup>39</sup> Byrne et al.,<sup>65</sup> Lombard et al.,<sup>288</sup> and Davanzo et al.<sup>117</sup>), that additional attention should be given to the handling and use of raw human milk in "vulnerable" neonates and instances of GBS culture-positive human milk with or without maternal mastitis. Byrne et al.<sup>65</sup> presented a review of GBS disease associated with breastfeeding and made recommendations to decrease the risk for transmission of GBS to infants via breastfeeding or breast milk. Some of their recommendations included confirming appropriate collection and processing procedures for GBS cultures<sup>412</sup> in medical facilities to decrease false-negative cultures; reviewing proper hygiene for pumping, collection, and storage of expressed breast milk with mothers; reviewing the signs and symptoms of mastitis with mothers; and utilizing banked human milk as needed instead of mother's milk. Davanzo et al.<sup>117</sup> describe proposed "best practice guidance" for managing human milk feeding and group B *Streptococcus* in developed countries. This guidance includes the following: (1) Do not routinely perform microbial cultures of breast milk from the mother of the term or preterm infant. (2) Interruption of breastfeeding in most situations of maternal mastitis and healthy full term infants is unnecessary, but conservative management, including milk removal, supportive measures, and antibiotics for the mother, are appropriate if her symptoms persist or worsen. (3) In the case of mastitis in mothers of preterm infants, drain the affected breast, culture the milk, and treat the mother empirically. If the milk is GBS-positive, then the milk should either be pasteurized prior to giving it to the premature infant or discarded until there is a subsequent negative culture of the milk. (4) Prevention and management strategies for EOD GBS infection should follow the revised CDC guidelines from 2010 and the more recent recommendations for the prevention of perinatal GBS disease from the AAP's Committee on Infectious Diseases and Committee on Fetus and Newborn,<sup>103</sup> 2011 [CDCP Prev Perinatal GBS Dis Rev Guidelines 2010, Comm on ID and Comm on Fetus Newborn Policy Statement re GBS prevention 2011].<sup>90</sup> These documents do not recommend routine discontinuation of breastfeeding, discarding breast milk, or pasteurization of breast milk after EOD GBS, because there is no evidence that this is protective against LOD

GBS. (5) In the situation of LOD GBS disease and a positive breast milk culture for GBS, treat the mother to eradicate colonization (ampicillin or amoxicillin plus rifampin), pasteurize or discard breast milk until adequate therapy has been given to the mother or there is a negative breast milk culture, track breast milk cultures through hospitalization, and consider adding rifampin to the infant's antibiotic treatment to eradicate colonization in the infant, even though the "eradication" of colonization is difficult and inconsistent.

When a breastfed infant develops LOD, it is appropriate to culture the milk. (See discussion of culturing breast milk earlier in this chapter.) Consider treatment of the mother to prevent reinfection if the milk is culture positive for GBS (greater than  $10^4$  CFU/mL), with or without clinical evidence of mastitis in the mother. Withholding the mother's milk until it is confirmed to be culture negative for a pathogen is appropriate and should be accompanied by providing ongoing support and instruction to the mother concerning pumping and maintaining her milk supply. Serial culturing of expressed breast milk after treatment of the mother for GBS disease or colonization would be appropriate to insure the ongoing absence of a pathogen in the expressed breast milk. There are reports of reinfection of the infant from breast milk.<sup>25,117,143,247,288</sup> Eradication of GBS mucosal colonization in the infant or the mother may be difficult. Some authors have recommended using rifampin prophylactically in both the mother and infant at the end of treatment to eradicate mucosal colonization.<sup>25,48</sup> (See Chapter 16 for management of mastitis in the mother.) A mother or infant colonized or infected with GBS should be managed with standard precautions<sup>102</sup> while in the hospital. Ongoing close evaluation of the infant for infection or illness and empiric therapy for GBS in the infant are appropriate until the child has remained well and cultures are subsequently negative at 72 hours. Occasionally, epidemiologic investigation in the hospital will utilize the culturing of medical staff and family members to detect a source of LOD in the nursery. This can be useful when more than one case of LOD is detected with the same serotype. Cohorting in such a situation may be appropriate. Selective prophylactic therapy for colonized infants to eradicate colonization may be considered, but unlike GAS or *Staphylococcus* infection, GBS infection in nurseries has not been reported to cause outbreaks. No data support conducting GBS screening on all breastfeeding mothers and their expressed breast milk as a reasonable method for protecting against spread of GBS infection via expressed breast milk or LOD GBS infection. Selective culturing of expressed breast milk may be appropriate in certain situations.

## TUBERCULOSIS

The face of TB is changing throughout the world. In the United States the incidence of TB rose from 1986 through 1993 and has been declining since then.<sup>67</sup> In 2013, the incidence rate was 3.0 cases per 100,000 population, which represents a decrease of 4.2% from 2012 (Alami et al<sup>3</sup>).

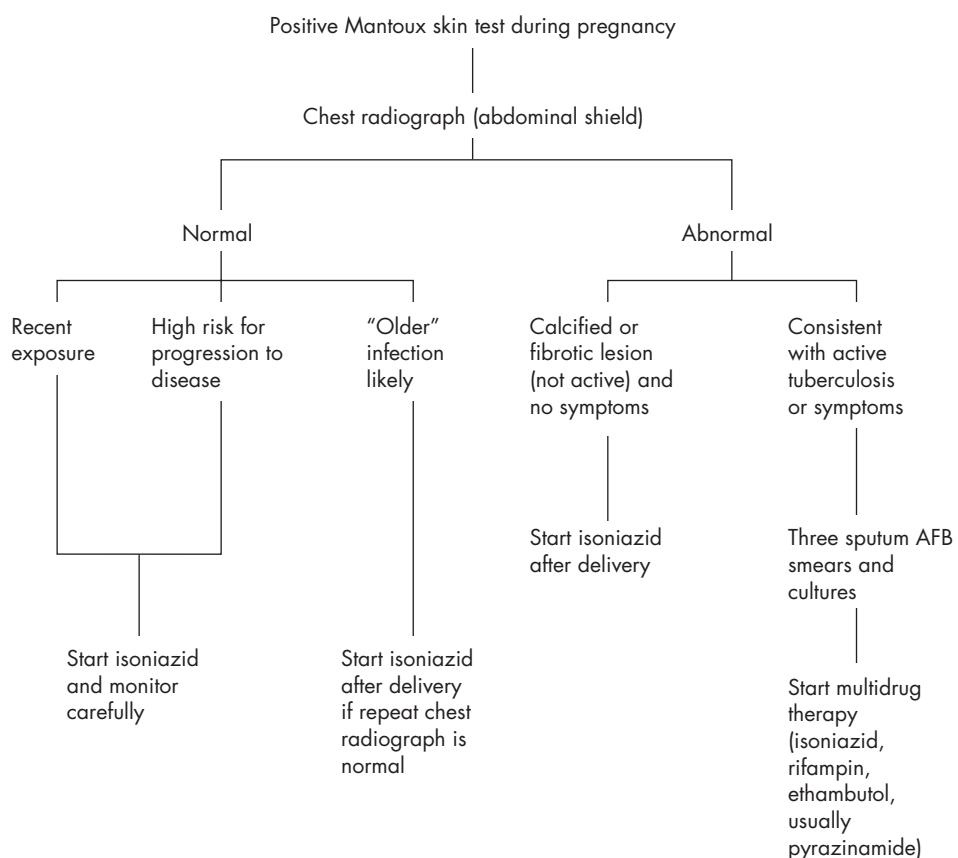

TB during pregnancy has always been a significant concern for patients and physicians alike.<sup>381</sup> It is now clear that the course and prognosis of TB in pregnancy are less affected by the pregnancy and more determined by the location and extent of disease, as defined primarily by chest radiograph, and by the susceptibility of the individual patient. Untreated TB in pregnancy is associated with maternal and infant mortality rates of 30% to 40%.<sup>407</sup> Effective therapy is crucial to the clinical outcome in both pregnant and nonpregnant women. TB during pregnancy rarely results in congenital TB, although congenital TB has a mortality rate as high as 50%.<sup>289</sup>

Any individual in a high-risk group for TB should be screened with a tuberculin skin test (TST). No contraindication or altered responsiveness to the

TST exists during pregnancy or breastfeeding. Interpretation of the TST should follow the most recent guidelines, using different sizes of induration in different-risk populations as cutoffs for a positive test, as proposed by the CDC.<sup>75</sup> Figure 13-2 outlines the evaluation and treatment of a pregnant woman with a positive TST.<sup>443</sup>

Treatment of active TB should begin as soon as the diagnosis is made, regardless of the fetus's gestational age, because the risk for disease to mother and fetus clearly outweighs the risks of treatment. Isoniazid, rifampin, and ethambutol have been used safely in all three trimesters. Isoniazid and pyridoxine therapy during breastfeeding is safe, although the risk for hepatotoxicity in the mother may be a concern during the first 2 months postpartum.<sup>436</sup>

Congenital TB is extremely rare, if one considers that 7 to 8 million cases of TB occur each year worldwide and that less than 300 cases of congenital TB have been reported in the literature. As with other infectious diseases presenting in the perinatal period, distinguishing congenital infection from perinatal or postnatal TB in infants can be difficult.

**Figure 13-2.** Evaluation and treatment of a pregnant woman with a positive tuberculin skin test. (From Starke JR: Tuberculosis, an old disease but a new threat to mother, fetus, and neonate, *Clin Perinatol* 24:107, 1997.)

Postnatal TB infection in infancy typically presents with severe disease and extrapulmonary extension (meningitis, lymphadenopathy, and bone, liver, spleen involvement). Airborne transmission of TB to infants is the major mode of postnatal infection because of close and prolonged exposure in enclosed spaces, especially in their own household, to any adult with infectious pulmonary TB. Potential infectious sources could be the mother or any adult caregiver, such as babysitters, day care workers, relatives, friends, neighbors, and even health care workers. Mittal et al. recently reviewed the management of the newborn infant exposed to their mother with TB.<sup>318</sup>

The suspicion of TB infection or disease in a household with possible exposure of an infant is a highly anxiety-provoking situation (Figure 13-3). Although protecting an infant from infection is foremost in everyone's mind, separation of the infant from the mother should be avoided when reasonable. Every situation is unique, and the best approach will vary according to the specifics of the case and accepted principles of TB management. The first step in caring for the potentially exposed infant is to determine accurately the true TB status of the suspected case (mother or household contact). This prompt evaluation should include a complete history (previous TB infection or disease, previous or ongoing TB treatment, TST status, symptoms suggestive of active TB, results of most recent chest radiograph, sputum smears, or cultures), physical examination, a TST if indicated, a new chest radiograph, and mycobacterial cultures and smears of any suspected sites of infection. All household contacts should be evaluated promptly, including history and TST with further evaluation as indicated.<sup>75</sup> Continued risk to the infant can occur from infectious household contacts who have not been effectively evaluated and treated.

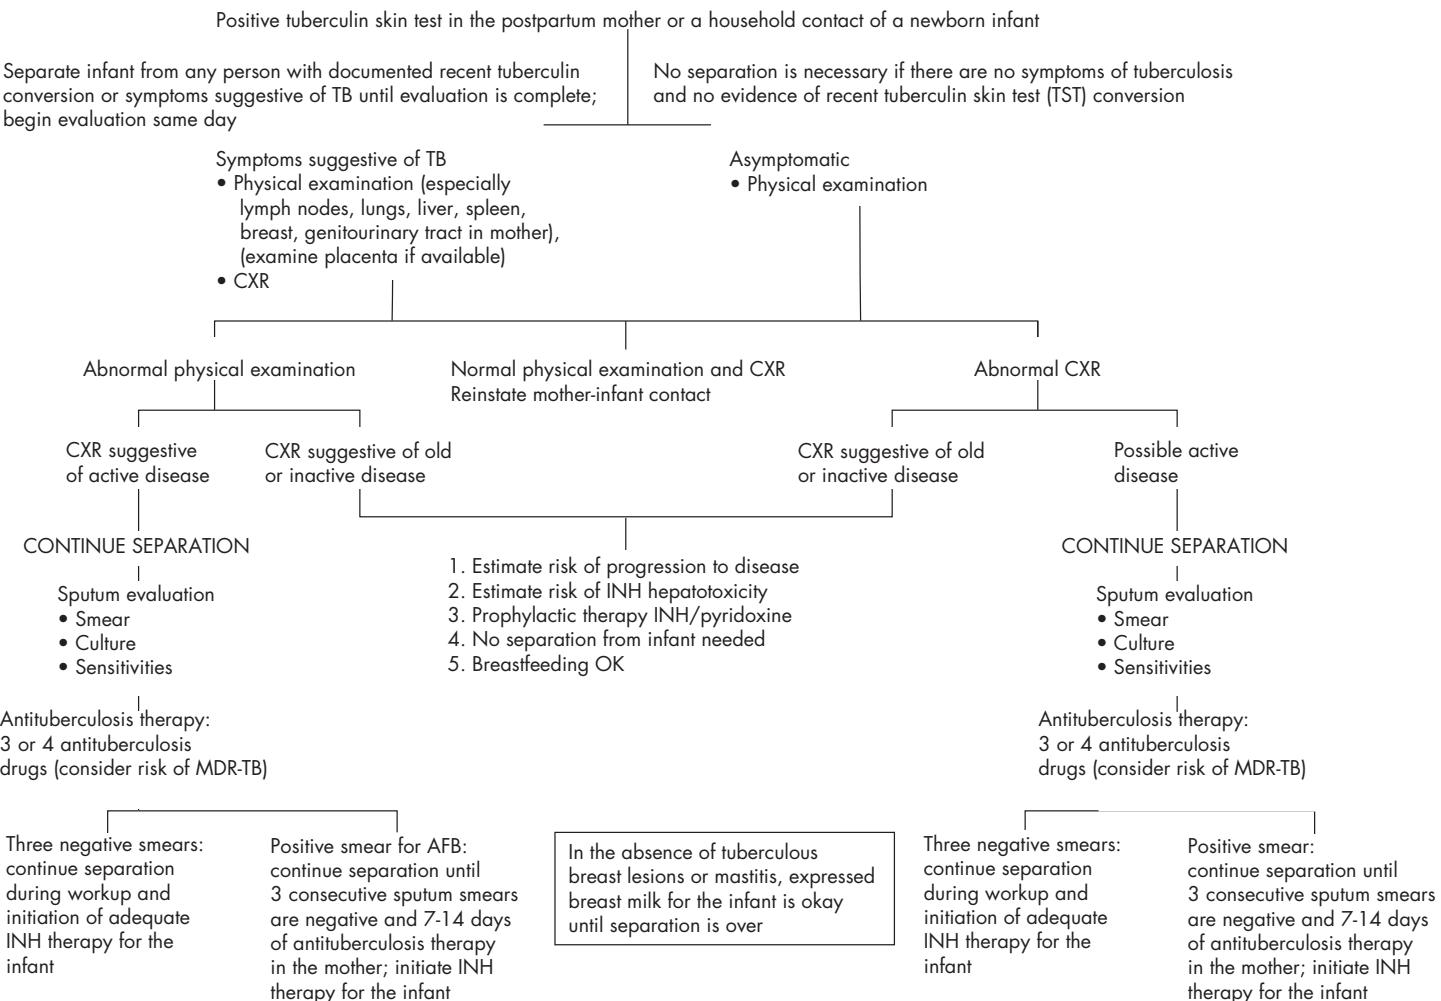

An infant should be temporarily separated from the suspected source if symptoms suggest active disease or a recent TST documents conversion, and separation should continue until the results of the chest radiograph are seen. Because of considerable variability in the course of illness and the concomitant infectious period, debate continues without adequate data about the appropriate period of separation.<sup>313</sup> This should be individualized given the specific situation. HIV testing and assessment of the risk for MDR TB should be done in every case of active TB. Sensitivity testing should be done on every *M. tuberculosis* isolate. Table 13-1 summarizes the management of the newborn infant whose mother (or other household contact) has TB.

Initiation of prophylactic isoniazid therapy in the infant has been demonstrated to be effective in preventing TB infection and disease in the infant.

Therefore, continued separation of the infant and mother is unnecessary after therapy in both mother and child has begun.<sup>107,126</sup> The AAP recommends isoniazid (INH) prophylaxis for all infants whose mothers have been diagnosed with active pulmonary TB in the postpartum period. The real risk requiring infant separation is airborne transmission. Separation of the infant from a mother with active pulmonary TB is appropriate, regardless of the method of feeding. However, in many parts of the world, after therapy in the mother and prophylaxis with isoniazid in the infant has begun, the infant and mother are not separated. With or without separation, the mother and infant should continue to be closely observed throughout the course of maternal therapy to ensure good compliance with medication by both mother and infant and to identify, early on, any symptoms in the infant suggestive of TB. The mother should be followed to confirm that she is no longer considered infectious, with negative smears and cultures within 2 to 4 weeks of beginning TB therapy.

Tuberculous mastitis occurs rarely in the United States, but it does occur in other parts of the world<sup>2,178,189,220,238,425</sup> and can lead to infection in infants, frequently involving the tonsils. A mother usually has a single breast mass and associated axillary lymph node swelling and infrequently develops a draining sinus. TB of the breast can also present as a painless mass or edema. Involvement of the breast can occur with or without evidence of disease at other sites. Evaluation of the extent of the disease is appropriate, including lesion cultures by needle aspiration, biopsy, or wedge resection and milk cultures. Therapy should be with multiple anti-TB medications, but surgery should supplement this, as needed, to remove extensive necrotic tissue or a persistently draining sinus.<sup>18</sup> Neither breastfeeding nor breast milk feeding should be done until the lesion is healed, usually after 2 weeks or more. Continued anti-TB therapy for 6 months in the mother and prophylactic isoniazid for the infant for 3 to 6 months is indicated.

In the absence of tuberculous breast infection in the mother, the transmission of TB through breast milk has not been documented. Thus even though temporary separation of infant and mother may occur pending complete evaluation and initiation of adequate therapy in the mother and prophylactic isoniazid therapy (10 mg/kg/day as a single daily dose) in the infant, breast milk can be expressed and given to the infant during the short separation. Breastfeeding can safely continue when the mother, infant, or both are receiving anti-TB therapy. Anti-TB medications (isoniazid, rifampin, pyrazinamide, aminoglycosides, ethambutol, ethionamide, *p*-aminosalicylic acid) have been safely used in infancy, and therefore, the presence of

**Figure 13-3.** Management of a newborn infant exposed to tuberculin-positive household contact. CXR, Chest X-ray film; INH, isoniazid; MDR, multidrug-resistant; TB, tuberculosis.

**TABLE 13-1**

Management of a Newborn Whose Mother (or Other Household Contact) Has Tuberculosis (TB)

Mother/Infant Status	Additional Workup Recommended <sup>1</sup>	Therapy for Mother/Contact	Therapy for Infant	Separation <sup>2</sup>	Breast Milk <sup>3</sup>	Breastfeeding <sup>3</sup>
1. TB infection, no disease <sup>4</sup>	None for mother/contact	Prophylactic <sup>5</sup>	None	No	Yes	Yes
2. TB infection: Abnormal CXR not suggestive of active disease		Decide active vs. inactive disease				
a. Symptoms or physical findings suggestive of active TB	Aerosolized sputum (culture, smears) <sup>6</sup>	Active disease: empiric <sup>5</sup>	Isoniazid <sup>7</sup>	Yes	Yes	No <sup>8</sup>
		Inactive disease: prophylactic <sup>5</sup>	None	No	Yes	Yes
b. No symptoms or physical findings suggestive of active TB	Aerosolized sputum in select cases	Prophylactic <sup>5</sup>	None	No	Yes	Yes
3. TB infection: Abnormal CXR suggestive of active disease	Aerosolized sputum (culture, smears) <sup>6</sup>	Empiric therapy <sup>5</sup>	Isoniazid <sup>7</sup>	Yes	Yes	No <sup>8</sup>
4. Active pulmonary TB: Suspected MDR TB	Aerosolized sputum (culture, smears) <sup>6</sup>	Consult TB specialist for best regimen <sup>9</sup>	Consult pediatric TB specialist <sup>9</sup>	Yes	Yes	No
		Consider bacille Calmette-Guérin vaccine				
5. TB disease: Suspected mastitis <sup>10</sup>	Aerosolized sputum (culture, smears) <sup>6</sup>	Empiric <sup>5</sup>	Isoniazid <sup>7</sup>	Yes	No <sup>11</sup>	No
6. TB infection: Status undetermined <sup>12</sup>	Perform/interpret CXR within 24 hours			Yes, until CXR interpreted (see a and b)	Yes	No
a. Abnormal CXR not suggestive of active disease	Proceed as in 2		As in 2	As in 2	As in 2	
b. Abnormal CXR suggestive of active disease	Proceed as in 3		As in 3	As in 3	As in 3	

<sup>1</sup>Further workup should always include the evaluation of the TB status of all other household (or close) contacts by tuberculin skin testing (TST), review of symptoms, physical examination, and chest X-ray (CXR). Sputum smears and cultures should be done as indicated.

<sup>2</sup>Separation should occur until interpretation of CXR confirms the absence of active disease, or, with active disease, separation should continue until the individual is no longer considered infectious: three negative consecutive sputum smears, adequate ongoing empiric therapy, and decreased fever, cough, and sputum production. Separation means movement to a different house or location, not simply separate rooms in a household. The duration of separation should be individualized for each case, in consultation with the TB specialist.

<sup>3</sup>This assumes no evidence of breast involvement, suspected TB mastitis, or lesions (except in status 5, when breast involvement is considered). The risk to the infant is via aerosolized bacteria in the sputum from the lung. Expressed breast milk can be given even if separation of mother and infant is advised.

<sup>4</sup>TST positive, no symptoms or physical findings suggestive of TB, negative CXR.

<sup>5</sup>Prophylactic therapy: isoniazid 10 mg/kg/day, maximum 300 mg for 6 months; pyridoxine 25 to 50 mg/day for 6 months. Empiric therapy: standard three- or four-drug regimens for 2 months, and treatment should continue for total of 6 months with isoniazid and rifampin when the organism is shown to be sensitive. Suspected MDR TB requires consultation with a TB specialist to select the optimum empiric regimen and for ongoing monitoring of therapy and clinical response.

*Continued*

**TABLE 13-1** Management of a Newborn Whose Mother (or Other Household Contact) Has Tuberculosis (TB)—cont'd

<sup>6</sup>Sensitivity testing should be done on any positive culture.

<sup>7</sup>Isoniazid 10 mg/kg/day for 3 to 9 months, depending on the mother's or contact's status; repeat TST at 3 months and obtain a normal CXR in the infant before stopping isoniazid. Before beginning therapy, a workup of the infant for congenital or active TB may be appropriate. This workup should be determined based on the clinical status of the infant and the suspected potential risk, and it may include TST after 4 weeks of age, with CXR, complete blood count, and erythrocyte sedimentation rate, liver function tests, cerebrospinal fluid analysis, gastric aspirates, and sonography or computed tomography of liver, spleen, and chest, if congenital TB is suspected.

<sup>8</sup>Breastfeeding is proscribed when the separation of the mother and infant is indicated because of risk for aerosolized transmission of bacteria. Expressed breast milk given to the infant via bottle is acceptable in the absence of mastitis or breast lesions.

<sup>9</sup>Consult with a TB specialist about MDR TB. Empiric therapy will be chosen based on the most recent culture sensitivities of the index patient or perhaps the suspected source case, if known, as well as medication toxicities and other factors.

<sup>10</sup>TB mastitis usually involves a single breast with associated axillary lymph node swelling and, infrequently, a draining sinus tract. It can also present as a painless mass or edema of breast.

<sup>11</sup>With suspected mastitis or breast lesions caused by TB, even breast milk is contraindicated until the lesion or mastitis heals, usually after 2 weeks or more.

<sup>12</sup>Patient has a documented, recent TST conversion, but has not been completely evaluated. Evaluation should begin and CXR should be done and evaluated in less than 24 hours to minimize separation of this person from the infant. Further workup should proceed as indicated by symptoms, physical findings, and CXR results.

Data from the Committee on Infectious Diseases, American Academy of Pediatrics: *Red book: report of the committee on infectious diseases*, ed 26, Elk Grove Village, Ill., 2003, American Academy of Pediatrics.

these medications in smaller amounts in breast milk is not a contraindication to breastfeeding.

Although conflicting, reports indicate that breastfeeding by TST-positive mothers does influence infants' responses to bacille Calmette-Guérin vaccine, the TST, and perhaps the *M. tuberculosis* bacillus. Despite efforts to identify either a soluble substance or specific cell fractions (gamma/delta T cells) in colostrum and breast milk that affect infants' immune responsiveness, no unified theory explains the various reported changes, and no evidence has identified a consistent, clinically significant effect.<sup>43,235,358,409</sup>

## Viral Infections

### ARBOVIRUSES

Arboviruses were originally a large collection of viruses grouped together because of the common mode of transmission through arthropods. They have now been reclassified into several different families: Bunyaviridae, Togaviridae, Flaviviridae, Reoviridae, and others. They include more than 30 human pathogens.

These organisms primarily produce either CNS infections (encephalitis, meningoencephalitis) or undifferentiated illnesses associated with fever and rash, severe hemorrhagic manifestations, and involvement of other organs (hepatitis, myalgia, polyarthritides). Infection with this array of viruses may also be asymptomatic and subclinical, although how often this occurs is uncertain. Some of the notable human pathogens include Bunyaviridae (California serogroup viruses), *Hantavirus*,

*Hantaan virus*, *Phlebovirus* (Rift Valley fever), *Nairovirus* (Crimean-Congo hemorrhagic fever), *Alphavirus* (western, eastern, and Venezuelan equine encephalomyelitis viruses, chikungunya virus), *Flavivirus* (St. Louis encephalitis virus, Japanese encephalitis virus, dengue viruses, yellow fever virus, tick-borne encephalitis viruses, West Nile virus), and *Orbivirus* (Colorado tick fever). Other than for Crimean-Congo hemorrhagic fever and for reported cases of Colorado tick fever associated with transfusion, direct person-to-person spread has rarely been described. Outbreaks in 2005 and 2007 of chikungunya virus infection in Reunion Island and in India appear to have involved infection in young infants probably secondary to vertical spread from mother to infant transplacentally.<sup>162,379,468</sup> A few cases of early fetal deaths were associated with infection in pregnant women. The cases of vertical transmission occurred with near-term infection in the mothers, and the infants developed illness within 3 to 7 days of delivery.<sup>162,379</sup> No evidence for transmission via breast milk or breastfeeding is available.

Overall, little evidence indicates that these organisms can be transmitted through breast milk. The exceptions to this include evidence of transmission of three flaviviruses via breast milk: dengue virus, West Nile virus, and yellow fever vaccine virus. Standard precautions are generally sufficient. With any of these infections in a breastfeeding mother, the severity of the illness may determine the mother's ability to continue breastfeeding. Providing the infant with expressed breast milk is acceptable. (See the discussion of dengue virus, West Nile virus, and yellow fever vaccine virus later in this chapter.)

In general, treatment for these illnesses is supportive. However, ribavirin appears to decrease the severity of and mortality from *Hantavirus* pulmonary syndrome, hemorrhagic fever with renal failure, and Crimean-Congo hemorrhagic fever. Ribavirin has been described as teratogenic in various animal species and is contraindicated in pregnant women. No information is available concerning ribavirin in breast milk, with limited information available on the use of intravenous or oral ribavirin in infants.

## ARENAVIRUSES

Arenaviruses are single-stranded ribonucleic acid (RNA) viruses that infect rodents and are acquired by humans through the rodents. The six major human pathogens in this group are (1) lymphocytic choriomeningitis virus, (2) Lassa fever virus, (3) Junin virus (Argentine hemorrhagic fever), (4) Machupo virus (Bolivian hemorrhagic fever), (5) Guanarito virus (Venezuelan hemorrhagic fever), and (6) Sabia virus. The geographic distribution of these viruses and the illness they cause are determined by the living range of the host rodent (reservoir). The exact mechanism of transmission to humans is unknown and hotly debated.<sup>27,76,145</sup> Direct contact and aerosolization of rodent excretions and secretions are probable mechanisms.

Lymphocytic choriomeningitis virus is well recognized in Europe, the Americas, and other areas. Perinatal maternal infection can lead to severe disease in the newborn, but no evidence suggests transmission through breast milk.<sup>31,246</sup> Standard precautions with breastfeeding are appropriate.

Lassa fever (West Africa) and Argentine hemorrhagic fever (Argentine pampas) are usually more severe illnesses, with dramatic bleeding and involvement of other organs, including the brain. These fevers more frequently lead to shock and death than do the forms of hemorrhagic fever caused by the other viruses in this group. Person-to-person spread of Lassa fever is believed to be common, and transmission within households does occur.<sup>233</sup> This may relate to prolonged viremia and excretion of the virus in the urine of humans for up to 30 days.<sup>370</sup> The possibility of persistent virus in human urine, semen, and blood after infection exists for each of the arenaviruses. The possibility of airborne transmission is undecided. Current recommendations by the CDC<sup>76</sup> are to use contact precautions for the duration of the illness in situations of suspected viral hemorrhagic fever. No substantial information describes the infectivity of various body fluids, including breast milk, for these different viral hemorrhagic fevers. Considering the severity of the illness in mothers and the risk to the infants, it is reasonable to avoid

breastfeeding in these situations if alternative forms of infant nutrition can be provided for the short term.

As more information becomes available, reassessment of these recommendations is advisable. A vaccine is in trials in endemic areas for Junin virus and Argentine hemorrhagic fever.<sup>237</sup> Preliminary studies suggest it will be effective, but data are still being accumulated concerning the vaccine's use in children and pregnant or breastfeeding women.

## CYTOMEGALOVIRUS

CMV is one of the human herpesviruses. Congenital infection of infants, postnatal infection of premature infants, and infection of immune-deficient individuals represent the most serious forms of this infection in children. The time at which the virus infects the fetus or infant and the presence or absence of antibodies against CMV from the mother are important determinants of the severity of infection and the likelihood of significant sequelae (congenital infection syndrome, deafness, chorioretinitis, abnormal neurodevelopment, learning disabilities).<sup>258</sup> About 1% of all infants are born excreting CMV at birth, and approximately 5% of these congenitally infected infants will demonstrate evidence of infection at birth (approximately 5 symptomatic cases per 10,000 live births). Approximately 15% of infants born after primary infection in a pregnant woman will manifest at least one sequela of prenatal infection.<sup>106</sup>

Various studies have detected that 3% to 28% of pregnant women have CMV in cervical cultures and that 4% to 5% of pregnant women have CMV in their urine.<sup>132,190</sup> Perinatal infection certainly occurs through contact with virus in these fluids, but it is not usually associated with clinical illness in full-term infants. The lack of illness is thought to result from the transplacental passive transfer of protective antibodies from the mother.

Postnatal infection later in infancy occurs via breastfeeding or contact with infected fluids (e.g., saliva, urine), but, again, it rarely causes clinical illness in full-term infants. Seroepidemiologic studies have documented the transmission of infection in infancy, with higher rates of transmission occurring in day care centers, especially when the prevalence of CMV in the urine and saliva is high. CMV has been identified in the milk of CMV-seropositive women at varying rates (10% to 85%), using viral cultures or CMV deoxyribonucleic acid (DNA) PCR.<sup>190,340,442,478</sup> CMV is more often identified in the breast milk of seropositive mothers than in vaginal fluids, urine, and saliva. The CMV isolation rate from colostrum is lower than that from mature milk.<sup>190,441</sup> The reason for the large degree of variability in the identification of CMV in breast milk

in these studies probably relates to the intermittent nature of the reactivation and excretion of the virus, in addition to the variability, frequency, and duration of sampling of breast milk in the different studies. Some authors have hypothesized that the difference in isolation rates between breast milk and other fluids is caused by viral reactivation in cells (leukocytes or monocytes) in the breast leading to "selective" excretion in breast milk.<sup>340</sup> Vochem et al.<sup>478</sup> reported that the rate of virolactia was greatest at 3 to 4 weeks postpartum, and Yeager et al.<sup>506</sup> reported significant virolactia between 2 and 12 weeks postpartum. Antibodies (e.g., secretory IgA) to CMV are present in breast milk, along with various cytokines and other proteins (e.g., lactoferrin). These may influence virus binding to cells, but they do not prevent transmission of infection.<sup>6,7,258,316,340,369,503</sup>

Several studies have documented increased rates of postnatal CMV infection in breastfed infants (50% to 69%), compared with bottle-fed infants (12% to 27%), observed through the first year of life.<sup>132,316,442,478</sup> In these same studies, full-term infants who acquired CMV infection postnatally were only rarely mildly symptomatic at the time of seroconversion or documented viral excretion. Also, no evidence of late sequelae from CMV was found in these infants.

Postnatal exposure of susceptible infants to CMV, including premature infants without passively acquired maternal antibodies against CMV, infants born to CMV-seronegative mothers, and immunodeficient infants, can cause significant clinical illness (pneumonitis, hepatitis, thrombocytopenia).<sup>64,115,187,186,271,301</sup> In one study of premature infants followed up to 12 months, Vochem et al.<sup>478</sup> found CMV transmission in 17 of 29 infants (59%) exposed to CMV virolactia and breastfed, as compared with no infants among the 27 exposed to breast milk without CMV. No infant was given CMV-seropositive donor milk or blood. Five of the 12 infants who developed CMV infection after 2 months of age had mild signs of illness, including transient neutropenia, and only one infant had a short increase in episodes of apnea and a period of thrombocytopenia. Five other premature infants with CMV infection before 2 months of age had acute illness, including sepsis-like symptoms, apnea with bradycardia, hepatitis, leukopenia, and prolonged thrombocytopenia.<sup>478</sup> In a prospective study done in the United States, Josephson et al.<sup>224</sup> examined the role of transfusions and breastmilk causing CMV infection in VLBW infants. In the mothers, the seroprevalence of CMV was 76.2% (352/462). In 301 infants receiving 2061 transfusions of CMV-seronegative and leukoreduced blood, there were no CMV infections linked to transfusion. Postnatal CMV infection had a cumulative incidence at 12 weeks

post birth of 6.9% (95% CI, 4.2% to 9.2%), and 5 of 29 CMV-infected infants developed symptomatic disease or died. Twenty-seven of the 29 infants received CMV-positive breast milk. Factors associated with a higher risk of postnatal CMV infection were a higher CMV viral load in the breast milk and a higher number of breast milk-fed days. This study also demonstrated that the use of CMV-seronegative and leukoreduced blood products is effective at preventing transfusion-related CMV infection. In a systematic review and meta-analysis, Lanzieri et al.<sup>268</sup> utilized data from 17 studies published between 2001 and 2011. They reported on 299 infants who received untreated breast milk. Of these infants, 19% acquired CMV infection and 4% developed a sepsis-like syndrome related to CMV infection. Among the 212 infants included who received frozen breast milk (at various temperatures and durations in different studies—18°C to 20°C for over 24 hours or 72 hours), 13% developed CMV infection and 5% had an associated sepsis-like syndrome. Although the overall rate of CMV infection related to breast milk was slightly lower in the untreated breast milk group there was no difference in the occurrence of sepsis-like syndrome in the two groups.

Relative to long-term sequelae related to postnatal CMV infection in VLBW infants, Vollmer et al.<sup>479</sup> followed premature infants with early postnatal CMV infection acquired through breast milk for 2 to 4.5 years to assess neurodevelopment and hearing function. None of the children had sensorineural hearing loss. There was no difference between the 22 CMV-infected children and 22 matched premature control CMV-negative infants in terms of neurologic, speech and language or motor development.<sup>479</sup> Neuberger et al.<sup>333</sup> examined the symptoms and neonatal outcome of CMV infection transmitted via human milk in premature infants in a case-control fashion; 40 CMV-infected premature infants were compared with 40 CMV-negative matched premature infants. Neutropenia, thrombocytopenia, and cholestasis were associated with CMV infection in these infants. No other serious effects or illnesses were found directly associated with the infection, including intraventricular hemorrhage, periventricular leukomalacia, retinopathy of prematurity, necrotizing enterocolitis, bronchopulmonary dysplasia, duration of mechanical ventilation or oxygen therapy, duration of hospital stay or weight, gestational age, or head circumference at the time of discharge. More recent studies do not clarify the long-term effects on the neurodevelopmental status of premature or LBW infants with symptomatic postnatal CMV infection.<sup>45,171,464</sup> They present contradictory evidence concerning the occurrence of adverse neurologic outcomes or sensorineural hearing loss in these children.

Exposure of CMV-seronegative, premature, or VLBW infants to CMV-positive milk (donor or natural mother's) should be avoided.<sup>422</sup> Various methods of inactivating CMV in breast milk have been reported, including HP, freezing ( $-20^{\circ}\text{C}$  for 3 days), and brief high temperature ( $72^{\circ}\text{C}$  for 10 seconds).<sup>132,150,173,438,506</sup> One small prospective study suggests that freezing breast milk at  $-20^{\circ}\text{C}$  for 72 hours protects premature infants from CMV infection via breast milk. Sharland et al.<sup>422</sup> reported on 18 premature infants (less than 32 weeks) who were uninfected at birth and exposed to breast milk from their CMV-seropositive mothers. Only 1 of 18 (5%) infants became positive for CMV at 62 days of life, and this infant was clinically asymptomatic. This transmission rate is considerably lower than others reported in the literature. CMV-seronegative and leukocyte-depleted blood products were used routinely. Banked breast milk was pasteurized and stored at  $-20^{\circ}\text{C}$  for various time periods, and maternal expressed breast milk was frozen at  $-20^{\circ}\text{C}$  before use whenever possible. The infants received breast milk for a median of 34 days (range: 11 to 74 days), and they were observed for a median of 67 days (range: 30 to 192 days). Breast milk samples pre- or postfreezing were not analyzed by PCR or culture for the presence of CMV.<sup>422</sup> Buxmann et al.<sup>64</sup> demonstrated no transmission of CMV in 23 premature infants receiving thawed frozen breast milk until 33 weeks (gestational age + postnatal age) (less than or equal to 31 weeks' gestational age) born to 19 mothers who were CMV-IgG negative. CMV infection was found in 5 premature infants of 35 infants born to 29 mothers who were CMV-IgG positive and who provided breast milk for their infants. Three of the five children remained asymptomatic. One child developed a respirator-dependent pneumonia, and the second developed an upper respiratory tract infection and thrombocytopenia in association with their CMV infections.<sup>64</sup> Yasuda et al.<sup>505</sup> reported on 43 preterm infants (median gestational age 31 weeks), demonstrating a peak in CMV DNA copies, detected by a real-time PCR assay, in breast milk at 4 to 6 weeks postpartum. Thirty of the 43 infants received CMV DNA-positive breast milk. Three of the 30 had CMV DNA detected in their sera, but none of the three had symptoms suggestive of CMV infection. Much of the breast milk had been stored at  $-20^{\circ}\text{C}$  before feeding, which the authors propose is the probable reason for less transmission in this cohort.<sup>505</sup> Lee et al.<sup>276</sup> reported on the use of maternal milk frozen at  $-20^{\circ}\text{C}$  for a minimum of 24 hours before feeding to premature infants in a NICU; 23 infants had CMV-seropositive mothers and 39 infants had CMV-seronegative mothers. Two infants developed CMV infection, which was symptomatic. They were both fed frozen and

then thawed milk from CMV-seropositive mothers.<sup>276</sup> Others have reported individual cases of CMV infection in premature infants despite freezing and thawing breast milk.<sup>302,353</sup> More recent studies, including a prospective cohort study of breast milk transmission of CMV by Josephson et al.<sup>224</sup> and a systematic review and meta-analysis of breast milk-acquired CMV infection in VLBW and premature infants by Lanzieri et al.,<sup>268</sup> demonstrate that frozen-thawed breast milk provides minimal protection, at best, against breast milk-acquired CMV infection.<sup>224,268</sup> It is clear that the simple freezing and thawing of breast milk does not completely prevent transmission of CMV to premature and VLBW infants. The efficacy of freezing and thawing breast milk for varying lengths of time to prevent CMV infection in premature infants has not been studied prospectively in a randomized controlled trial. Eleven of 36 neonatal units in Sweden (27 of which have their own milk banks) freeze maternal milk to reduce the risk for CMV transmission to premature infants.<sup>353</sup>

A prominent group of neonatologists and pediatric infectious disease experts in California, who recognize the significant benefits of providing human milk to premature and LBW infants, recommend screening mothers of premature infants for CMV IgG at delivery and, when an infant's mother is CMV IgG positive at delivery, using either pasteurized banked human milk or frozen and then thawed maternal breast milk for premature infants until they reach the age of 32 weeks.<sup>496</sup> In consideration of the low rates of CMV virolactia in colostrum<sup>186,442</sup> and the predominant occurrence of virolactia between 2 and 12 weeks (peak at 3 to 4 weeks) postpartum,<sup>478,506</sup> they reasonably propose beginning colostrum and breast milk feedings for all infants until the maternal CMV-serologic screening is complete. They recommend close observation and follow-up of premature infants older than 3 weeks of age for signs, symptoms, and laboratory changes of CMV infection until discharge from the hospital or out to 32 weeks postconceptual age.<sup>496</sup> Additional research and discussion will be necessary to devise a protocol for the use of human milk in premature and VLBW infants to optimize their growth, development, and immune protection at the same time as preventing the risk of acquiring postnatal CMV infection.

There has been much discussion of the use of CMV immunoglobulin and/or antiviral medications (acyclovir, ganciclovir, valganciclovir) to treat women during pregnancy in order to protect against congenital CMV infection. Although these agents have also been used to treat infants with symptomatic congenital CMV and symptomatic acute postnatal CMV infection, they have not been studied as prophylaxis against postnatal CMV infection.

Full-term infants can be safely fed human milk from CMV-seropositive mothers because, despite a higher rate of CMV infection than in formula-fed infants observed through the first year of life, infection in this situation is not associated with significant clinical illness or acute or long-term sequelae.

## DENGUE DISEASE

Dengue viruses (serotypes dengue 1 to 4) are flaviviruses associated primarily with febrile illnesses and rash, dengue fever, dengue hemorrhagic fever, and dengue shock syndrome. The mosquito *Aedes aegypti* is the main vector of transmission of dengue virus in countries lying between latitudes 35 degrees north and 35 degrees south. More than 2.5 billion people live in areas where transmission occurs; dengue virus infects over 100 million individuals a year and causes approximately 24,000 deaths per year.<sup>177,181</sup> Although dengue hemorrhagic fever and dengue shock syndrome occur frequently in children younger than 1 year of age, they are infrequently described in infants younger than 3 months of age.<sup>185</sup> There are also differences in the clinical and laboratory findings of dengue virus infection in children, as compared to adults.<sup>244</sup> Boussemart et al.<sup>56</sup> reported on two cases of perinatal/prenatal transmission of dengue and discussed eight additional cases in neonates from the literature. Prenatal or intrapartum transmission of the same type of dengue as the mother was confirmed by serology, culture, or PCR. Phongsamart et al.<sup>373</sup> described three additional cases of dengue virus infection late in pregnancy, with apparent transmission to two of the three infants and passive acquisition of antibody in the third infant. Sirinavin et al.<sup>430</sup> reported on 17 cases in the literature of vertical dengue infection, all presenting at less than 2 weeks of age, but no observations or discussion of breast milk or breastfeeding as a potential source of infection were published. Watanaveeradej et al.<sup>487</sup> presented an additional three cases of dengue infection in infants, documenting normal growth and development at follow-up at 12 months of age.

It has been postulated that more severe disease associated with dengue disease occurs when an individual has specific IgG against the same serotype as the infecting strain in a set concentration, leading to antibody-dependent enhancement of infection. The presence of preexisting dengue serotype-specific IgG in an infant implies either previous primary infection with the same serotype, passive acquisition of IgG from the mother (who had a previous primary infection with the same serotype), or perhaps acquisition of specific IgG from breast milk. Watanaveeradej et al.<sup>487</sup> documented transplacentally transferred antibodies

against all four serotypes of dengue virus in 97% of 2000 cord sera at delivery. Follow-up of 100 infants documented the loss of antibodies to dengue virus over time, with losses of 3%, 19%, 72%, 99%, and 100% at 2, 4, 6, 9, and 12 months of age, respectively.
